He stated that the operation was first proposed five years ago, its object being, first, to cut off the blood supply to the tumor, and, secondly, to alter the nerve supply of that organ. After describing the technic as practised by him at the present time, he enumerated the following points in favor of the operation: (1) From the standpoint of its mortality it is a minor operation. The patient can leave her bed at the end of a week; there is no shock attendant thereon; nor is there a protracted convalescence. If the method fails it can do no harm. (2) It does not destroy the family relation. Women can conceive after its performance. (3) It is applicable in desperate hemorrhagic cases in which a more radical operation cannot be performed at the time, and does not prevent resort to this if subsequently necessary. (4) It can be employed in cases in which such complications exist as to contraindicate a radical operation, as cardiac or other organic disease. (5) It may be employed in all cases in which the patient objects to the abdominal operation on account of the scar, or when she fears the shock of the greater operation. (6) It is of use in all cases in which the tumor is not of burdensome size and is associated with profuse bleeding. It is not applicable in pedunculated tumors of the submucous or subperitoneal variety.

DR. A. J. C. SKENE of Brooklyn remarked that hysterectomy for fibroid tumor is at the present time so successful

that few will consider any other method. In choosing the method of operation one should be guided by the age of the patient. He strongly objected to the removal of the sexual organs in young women. When the woman is near the menopause, however, he would prefer to perform hysterectomy. Statistics show that more women die after hysterectomy than from fibroids alone. In appropriate cases, his experience has agreed with that of Dr. Martin. He thinks the operation is impossible in the intraligamentous variety of tumor and very difficult in cases of multiple fibroids. The ligation of the artery is a difficult procedure. He emphasized the importance of a primary curettage of the uterine cavity. The diseased mucosa must be removed.

DR. MARTIN, in reply, stated that suppuration has never occurred in his experience after the operation, for the reason that he is careful in his technic.

The President of the Section, DR. WILLIAM JAPP SINCLAIR of Manchester, England, read an admirable address upon

INJURIES OF PARTURITION; THE OLD AND THE NEW,

in which he gave the history of the progress in obstetrics during the past two hundred years. He compared the methods of the Sixteenth Century, as practised by Chamberlain and Mauriceau, with the methods in vogue at the present time. Midwifery, he claimed, has become to-day too largely surgical, and the gynecology of to-day is largely required because of too frequent interference on the part of the obstetrician. Childbed morbidity is due mainly to the use of forceps. He quoted Collins' assertion that instruments should not be employed more than six times in 4000 cases. During the second period of the history of obstetrics, from the time of the introduction of anesthesia until the adoption of antiseptic methods, important advances were made. Emmet's operation and the work of Marion Sims in the cure of vesicovaginal fistulae belong here. The dangers of anesthesia are uterine inertia and the tendency to the too early use of forceps, with resultant perineal and vaginal laceration. The third period of anesthesia and antiseptic methods combined, began in 1870-73. The danger here is again due to too frequent and too early interference. The student of to-day learns surgery, which he never practises, and practises midwifery, which he never learns. During the last four years there has arisen a strong revulsion to the use of the forceps in Germany, and statistics show now that they are employed there only in about 1.03 per cent. of labor cases. In conclusion, he emphatically urged more careful instruction in obstetrics in the medical colleges.

The discussion on

THE VAGINAL *versus* THE ABDOMINAL ROUTE IN DEALING WITH INFLAMMATORY CONDITIONS AND TUMORS IN THE PELVIS

was introduced by DR. E. W. CUSHING of Boston. He stated that in making the selection of a route much depends upon the personal equation of the operator himself, and upon his medical training. He who sees every operation of this kind performed by the abdominal route will

adopt that method, while he whose experience lies entirely in the vaginal method will operate in that way. The mere item of the length of a man's finger may decide the point. It is difficult for a man to train himself in both methods, so that it becomes a matter of indifference as to which he adopts. In the vaginal operation, there are some advantages, such as the absence of cicatrices, so objectionable in the abdominal method, as well as the danger of hernia. There is also a difference in the amount of shock—there is much less in the vaginal operation on account of the less exposure and manipulation of the intestines. In truth, most of the shock of any operation is probably due to hemorrhage, and if this is prevented the amount of shock will not be noticeable. In vaginal hysterectomy, greater difficulty is experienced in avoiding the ureters, and the entire operation is more difficult than the abdominal procedure; it is easy to lose one's landmarks and to become confused. In the abdominal operation there is a greater certainty of diagnosis. It is much easier to work by sight and much easier to meet any complications that may arise. Weak or fat women are better operated on from below. The size and mobility of the uterus as well as the character of the discharges are general considerations to be studied. Abdominal hysterectomy is the rule for fibroid tumors in America. In France, morcellation is the rule because they are ignorant of our methods. Jacobs and Ségond, after visits to this country, are now performing the American operation. A small tumor, one not more than four or five inches in diameter, is most suitable for morcellation. In regard to malignant tumors of the uterus involving the fundus, the cervix should be sewed up and the enlarged uterus removed from above. Carcinoma of the cervix may be removed by the Clark operation, which is long and difficult, but the better method in the case of ordinary tumors is the operation from below. Inflammatory conditions of the pelvis can be removed by experts as well from below as from above.

DR. SKENE said that twenty years ago he suggested that pus in the ovaries and tubes might be readily reached through the vagina. The abdominal operation was the rule but now the best men are advocating the vagina as the most suitable route. In cases of smaller pus-sacs he opens from above rather than through the vagina. In case of small-sized uterine fibroids he prefers to leave the uterus alone or else adopt Martin's operation.

DR. JOHN CAMPBELL of Belfast said that the route ultimately adopted will depend largely upon the results of statistics, which as yet are to be compiled, and which present statements of the mortality and final results. The greater number of tumors are apparently removed by the abdominal route. In cases of limited inflammation, he prefers the abdominal route, but if the inflammatory condition is more diffused he operates through the vaginal vault, then, in case a large pus cavity is opened, it can be thoroughly drained, and in case of difficulty in entering the vaginal vault, a hysterectomy can be performed.

DR. H. T. HANKS of New York remarked that only star operators should attack certain inflammatory condi-

tions from below. The average gynecologic surgeon should not operate on a ruptured tubal pregnancy from below, nor should the vaginal operation be performed in cases in which there is a certainty of the presence of appendicitis.

DR. J. F. W. ROSS of Toronto stated that in Canada the patient does not trouble herself about the abdominal scar. As to hernia, it is not very common after the abdominal operation, and we are now beginning to hear of vaginal hernia, which is a much more serious condition than abdominal rupture. If it is proper to remove pus-tubes through the vagina it is just as proper to remove a fundal carcinoma that way. Want of space is a great defect in the vaginal route. Pus-tubes cannot be effectively removed from below, portions of the tube almost invariably being left. The removal of an organ not diseased in order to make a way of escape for pus is not admissible. In septic cases, with the patient very ill and when only a temporary opening is required, the vaginal opening is proper. It is impossible, as stated by Hentrotin, to say just where an abscess is located before the operation.

DR. A. LAPHORN SMITH of Montreal stated that he was an out-and-out advocate of the abdominal method. With the Trendelenburg posture, the abdominal surgeon is the master of the situation. The majority of women with pus-tubes are sterile, and in these cases the vagina is too narrow to permit of a suitable operation.

DR. BERRY HART of Edinburgh believed that one should not be a partisan of either route, but that one should decide which is the best operation in any given case. In the majority of cases, the abdominal route is the best, but in certain instances the vaginal incision gives excellent results.

DR. A. F. CURRIER of New York believes that the advantage *par excellence* of the vaginal route is the thorough drainage to be secured thereby. He has seen decided shock after the vaginal operation.

The President, DR. SINCLAIR, stated that he has operated on ruptured tubal pregnancy through the vagina with success. The operation is practically extraperitoneal on account of the presence of adhesions.

At 12.15 the section adjourned to the Royal Victoria Hospital to view a demonstration by DR. HOWARD KELLY of Baltimore of an examination of the female bladder and ureters.

SECTION IN ANATOMY AND PHYSIOLOGY.

FIRST DAY—SEPTEMBER 1ST.

THE BEST METHODS OF TEACHING ANATOMY

was the subject chosen for discussion, and this was opened at considerable length by PROFESSOR ALEXANDER MACALISTER of Cambridge, England. He was followed by DR. SHEPHERD of Montreal and several other Canadian and American speakers. The general feeling of the meeting seemed to be decidedly in favor of lightening the anatomic burdens of the over-driven student by cutting out matter which was only of theoretic interest. The only speaker who dissented from this view

was PROFESSOR MICHAEL FOSTER, who was of the opinion that a man might be taught too much physiology, but could never be overloaded with anatomy. As regards the methods of teaching, there was more divergence of opinion, and different views were expressed as to the value and scope of demonstrations, lectures, examinations, etc., as methods of teaching, all, however, being agreed as to the fundamental importance of practical work in the dissecting-room. The discussion was prolonged until twelve o'clock, when the reading of papers commenced. These were of purely anatomic interest and evoked little discussion. During the course of the meeting, lantern demonstrations were given by PROFESSOR PRIMROSE of Toronto on the method of teaching by means of frozen sections, and by PROFESSOR W. H. THOMPSON of Belfast on the degenerations resulting from lesions of the sensory cortex. A beautiful series of microscopic specimens illustrating the histology of the parathyroid gland, which were sent by DR. D. A. WALSH of Edinburgh, were laid out in an adjoining room.

ANNOUNCEMENT.

THE AMERICAN PEDIATRIC SOCIETY.

THE American Pediatric Society is making a Collective Investigation of Infantile Scurvy as occurring in North America, and earnestly requests the cooperation of physicians, through their sending of reports of cases, whether these have already been published or not. No case will be used in such a way as to interfere with its subsequent publication by the observer. Blanks containing questions to be filled out will be furnished on application to any one of the committee. A final printed report of the investigation will be sent to those furnishing cases.

[Signed.]

J. P. CROZER GRIFFITH, M.D., *Chairman*,

Committee.

THERAPEUTIC HINTS.

Benzoate of Soda in the Treatment of Grippe.—No drug has given more favorable results in the treatment of *grippe* than benzoate of soda. It may be given in capsule or powder form, the usual dose being ten grains three or four times a day. When muscular symptoms are pronounced, the following combination acts admirably:

℞ Sodii benzoas	3 ii
Salol	3 i
Phenacetin	gr. xxxvi.

M., and ft. chart No. xii. Sig. One powder every four hours.

A Gargle for Sore Throat.—From 12 to 20 grains of ammonio-ferric-alum dissolved in eight ounces of water, and gargled at frequent intervals, will relieve ordinary cases of "sore throat" within a few hours.

Creasote Emulsion in Pulmonary Tuberculosis.—One of the best methods of administering creasote, especially in the case of children or those in whom the stomach is irritable, is in the form of an emulsion with cod liver oil, as follows:

℞ Creasoti (beech)	℥. xlviii—3 ii
Gum acaciæ	gr. xlviii
Glycerini	℥ ss
Ol. gaultheriæ	℥. x
Emuls. ol. morrhue, q. s. ad.	℥ vi.

M. Sig. Teaspoonful one hour after meals.

A Cough Mixture for Consumptives.—Although it seldom is justifiable to administer morphin in any form to allay the cough in pulmonary tuberculosis, during the last stage of the disease the following combination will be found to act admirably in procuring a cessation of the cough and inducing the sleep of which the patient so often is in need:

℞ Potassii cyanidi	gr. iv
Morphiæ sulph.	gr. iss
Spt. chloroformi } aa	℥ iss
Tr. hyoscyami	
Syr. acaciæ	℥ iv
Syr. simplicis, q. s. ad.	℥ viii.

M. Sig. Teaspoonful every three hours.

An Excellent Diuretic Pill in cases of dropsy of cardiac origin is the following:

℞ Scillæ, pulv.	
Digitalis, pulv.	
Caffeinæ citratis } aa	gr. xxx
Hydrarg. chlor. mitis	gr. v.

M. et. ft. pil. No. xxx. Sig. One pill thrice daily, after meals.

For the First Stage of Bronchitis.—

℞ Potassii citratis	℥ ss
Apomorphiæ hypochlor.	gr. i
Syr. ipecac.	℥ ss
Suc. limonis	℥ ii
Syr. simplicis, q. s. ad.	℥ iv.

M. Sig. Dessertspoonful in water every three hours.

For Acute Colic.—One of the best mixtures for the relief of that type of acute colic so frequently met with after indiscretion in diet, is prepared as follows:

℞ Chloroformi	℥ iss
Tr. opii deodorat.	℥ i
Camphoræ	gr. xv
Ol. cajaputi	℥ i
Aquæ, q. s. ad.	℥ ii.

M. Sig. Dessertspoonful every two or three hours.

For Atonic Dyspepsia.—An admirable tonic mixture for a patient recovering from atonic dyspepsia is the following:

℞ Strychniæ sulph.	gr. ss
Acid. nitromuriatici	℥ ss
Tr. gentianæ comp. } aa	℥ ii.
Tr. cardamomi comp.	

M. Sig. Dessertspoonful in water after meals.

ORIGINAL ARTICLES.

THE EXTRACTION OF NON-ABSORBABLE LIGATURES.

By JAMES S. CHENOWETH, M.D.,
OF LOUISVILLE, KY.

SINCE the days of Ambrose Paré, probably no one item connected with the technical details of a surgeon's work has given him more concern than has the subject of ligatures. Almost every conceivable suture-material has been tried, but the ideal ligature—strong, pliable, readily sterilized, tying smoothly and tightly, absorbable, but never too soon absorbed—has yet to be discovered. Almost the world over, the question has narrowed down to the use of silk, silkworm-gut and catgut, which most nearly approximate the ideal, but each of which is lacking in some essential particulars. When small vessels are to be dealt with in clean tissues, and little tissue is to be included in the ligature, properly prepared gut of small size leaves nothing to be desired, but under the reverse conditions few surgeons are willing to trust to it. The large strands of gut are difficult to sterilize, difficult to tie, and still more difficult to securely knot for a sufficient length of time to insure occlusion of the blood-vessels. Silk, on the other hand, is easily sterilized without loss of strength, is pliable, and ties smoothly and firmly, but it is non-absorbable. The latter fact is a very serious drawback to the use of the silk or silkworm-gut ligature under conditions which for other reasons make it almost a matter of necessity.

Even if sterile, a large non-absorbable ligature strangulating a considerable mass of tissue not infrequently fails to become encysted and acts as a foreign body; while, if the ligature or included tissue contains infectious material, the almost inevitable result is a discharging sinus, persisting until the ligature cuts through its pedicle and is extruded. To hasten the discharge of this ligature, two plans have been in common use: (1) the ends of the ligature have been left long, hanging from the angle of the wound, traction being made upon them in one of several ways; (2) the ends have been cut short and, failing to become encysted, the ligature has been "fished" out with some convenient instrument. Both of these methods are uncertain in their results and carry positive danger of injury to the vessels of the pedicle, or

to other structures which may have become adherent thereto.

My attention was especially called to this subject eighteen months ago when I had under my care a young man with a disorganized kidney which had to be removed. Twenty months previously I had performed a nephrotomy on the left kidney, following it six months later by a perineal section, great improvement in his general health and comfort resulting, but the constant leakage was very annoying and the prospects of eventually saving his kidney were so slight that at his urgent request its removal was decided upon. Having become somewhat familiar with operative methods by this time, he was very much concerned about the length of time it would require for the ligature to come away from the pedicle. The pluck displayed by this man during his long siege had elicited the sympathy of all with whom he had come in contact, and we set to work to devise means of surmounting the difficulties presented, and of getting him well in the shortest possible space of time that he might accept a position then being held open for him.

No more feasible plan presenting, the kidney was removed by the extraperitoneal route, six silk ligatures being required on the thickened pedicle. The knots were made to fall on the outer surface of the pedicle and as close together as possible, and the ends, left long, were brought out through a large rubber drain, after being marked for future identification. On the seventh day, convalescence having been uninterrupted, the drain was removed and each ligature in turn being held taut it was followed down by the finger and the knot located. It was then an easy matter to clip the ligature against the finger tip, which protected the structures of the pedicle. Recovery was prompt, and our former patient is now the valued superintendent of the water-works and electric-light plant of a thriving little town in a neighboring State.

The use of the endoscope (Klotz tube and Otis lamp) suggested itself to me about this time and has since proved of service, the ends of the ligature being drawn through the tube which is pushed down to the knot, when the thread can be cut with delicate long-handled scissors under the direction of the eye. Each of these methods is open to certain serious objections and drawbacks. In many cases an otherwise unnecessarily large drain must be kept in place for

some days, until the vessels are perfectly occluded. The necessary manipulations are somewhat painful and at the same time the ligature at the bottom of a long tortuous tract may defy such efforts at removal.

Attention was then directed to the application of the ligature in such a way that its knot might be untied and the thread extracted after its period of usefulness had expired. The necessity for thus providing for the removal of ligatures will hardly occur save in deep wounds and where considerable tissue must be constricted by the thread, and in such cases a friction knot on the first turn cannot be safely dispensed with. After some experimentation I hit upon a plan which at first sight appeared to solve the problem. A small but strong silk thread was laid under each knot as it was tied down, and one end of the ligature was cut short while the other, together with the "tractors," previously placed, was brought out of the wound. Traction on the last loop, aided by a slight see-saw motion, readily loosened the second knot. With one end of the ligature cut short (sometimes it seemed dangerously so) the first knot, if single, could also be untied, but not as readily as the other, as the thread could not be placed as squarely under the knot.

When the friction knot was substituted for the single knot on the first turn, trouble was frequently experienced, the threads rolling, becoming twisted and tightly locked. This did not often occur with a *soft, dry* twisted ligature or when *dry braided* silk was used, but if the ligature material was thoroughly wet and tightly tied, an undue amount of force was required to loosen the knot, if this could be accomplished at all. This difficulty was most frequently experienced when the ordinary twisted pedicle silk was used. This defect was partly overcome by looping the thread on the second turn of the friction knot

FIG. 1.

when, the second knot having been untied, traction on this end of the ligature, followed by traction on the first "tractor," would loosen both turns of the knot. The working of this device, however, was still far from perfect. By cutting one end of the ligature short and by using soft or braided silk moderate traction would usually untie the knot, but it appeared to me that this ease of execution was obtained at the expense of safety. This device was

shown and its defects pointed out by me at a meeting of the Louisville Surgical Society March 9, 1896. Dr. Ap. Morgan Vance of Louisville had been present at the operation previously mentioned and had taken great interest in the question of the disposal of the ligatures. At this meeting of the Society, Dr. Vance demonstrated the use of a very ingenious device for burning through and liberating such ligatures. It depended upon the substitution

FIG. 2.

of a platinum loop for the "tractors," the end of the loop being brought out through the rubber drain. At the proper time, by means of a cautery battery, the wire was to be heated, when slight traction on the end of the ligature, left long for the purpose, would bring it away. Though theoretically perfect, many practical difficulties were found in the way of the extended application of this procedure, and in an endeavor to avoid some of its defects I finally devised a method of knot-tying, which, I think, cannot fail to serve a useful purpose in many cases of nephrectomy, hysterectomy, tubal operations, and possibly ovariectomy; in short, in all cases in which moderate traction can safely be made on the pedicle.

FIG. 3.

Looping the left hand thread (or reversing the steps, as may be most convenient), the loop is carried under its fellow, making two turns (a simple friction knot, except made with a loop on one side and a single thread on the other). A pair of hemostatic forceps previously snapped on the free end of the looped thread will facilitate handling. A second knot is now made over this by carrying the single thread back over the loop, tying a single bow knot.

If greater security is desired, it may be attained by tying a catgut thread tightly about the ligature ends close to the knot, which will insure against slipping by accidental traction when completing the dressing; or a preferable plan in some cases is to complete the second knot like the first, by looping the single thread and making a friction knot between the two loops. This knot is easily and quickly tied, and with a single thread is perfectly secure, and can be untied at any time with ease by traction applied alternately to the ligature ends, which must be left long for this purpose. The loops may be made short and left at the bottom of the wound, or, longer loops being made, brought out with the ends of the ligature and clamped together with a hemostat, when all risk of disturbing the knot by accidental traction on the one important thread is avoided.

The special advantages possessed by this knot are apparent: (1) No special apparatus or assistance is required in its application; (2) only one thread is employed; (3) the knot is easily, quickly, and securely tied; (4) it can only be disturbed by traction on one thread; (5) it is readily untied by moderate traction; (6) there is no danger of locking of the thread; (7) only a small opening is necessary for the emergence of the ligature ends and the removal of the ligature.

EPILEPSIA ALKOHOLICA.¹

BY HEINRICH STERN, PH.D., M.D.,
OF NEW YORK.

MORE powerful than the Pope in the darkest periods of medieval ages, more potent than the strongest bonds of solidarity, more arbitrary than any religious decree has ever been, alcohol holds its sway over the entire world and rules indomitably the fate of nations and of man. The influence of alcohol, conquering the mightiest and overwhelming the fittest, was deified, for humanity in its childhood, at the dawn of civilization, idolized and worshiped all, which to it was invincible, impenetrable, and mysterious. Alcohol has exterminated tribes, caused the degeneration of nations, created unhappiness and suffering, spread destitution and misery, and exerts its baneful influence even upon the unborn progeny.

Small doses of alcohol increases the appetite and the digestive function, causing an augmented flow of gastric juice. In larger quantities, the appetite is lost and nausea may appear, while the digestive power is suspended. Long-continued indulgence in alcohol produces, among the somatic symptoms, dyspepsia and gastric catarrh, fatty and atheroma-

tous degeneration of blood-vessels, heart, liver, and kidneys, hyperesthesia, anesthesia, and, in a few advanced cases, hemianesthesia. It produces sensory disturbances, as of vision, loss of pupillary reflexes, subjective noises (ringing and tingling); motor disturbances, as tremor, gross or fibrillary twitchings of the tongue, disturbances of speech; in grave cases, epileptic neuroses, and finally paralytic conditions of the muscular system. Among the psychic symptoms occurring as the result of excessive use of alcohol are gradual decrease of memory, confusion of judgment, impoverished imagination, decrease of moral sense (complete moral degeneration in very advanced cases) and morbid irritability.

Such is the somatic-psychic result of chronic alcoholism. These changes are more or less pronounced, and are dependent in their degree of severity upon different facts, among which I may enumerate the form of alcohol beverage and chemical type of alcohol used, the duration of alcoholic poisoning and resistance of the individual constitution, and environment. The mildest type of chronic alcoholism is represented in the drinker who indulges in alcoholic beverages more on account of habit than of desire. This species of habitual drinker is often for a long time enabled to attend to his vocation, and with the exception of a chronic gastric catarrh and occasional attacks of hemicrania and vertigo, no other bodily symptoms of alcoholism may be detected. The more advanced types of alcoholism, however, present in addition thereto a train of neurotic symptoms such as tremor, paralysis, epilepsy, and disturbances of intellect. One symptom, though, every stage and every degree of chronic alcoholism possesses in common, and that is the defect of the moral sense, the progressing decay of morality. In the beginning it is not easily detectable and often is recognizable only in the indifference toward family ties, in inattention to the demands of refinement, in the relaxation and cessation of former ideal aspirations, and in a too yielding and condescending disposition. Toward the latter stages of alcoholism there is complete decay of ethical sense and of morals.

This alcoholic degeneration which, *per se*, does not necessarily indicate a well-defined disease of the mind, is the basis of the real psychosis. Chronic alcoholism, especially in its initial and less-advanced stages, often only predisposes the drinker to neuroses of intellect, and makes him particularly susceptible to contagious and infectious diseases. In severer cases of alcoholic poisoning we find the vitality and resistance completely undermined, and we meet with grave disturbances of psychical life. These disturbances are all of a toxic origin and are pronounced

¹ Read before the New York Medico-Legal Society.

cachectic phenomena, which, though not solely and absolutely characteristic of alcohol poisoning, occur always in typical forms after abuse of alcohol, thus suggesting their dependence upon the toxic influence of the latter. In the train of alcoholic degeneration we notice a number of distinct types of psychoses, among which are delirium tremens, delirium tremens febrile, alcoholic melancholia, alcoholic mania, alcoholic dementia and alcoholic epilepsy.

Alcoholism in its acute and chronic form, may become an important etiologic factor of epilepsy, and before proceeding further, I may be justified in explaining in a few words that "epilepsy," according to our present state of knowledge, implies, (1) loss of consciousness with tonic-clonic convulsions of one or more muscles of the body—the so-called *grand mal*; (2) loss of consciousness without or with only very slight convulsive movements—*petit mal*; and (3) certain phenomena acting as equivalents to the typical symptoms. Epilepsy, like fever or cough, is only a symptom, and not a disease *per se*. For the sake of convenience it may be subdivided into two great classes, *viz.*, epilepsy caused by traceable organic disease, and epilepsy which may be termed idiopathic. I further divide symptomatic epilepsy into that form caused by anatomic changes—*molecular epilepsy*, and that caused by toxic influences, toxic epilepsy, and classify idiopathic epilepsy as being not traceable to anatomic substrates of pathologic change, or to toxic influences. The idiopathic type is an affection of the vasomotor center in the medulla oblongata (probably also of the center in the cortex cerebri) and is dependent for its manifestations upon an increased irritability of the same; and we may term this type a vasomotor neurosis.

Symptomatic epilepsy—the type produced by organic lesions or by chemic influences—does not resemble the idiopathic type. Some observers have noticed, however, that the more deviating and atypical the seizures are, the more both types resemble each other, and that in some cases all phenomena of the idiopathic type also occur in the symptomatic form, and *vice versa*, in certain cases the lines of demarcation between the two types are finally obliterated. Such cases have been recorded by Meyer, Levy, Hirt, Landouzy, Sireday, and Adamkiewicz.

And now let us see what different authors have to say about the etiologic relation of alcoholism to epilepsy. Schüle says, "Much greater and more pronounced [than the effects of acute alcohol poisoning] are the injurious results of chronic alcoholism. This is manifested in two ways, (a) on the blood, the corpuscles of which change the coagulability of

the fluid being increased, and (b) on the nerves whose functional activity first become stimulated, then over-excited and finally paralyzed. In grave cases we find here the motility neuroses of epilepsy." Portal states, "Experience has proven that not only children but adults after excessive use of food stuffs—and especially of alcoholic beverages—have become epileptic. Tissot and other observers of this type of epilepsy have found some cases where the seizures lasted only during the time of the acute indigestion, but they report other cases in which, after the indigestion had disappeared, the attacks recurred and become more frequent and violent." Magnan asserts, that those acute alcoholics who have epileptic seizures nearly always indulge in absinthe.¹ He thinks that those in whom acute alcoholism occurs, and in whom the epileptic symptoms do not appear, are users of wine or brandy. Nothnagel says, "Although not so frequently as generally supposed, certain causes seem actually to be the etiologic factors of epilepsy. The first place among these causes belongs to the habitual drinking of great quantities of alcoholic liquids, in other words, to dipsomania. *Epilepsia potatorum* has long since been recognized. The seizures of the latter, leaving aside the complications and violent symptoms of alcoholism in the intervals, are nearly analogous to the attacks of ordinary epilepsy. . . . The first appearance of the seizures does not always precede the other grave symptoms of alcoholism, but the epileptic seizures may even introduce the whole train of symptoms characteristic of that condition. The first seizure occurs now and then just after a heavy intoxication, at other times, however, at such a period when, on account of certain reasons, total abstinence had been observed; in still other cases an external accidental influence effected the first insult." Nothnagel, in his further explications, disproves Magnan's assertion that the epilepsy of drinkers is caused only by the excessive indulgence in absinthe, and he shows that although comparatively little absinthe is consumed in Germany, the *epilepsia alcoholica* is not of rare occurrence in that country.

Hamilton states, "Alcoholic epilepsy I do not regard as being the rare affection some authors consider it. In cases of prolonged saturation, where perhaps there are no other symptoms of chronic alcoholism, I have found it perhaps associated with the trance state (cataleptoid) or appearing in the

¹ The leaves and tops of *artemisia absinthium* contain absinthin, a very bitter, yellowish-white constituent and a volatile oil, to which the effects upon the nervous system are principally due. A tincture, flavored with aromatics, form the cordial "absinthe" largely used in France, where its injurious effects have attracted the attention of the sanitarians. Absinthe certainly exerts a specific physiologic action, but it must not be forgotten that the preparation is of an extremely alcoholic nature.

psychic form. . . . Alcoholic and absinthe epilepsies are usually preceded and followed by symptoms indicative of profound saturation. . . . Alcoholic epilepsy is symptomatic. The meningeal thickening of alcoholic origin may be the pathologic basis of very intractable paroxysms."

Westphal observed epileptic seizures in individuals, who only manifested an epileptic condition during an attack of delirium tremens.

Forel noticed that, "Whisky drinkers, especially, develop *epilepsia alcoholica*, which is curable through abstinence." Demme says, "From cases occurring during a period of twenty-eight years at the Jenner Hospital for Children, we have collected a series of published observations, partly from the twenty-second, partly from the twenty-seventh yearly report, which confirms the truth of the conclusions that the artificial increase in arterial tension produced through the influence of alcohol is full of risk and is irrational. There are cases of epilepsy and chorea in older children not affected with hereditary alcoholic influence, in which, according to the history of the case, the copious and steady use of alcoholic drinks was unquestionably responsible for the seizures; the etiologic importance of the alcohol in these cases is proved by the fact that after the complete withdrawal, while under hospital care, without the use of medicine, the epileptic attacks ceased, and the chorea was cured within a comparatively short time. With reference to the question as to whether in childhood the more serious illnesses are directly influenced by the early use of alcohol, I repeat that, in accordance with our observations, there is no doubt that marked excesses in the ingestion of brandy, also of wine, may lead to general epilepsy, certainly one of the most serious and obstinate diseases of the nervous system. Fortunately, however, this result of alcoholism is of rare occurrence."

The observations of Dr. James Edmunds are also appropriate in this connection. These demonstrate the probability of the sequence of convulsions and other forms of brain irritation after the plentiful use of alcoholic drinks given by mothers and nurses for the purpose of quieting the infant.

Alcoholism, however, is not only a possible etiologic factor of epilepsy in the case of the subject himself, but also of epileptic or epileptiform affections in his offspring. I do not say that the acquired epilepsy of the parent *per se* is transmitted to the children or to the following generations, but I do assert that the alcoholic degeneration¹ (which is not merely a symptom but a traceable somatic deteriora-

tion) under certain conditions is apt to produce again in the progeny the epileptic symptom of the parent, and this even occasionally in a more pronounced and aggravated form. In other words, the inherited alcoholic degeneration predisposes the offspring to an early epilepsy.

Krafft-Ebing says: "It is probable that otherwise mentally sound and sober parents if coitus and intoxication accidentally concur, beget imbecile and even idiotic, or epileptic-idiotic children." Hitzig states that the offspring of drinkers inherit as great if not a greater tendency to diseases of the nervous system than the children of nervous parents or those of unsound mind; such children, he says, die from convulsions and other epileptic conditions very early in life, more frequently even than do the children of nervous parents.

Demme, during a period of twelve years, acquired accurate knowledge of the private circumstances of ten families belonging on the one hand to the drinking, on the other to the temperate, class. Thus of fifty-seven children of habitual drinkers there were only ten, or 17.5 per cent. in normal condition during their childhood, while of the sixty-one children of the temperate families, 50 or 81.9 per cent. were in a normal state in their youth. Out of the fifty-seven children of the drinkers, twenty-five died during the first weeks or months of life, some from lack of vitality and some through eclamptic seizures (edema of the brain and its membranes). Six children were idiots, five children remaining almost dwarfish. Five children, as they grew older, became subject to epileptic attacks. One boy was afflicted with severe chorea, which terminated in idiocy. Five children had congenital diseases. Two of the epileptics referred to were themselves alcoholics as a result of hereditary transmission; the outbreak of their trouble was directly connected with pronounced acute alcoholism and was directly continuous with it.

Schüle remarks: "The instances of epileptic children begotten during intoxication, which were procured by Demeaux, Flemming, Ruer, and others, are not only testified to by their sad frequency, but are also proved experimentally by the birth of healthy offspring if the father in the meantime became freed from his passion." Tiedeman is of the opinion that children generated during intoxication will suffer from such incurable nervous disease as epilepsy, and he thinks that posterity suffers for the sins of the fathers. Wilson states that the descendants, without possessing a special appetite for strong drink, and in the absence of certain specific, morbid manifestations, are singularly liable to mental and nervous diseases, especially to convulsions and epilepsy. Torget is of the opinion that

¹ I refrain from speaking of the inherited alcoholic habit of the parents, which may be the result and symptom of an inherited psychopathic affection.

chronic alcoholics always beget epileptic children, while an acute and accidental intoxication of the father at the time of coitus would not produce such a result in the offspring.

Although epilepsy due to alcoholism is a well-recognized fact, the literature upon this subject is quite scarce, and wherever I have found quotations alluding to that condition they invariably have been only of an abbreviated nature. It seems to me that either sufficient attention has not been given by otherwise careful and painstaking observers to the epileptic symptom of alcoholism, or that they have considered the latter such a well-proven fact that they have deemed it unnecessary to present conscientiously prepared statistics or to attempt pathologic explanations.

Alcoholism—especially in its chronic form—is rather a typical condition of somatic and psychic deterioration than a clearly defined disease, a condition which is characterized by lesions of the nervous system and the viscera, by grave disturbances of nutrition, and by pronounced intellectual and ethical deterioration. Congestive and inflammatory processes, sclerosis, steatotic and atheromatous degeneration, affect the different tissues and organs of the body and produce their specific and typical train of symptoms. Hence, the epileptic symptom of alcoholism is the outcome of chemic or anatomic changes.

Although alcoholism produces easily recognizable anatomic changes, which in turn may again give rise to epilepsy or other symptoms of degeneration, I hold that those chemic alterations of the composition and vital energy of the plasmic units, which we cannot definitely comprehend at the present day, and which in this instance are brought about by the influence of alcohol, are the principal causative factors of the type of epilepsy in question and of kindred neuroses. The nutritive exchange of the cells in an organism saturated with alcohol is impaired. The normal vital activity of the plasmic unit, its inherent ability to affect chemic change, is partly or totally suspended, is paralyzed, if physiologically, and poisoned, if chemically, viewed. This is especially true of the cells of the nerves, and if nerve matter and nerve tissue becomes in any way impaired, serious consequences will result in the nervous system as well as in the system at large.

Anatomic changes may be the result of impaired molecular nutrition, but long before these are developed and are recognizable, chemic changes must necessarily have taken place. We must turn to physiologic and pathologic microchemistry, therefore, and not to mere pathologic anatomy, if we wish to trace the very beginnings of degeneration. That

the chemic changes due to alcoholism, even if no anatomic degeneration has taken place, are alone capable of producing the neuroses of alcoholism, as epilepsy, is my firm conviction, although I cannot conclusively demonstrate it to-day.

Concerning the symptomatology of *epilepsia alcoholica*, I wish to state that while in some cases epilepsy is only of secondary importance, being merely an occasional symptom of the alcoholic condition, it is necessarily of the utmost value and consequence in such cases, in which the other symptoms of a former alcoholism have disappeared or are obliterated, for *epilepsia alcoholica* will persist as long as the epileptic seizures continue, as it originated as a result of alcoholism. The latter, in the meantime, may apparently have been obliterated. The general characteristic indications of the condition of acute or chronic alcoholism, plus the symptoms of epilepsy in its *petit* or *grand mal* or equivalent variety, are also the characteristic features of *epilepsia alcoholica*. However, these symptoms do not all appear together. During the paroxysms the epileptic features are easily recognizable, while during the intervals the symptoms of alcoholism may more or less present themselves. In many cases, during long intervals, especially, there are even no characteristic evidences of alcoholism. The *petit* and *grand mal* varieties, the first with a comparatively long-continued unconsciousness, were the conditions met with in my cases. I have not as yet seen a case of alcoholic epilepsy in the state of the epileptic equivalent.

I am able to report five cases of pure alcoholic epilepsy which have occurred in my private practice. This number may seem large but certainly is not unusually so in this region, for I contend that *epilepsia alcoholica* is of much more frequent occurrence than practitioners in general are led to believe. If the physician spares neither time or labor in minutely studying the previous history of his alcoholic patients, he will soon be convinced that the convulsions and unconsciousness will possess an epileptiform or a genuine epileptic character in many instances.

CASE I.—H. W., male, aged 41, of German extraction, married, musician, comes from a healthy stock. With the exception of the usual exanthematous diseases of childhood, he had never been sick, and showed no symptoms of any organic affection. In his thirty-seventh year he suffered from the strain of incessant work, and to prevent collapse he resorted to the excessive use of alcoholic stimulants. One night, when playing in an orchestra, he had what he considered a "fainting spell"—a loss of consciousness of about one minute's duration. After that time he experienced severe headaches, occasionally continuing for three days, and kindred attacks,

sometimes two or three in succession. During this period, in which he continued to drink, his wife noticed a progressing *debilitas memorie* and a slower and more retarded manner of speech, also occasional paroxysms with loss of consciousness and consequent stupor. The deprivation of alcohol, and a general anti-alcoholic treatment improved the patient to such an extent that he now has, on an average, only about one seizure in two months, the attack being of the nature of *petit mal*.

CASE II.—J. P., male, aged 49, German, unemployed, married, father of three healthy children; parents were healthy and lived to old age; no neuroses in other members of the family. The patient did not remember ever having been sick. Examination revealed irritability in the epigastric region and internal hemorrhoids. Six years before I saw him the patient, on account of reverses in business, contracted the alcohol habit. He occasionally drank until he became unconscious and remained in a lethargic condition for thirty hours or longer. About a year afterward, typical epileptic paroxysms set in. These always occurred after a well-marked prodromic stage of headache and vertigo, and were ushered in by an aura epileptica of a sensorial nature, the patient experiencing a sensation of something rising from the stomach to the pharynx.

I happened to be present during about sixty attacks of this nature, each one invariably being preceded by the characteristic epileptic cry. Unconsciousness, tonic-clonic convulsions, cyanosis, grinding of the teeth, foaming at the mouth and post-epileptic stupor and weakness characterized the attacks. On account of spasmodic contractions of the urethra after the paroxysms, I had to resort occasionally to the use of the catheter, the introduction of which was difficult. Analysis never revealed the presence of any abnormal urinary constituents.

At the present time the patient is well nourished. Tremor is present in hand and feet, speech is very slow and incoherent, and there is occasional aphasia. Progressing amnesia, deterioration of intellect and loss of will power are marked. The epileptic attacks, though rarer, continue, but three or four always occur in succession—within six or eight hours. Sooner or latter the patient may be the subject of epileptic dementia.

CASE III.—On June 1, 1895, I was called to see J. A., female, aged 45, Irish, married, mother of eight children who are all alive. Personal and family history good. The patient complained of "sour stomach" and "sick headache." A superficial examination convinced me that she had been drinking, which she admitted. Family affairs had driven her to the use of whisky, the first dose of which she had taken two days previously. After prescribing a powder containing acetanilid, bicarbonate of soda and citrate of caffein, I left her. Toward evening of the same day I again was summoned. I found the patient in a state of somnolence. The attendants told me that she had had "a fit and twitchings all over the body." Soon after she awoke and regained her senses, but within a few

minutes she had a second attack, which was undoubtedly of an epileptiform type. During the night she had two similar seizures. The occurrence of previous epileptic paroxysms was absolutely denied by the family and by the patient herself. The following day she felt quite comfortable, although complaining of slight vertigo and a burning sensation in the urethra during micturition. The epigastric region was tender on percussion, congestion of the liver and gastrohepatic catarrh being present.

On June 2d an analysis of the urine demonstrated the presence of mucin and alkaline phosphates in excess, and of acetone (C_3H_6O) and diacetic acid ($C_6H_{10}O_3$). On June 4th there were traces of acetone and diacetic acid, and on the 6th the urine was perfectly normal.

The patient discontinued the use of alcohol until the middle of March, 1896, when she indulged freely again. On the 18th of that month she had an epileptic seizure similar to those which occurred during the previous June. On March 20th, 24th, and 25th the attacks recurred. On the latter day I observed some characteristic features of alcoholism, there being tremor and trembling of the tongue, great impairment of the appetite and digestion and obstinate constipation. Amnesia, semi-unconsciousness, hallucinations, great fear and a suicidal tendency, which were reported to me, convinced me that her state was one of melancholia alcoholica. The hallucinations continued and were of a religious character. This condition lasted for about two weeks, during which time she refused all nourishment but milk. The urinalysis showed an excess of alkaline phosphates and traces of acetone and diacetic acid.

From July 16th to July 26th the epileptic seizures recurred at intervals, the tremor, incoherent language, melancholia and defective memory continuing. During the night of September 5th I was summoned to the patient and found her lying on the floor breathing heavily and totally unconscious. Her eyes were staring and wide open. From that time until October 6th she was more or less unconscious but had some lucid intervals of very short duration. During a fortnight a quasi-continuous convulsive epileptic condition prevailed, the patient having as many as fifteen daily seizures. Repeated urinalyses revealed the presence of acetone and diacetic acid. After being in a profoundly comatose state she finally died on October 6th. The family did not permit an autopsy.

CASE IV.—G. H., male, aged 38, American, merchant. Individual and family history good. This patient had a peculiar habit of going once a month "on a spree," and generally stranded in some suburban town, from whence he came back to the city a sober man again. In March, 1895, during one of his whisky excursions, he suddenly developed symptoms which seemed peculiar and strange to the trained eye of the innkeeper at whose place he stopped, and that evening he was brought to my house and left under my care. During the night he had a specific attack of epilepsy. Physical and psy-

chical examinations on the next day revealed the presence of flabby muscles, deficient reflex irritability, a fresh wound on the tongue, from biting, extreme nervousness, restlessness, insomnia, a very slow manner of speech, and a morbid state of dreariness and discouragement. The urinalysis showed an excess of phosphates.

Energetic anti-alcoholic treatment (partly of a moral nature) resulted in a perfect cure of the alcoholic condition, as well as of the epileptic symptoms. The patient became a total abstainer and has remained so ever since. He is now a man of 250-pounds' weight, healthy, vigorous, and ambitious.

CASE V.—M. H., female, aged 40, German, spinster, weakly developed, first came under my care about two years ago. Her former physicians had ordered her to take cognac as a general tonic and stimulant. She thus contracted a moderate liquor habit. When first seen she complained of dizziness, migraine, disturbed vision, neuralgic pains in the dorsal region of the spine, forgetfulness, aphasia, and occasional unconsciousness. She explained that "a peculiar sensation would come over her and she would faint." I repeatedly had occasion to be present during some of these attacks, and I am convinced that they were epileptiform, resembling *petit mal*. She had her first seizure about three months after her medicinal indulgence in alcohol. Previous epileptic attacks were positively denied. The use of alcohol was forbidden and the attacks became less frequent. The patient has had no seizure for the last eight months.

The earliest period at which any of my patients have first been attacked with alcoholic epilepsy has been during the thirty-seventh year, and the latest period during the forty-fifth year. The number, however, is too small from which to draw any deductions as to the period of life in which *epilepsia alcoholica* most frequently occurs. Case III., interesting in every respect, is particularly so on account of the absence of glucose and the unfailing presence, after the attacks, of both acetone and diacetic acid in the urine.¹ To my mind, there is no doubt that the occurrence of acetone and diacetic acid in this

instance was due solely to alcohol, particularly so as the patient at those periods had no desire for food at all and sustained life with small quantities of milk only.¹

This is the more convincing when we consider the relationship of alcohol to acetone and ethyl-diacetic acid.

Ethyl acetate, $C_2H_5O.O_2H_5$, is prepared by distilling an acetate with sulphuric acid, H_2SO_4 , and alcohol, $C_2H_5.OH$. Metallic sodium dissolves in ethyl acetate, with the formation of sodaceto-acetic ether and sodium ethylate.

If acetic acid is added to the solid product, acetic ether (ethyl-diacetic acid) $CH_3CO.CH_2.CO.OC_2H_5$ ($C_6H_{10}O_5$), separates as an oily liquid. Ethyl-diacetic acid under the action of alkalies takes up water and decomposes into acetone, alcohol, and carbon dioxide, $C_6H_{10}O_5 + H_2O = C_3H_6O + C_2H_5O + CO_2$.

Alcohol, in my opinion, caused acetonemia and diacetemia in the case of the third patient. One or the other or both of these conditions may possibly have been the direct etiologic factor or factors in the epileptic attacks. However, there is no doubt that the long-continued comatose condition before the final catastrophe was due to diacetemia, or to a very kindred condition.

As to the prognosis of *epilepsia alcoholica*, I can only say that it depends entirely on the alcoholic condition of the system. As for the treatment, the usual antidotes for alcoholic poisoning and saturation should be administered.

From a medico-legal standpoint, *epilepsia alcoholica* should prove very interesting. While alcoholic intoxication, according to the prevailing laws, does not excuse from legal responsibility, the peculiar epileptic consciousness, or rather unconsciousness will, at least it has done so in one or two instances on this side of the Atlantic. The great cardinal factor, alcoholism, is not recognized by our antiquated system of justice as a legal cause of irresponsibility, but the more occasional symptom of that condition, *epilepsia alcoholica*, if brought forward as a defense, would, in all probability, be recognized as such.

¹ Detection of acetone. (Heinrich Stern, "Urinalysis," New York, Pelton, 1897.) Chautard's test: Reagent, aqueous solution of magenta decolorized by sulphurous acid. To five cubic centimeters of the urine add one drop of the reagent. If acetone is present in quantities over 0.01 per cent., a violet color will appear after five minutes.

By Lieben's test: Reagents, potassium iodid and liquor potassæ. Distill a small quantity of the urine, if possible. Take into a test-tube four cubic centimeters of liquor potassæ, add 1.35 grams of potassium iodid and boil; next float the urine (a distillate, if possible) upon the test solution. Notice at the point of contact precipitation of phosphates, which becomes yellow and filled with molecules of iodoform if acetone is present.

Detection of ethyl-diacetic (diacetic) acid by V. Jaksch's test: Reagents, ferric-chlorid solution, sulphuric acid, and ether. To the freshly voided urine add a few drops of ferric-chlorid solution. If phosphates are thrown down, filter and add a few drops more of the ferric-chlorid solution to the filtrate. If a red color appears, boil half the quantity of urine and to the other half add some sulphuric acid and ether. If the red color is not pronounced, or does not occur at all in the boiled urine, and if it becomes of a lighter shade after twenty-four hours in the sulphuric acid-ether-mixture, and if acetone in excess is found in the distillate, diacetic acid is present.

¹ Acetone and diacetic acid may be products of albumin decomposition, and acetone occasionally appears after the excessive use of food-stuffs rich in proteid matter. The amount of milk taken by this patient was, however, so very insignificant that the formation of acetone and diacetic acid can only be ascribed to the excessive use of alcohol.

**SHORTENING THE ROUND LIGAMENTS
 THROUGH THE ANTERIOR VAGINAL
 FORNIX FOR POSTERIOR DIS-
 PLACEMENTS OF THE
 UTERUS.¹**

By J. RIDDLE GOFFE, M.D.,
 OF NEW YORK;

PROFESSOR OF GYNECOLOGY IN THE NEW YORK POLYCLINIC
 MEDICAL SCHOOL AND HOSPITAL; VISITING GYNECOLOGIST
 TO THE NEW YORK CITY HOSPITAL.

It is an accepted axiom of therapeutics that the greater the number of drugs recommended for a specified condition the greater the probability that none of them is reliable. What is true of drugs is also true of surgical procedures, and no study of treatment illustrates this principle more conspicuously than the management of retrodisplacements of the uterus.

The consensus of opinion is now centering upon the round ligaments as the most serviceable structures to utilize in any method which aims at maintaining the uterus in a normal, anteverted position, and the operation which is most popular at the present time is that of Alexander. The objections to this are its narrow field of application, the uncertainty in all cases of finding the round ligaments sufficiently strong at this part of their course to withstand the necessary manipulations and strain, the unsightly scars which the operation necessitates, and the increased susceptibility to hernia.

The field of application of Alexander's operation has been extended to include cases of adherent uteri by introducing the preliminary steps of a vaginal section, breaking up the adhesions, and setting the uterus free. But when once the vagina has been incised and the pelvic cavity entered, the opportunity

is offered of shortening the round ligaments through the vaginal incision, and thus relieving the patient of the additional inguinal wounds, the danger of herniæ, and the objectionable scars.

As the majority of persistent retrodisplaced uteri are associated with more or less extensive disease of the appendages and accompanied by adhesions, the vaginal incision becomes necessary if Alexander's operation is to be employed. Mackenrodt took advantage of the situation thus presented in making the vaginal incision anterior to the cervix, separating the bladder from the uterus, entering the peritoneal cavity through the peritoneal fornix between the bladder and the uterus, passing his finger over the uterus, setting the organs free from their adhesions, and stitching the uterus to the vaginal walls. I have performed this operation a number of times, with most satisfactory results as far as the relief of all symptoms was concerned. The unfortunate interruption of pregnancy in some cases and the serious consequences attending labor in others, which were reported by operators in Germany, were sufficient to deter further employment of the procedure. The feature of the operation which was fatal to its success was the involvement and fixation of the anterior wall of the uterus, preventing its proper development and expansion during gestation. If this could be eliminated, the remaining steps of the operation seemed to present the best method of dealing with persistent retroposed uteri. The advantages of the operation impressed themselves so favorably upon a number of different operators that we find them vying with each other in endeavoring to modify it in such a manner that the fixation of the uterus itself might be avoided while its normal position was maintained. That they should turn at once to the round ligaments as the proper means through which to accomplish this is most natural; and we find Wertheim¹ attaching the round ligaments at a point one or two centimeters from the horns of the uterus to the vaginal wall, and in one case simply shortening the round ligaments by doubling them on themselves and fastening them in that position by means of silk sutures. Guenther,² after setting the organs free from their adhesions, working through the anterior vaginal incision, suspended the uterus by its round ligaments by passing a silk suture through the abdominal wall from within outward and tying it on the skin. Kiefer,³ of Martin's clinic, adopted a more systematic plan of doubling the round ligaments on themselves, after Mann's method, working through the anterior vaginal incision. He also proposed suspending the

¹ Read at the Twenty-second Annual Meeting of the American Gynecological Society, held at Washington, D. C., May 4, 5 and 6, 1897.

¹ *Centralblatt f. Gyn.*, March 7, 1896.

² *Ibid.*, March 28, 1896.

³ *Ibid.*, April 11, 1896.

uterus by the round ligaments, passing the needle through the abdominal walls from without inward, guiding its point by his finger passed through the vaginal incision.

Byford¹ of Chicago working along the same lines at the same time, not only shortened the round ligaments through the vaginal incision, but strengthened this support by attaching the fundus of the uterus by means of two catgut sutures to the bladder peritoneum at as high a point as could be reached. The latter procedure he regards as an additional safeguard in that it assures a return of the fundus forward during the contraction of an emptying bladder. Dr. Byford announced that he had operated upon ten patients by this method, and in each instance the uterus had remained in a normal mobile position without the aid of a pessary at any time.

During March, 1896, I operated upon a woman at the New York Polyclinic for the relief of an adherent, retroverted uterus. I intended to perform the Mackenrodt operation, but in separating the firm adhesions about the appendages of the right side the ovary was so badly mutilated on account of its degenerated condition that I decided to remove it. In doing so I caught up the round ligament, as well as the tube, in the ligature, and thereby shortened it so much that it noticeably steadied the uterus in its anteverted position. I therefore decided to utilize that structure for maintaining the position of the organ, and, catching up the round ligament of the opposite side, I doubled it upon itself and fastened it in that position with fine silk sutures. The result was all that could be desired in every particular. The woman returned repeatedly to the Polyclinic after dismissal from the hospital, and the success of the operation was demonstrated over and over again to the members of the class throughout the remainder of the session.

Stimulated by this success and by the reports of the various operators previously mentioned, I decided to systematically make use of the method in suitable cases in order to test its feasibility and value. I found that by making a free longitudinal incision along the anterior vaginal wall and separating widely the tissues between the uterus and bladder, it was not a difficult matter to pass one or two fingers over the fundus of the uterus, break up adhesions, and turn the uterus down through the incision into the vagina. It is surprising to one who has not attempted or witnessed it to discover how much more accessible, either for removal or for conservative treatment, the ovaries and tubes are through this anterior incision than through an opening into Douglas' pouch. After delivering the fundus into the

vagina the appendages, first of one side and then of the other, can be separated from their adhesions and brought down also into the vagina, where, within easy reach and in plain view, they may be removed or treated, as may be indicated, in accordance with the most approved idea of conservative work. In this way I have removed pus-tubes and ovaries, set the appendages free, tested the patency of tubes, excised ovaries, etc., finishing the operation in all cases by shortening the round ligaments. In some instances I have opened the sheath of the round ligament with an aneurism-needle, lifted the ligament out of its bed, lapped it upon itself, stitched it in that position with two silk sutures, and allowed it to disappear again beneath the peritoneum. My object in this was to take up more slack in the ligament, thinking I could make it run in its sheath, as is done by pulling upon it in Alexander's operation; but in each instance I found the ligament so adherent to its bed that it had to be dissected out by slipping the aneurism-needle, which had been hooked around it, back and forth, which procedure was attended by a most annoying hemorrhage. I, therefore, have abandoned this step of the operation, and content myself with simply catching up the ligament with artery forceps, lapping it upon itself, and stitching it with fine, twisted silk.

The technic of the operation is as follows: The patient is prepared as for vaginal hysterectomy. As a preliminary step the uterus is thoroughly curetted and packed with iodoform-gauze. Steadying the uterus by dragging down the cervix strongly with tissue forceps, a transverse incision is made across the vagina, about one inch in front of the cervix. It is better to make this incision at some distance from the cervix instead of at the vaginal junction because it allows the cervix to swing back more freely when delivering the fundus into the vagina. By blunt dissection, as in hysterectomy, the bladder is dissected from the uterus up to the peritoneal fornix. The edge of the transverse incision is then caught by two artery forceps near the median line, and while the anterior vaginal wall is steadied by these forceps a longitudinal incision, the entire length of the vagina, is made at right angles to the first incision, from its middle point to the base of the urethra. This extends through the vaginal wall. The bladder is then dissected from the vagina for a distance of an inch or an inch and a half on each side of the incision. The hemorrhage during this part of the procedure is very inconsiderable, consisting usually of general oozing. Any points which show a tendency to bleed may easily be caught in forceps and twisted or ligated. The peritoneum is now opened, and torn freely toward each side by passing the two index-fingers

¹ THE MEDICAL NEWS, October 31, 1896.

through and making lateral pressure. The finger can now be readily passed over the uterus and a thorough examination made of the retro-uterine space, the appendages, and the whole pelvic cavity. If there are no adhesions in the pelvis, it is a simple maneuver to hook the finger over the free border of the broad ligament near one horn of the uterus and bring it into the opening. By lifting the bladder with a strong retractor and making traction by the finger hooked over the broad ligament, the uterus can readily be delivered into the vagina by dragging down first the adjacent horn, then the fundus, and finally the other horn. It requires some patient manipulation to accomplish this with the fingers, but it avoids puncturing the uterus with any sharp instrument like a tenaculum or bullet forceps. The round ligament is now caught up with artery forceps as far from the horn of the uterus as will permit the point at which it is caught being drawn to the site of origin of the ligament. This distance varies from two and a half to three inches. A needle armed with fine, twisted silk is now passed through the round ligament midway between the forceps and the uterus, and again through the round ligament at a point an equal distance from the forceps on the distal side, and the suture tied. Another suture is passed through the round ligament at the point at which it is caught by the forceps and made fast at the point of origin of the round ligament from the uterus. One or two more interrupted sutures may be passed through the three segments of the ligament as they lie side by side between these two sutures, to relieve the strain on the first two and make the attachment more secure. The round ligament on the opposite side is treated in the same way, and the uterus returned to the peritoneal cavity. The longitudinal incision in the vagina may now be closed with a running catgut suture, closing the entire wound immediately, although I prefer to leave a small opening at the end of the incision next to the uterus and to tuck in a short piece of gauze, such as is usually employed for packing the uterus, between the bladder and the uterus, where I leave it for a day or two for the purpose of drainage. The vagina is now lightly tamponed with a strip of gauze, a self-retaining catheter is inserted into the bladder, a T-bandage applied, and the patient is ready for bed.

In cases complicated by extensive adhesions between the appendages and surrounding structures, or about the uterus itself, these must be carefully separated before the uterus can be drawn into the vagina. After the uterus has been delivered the appendages may also be drawn down and treated, as has been previously said, either by exsection, resection, amputation, or removal.

I have operated upon a number of patients by this method apparently with most satisfactory results. They have been under observation for periods varying from one year to two months. None of them has become pregnant, as far as I know. I simply introduce the method here as a suggestion, with the hope that it may commend itself, and be subjected to a thorough trial in other hands.

NOTES ON THE ADVISABILITY OF UTERINE TAMPONAGE AFTER CURETTAGE.¹

BY J. O. POLAK, M.D.,
OF BROOKLYN, N. Y.

IN the September, 1896, number of the *American Gynecological and Obstetrical Journal*, Dr. J. H. Rishmiller of Minneapolis called attention to the indiscriminate use of gauze within the uterine cavity. Two clinical truisms from his paper exactly coincide with the writer's experience, *i. e.*, that the average temperature of the patient after curettage is lower without than with gauze packing; secondly, that the intra-uterine tamponage is a potent factor in the etiology of salpingitis.

From a varied and extensive employment of gauze for drainage or as a tampon within the uterus, the following facts have been noted: A strip of gauze will not drain the uterus unless the free end rests in a mass of absorbent material; even then, when this mass becomes saturated, drainage ceases and, the meshes being filled, further capillary action stops. Plain sterilized wicking drains better than gauze loaded with fixing agents and iodoform. Finally, firm packing retards rather than favors good drainage, as by its presence it excites the uterus to contract and forces the tampon down to plug the internal os, and hence the secretions are retained, and not finding an outlet are dammed back through the tubal orifices, with disastrous results. One or two drams of mucopus has followed the withdrawal of the packing in a large proportion of drainage cases. This amount of secretion was less in those instances in which the uterus had been washed out with a normal salt solution before the tamponade was introduced, and greatest in those in which a weak sublimate solution had been used for irrigation.

The writer has employed a gauze drain following curettage in 187 cases, and is convinced that drainage did not continue for more than twenty-four hours. Aside from this clinical demonstration, the gauze removed at this time was tested by placing one end in a basin containing normal salt solution while the free end was allowed to lie in a mass of loose gauze. At the end of two hours the receiving gauze was not even moistened. Other experiments on the

¹ Read before the Kings County Medical Association.

same lines have given very similar results. If drainage is to be used within the uterus, all that can be gained by its employment will be accomplished within twelve hours. Two cases of pyosalpinx have been directly traced to an intra-uterine tamponade. These patients were examined under ether prior to curettage, and the tubes were found to be normal. In a septic case in the writer's service, after thorough intra-uterine irrigation, a twist gauze drain was introduced to the fundus, and within four hours all drainage had ceased externally, yet on withdrawal, decomposing fluids escaped through the cervix, and the patient's temperature fell. After each re-introduction of the drain the fever increased.

In uterine hemorrhage we have a valuable means of control in the employment of gauze, but in order to make a firm compress, damp gauze must be used. After the bleeding has been controlled the gauze should be withdrawn little by little, and not all at once, as occasionally a secondary hemorrhage will occur immediately upon emptying the uterus. As a result of his experience, the writer prefers to drain by artificial means *only* in those cases in which the condition is a septic one, or when hemorrhage is free. In the former instance, the insertion of a Morris gutta-percha tube, which should be left in place for twelve hours, will suffice, while in the latter, a firm intra-uterine tamponade, which should be gradually withdrawn when uterine contraction occurs, is not objectionable. In aseptic cases the uterus will look after itself.

CLINICAL MEMORANDA.

CHOLELITHOTOMY; REPORT OF SEVEN CASES.

By I. S. STONE, M.D.,
OF WASHINGTON, D. C.;

SURGEON TO THE COLUMBIA HOSPITAL FOR WOMEN.

THE removal of calculi from the gall-bladder and the cystic duct may be accomplished without great danger to the patient, and afford prompt relief from persistent if not dangerous symptoms. It may be seen by reference to the following report that the clinical history of the condition varies greatly. There is no positive diagnostic sign by which one may ascertain the cause of biliary obstruction. We see many patients afflicted with jaundice, pain, nausea, and other symptoms who rapidly recover under appropriate treatment while others have recurrent attacks of pain and gastric symptoms, perhaps without jaundice, who have gall-stones and are permanently relieved only by operation.

The method of operating adopted by the writer is that given by Greig Smith in his work on "Abdominal Surgery," only with a preference for suturing the peritoneum to the sac instead of the sac to the skin. Mr. Smith mentions the fact that suture of the sac to the skin often

results in the production of a permanent fistula, and says: "Therefore, if we seek to have a fistula which will spontaneously contract and close, we must leave between the walls of the bladder and the skin a bare surface which will granulate freely." An incision is made just below the rib, over the gall-bladder, outside of and parallel to the rectus muscle. The peritoneum, when divided at this point, appears thick and firm and less elastic than in the median line, as there is less connective tissue between it and the underlying fascia. The gall-bladder once reached, and the diagnosis confirmed, a search is made for the ducts to ascertain if they are occluded. This may be quite difficult or impossible in some cases. If a stone is found in the cystic duct it is a better plan to aspirate the distended bladder, pack sponges around the sac, and remove the stone before the sac is sutured to the skin or peritoneum, but if stones are found only in the bladder the sac may be sutured at once and the stones removed.

A sound may be used for exploratory purposes, but there usually is abundant proof of the patency of the cystic duct in the abundant discharge of bile after the obstruction is removed. This does not insure the patency of the common duct, however, which must be carefully examined before the wound is closed. After thorough irrigation of the bladder, a drain is inserted and the wound neatly closed around it. There is no necessity of flushing the abdominal cavity, as all fluids may be readily removed by means of sponges.

CASE I.—Mrs. M., aged thirty, had had pain and swelling below the ribs in the region of the gall-bladder for several months before I was consulted with regard to the case by Dr. Mauss of this city. The tumor resembled an enlarged kidney, was somewhat tender and was movable in every direction except downward. The patient was admitted to Columbia Hospital, and an operation was performed on June 18, 1892. The opinion had been expressed by several physicians present that the tumor was a large kidney. It proved to be a distended gall-bladder, which contained several large stones. I neglected to take the precaution, however, to see that the cystic duct was open, as in subsequent operations. The wound refused to heal, and after several months, a stone was found in this duct, and a second incision was made for its removal. The patient made a perfect recovery, the sinus remaining after the first operation healing promptly.

CASE II.—Mrs. C., aged thirty. Referred to me by Dr. Carter of Virginia. All the symptoms in this case were acute, and a diagnosis of appendicitis had been made by her physician. The patient had had pain for more than a week between the rib and anterior superior spine of the ilium, the space being occupied by a tumor which was tense, tender to the touch, and only slightly movable under manipulation. Her pulse was 120 and temperature 102° F. She was removed from her home in Virginia to Columbia Hospital, and an operation performed on May 10, 1895. My diagnosis of distended gall-bladder due to the presence of a stone proved to be correct. The gall-bladder was sutured to the peritoneum, opened, and a stone weighing thirty grains was removed from the cystic duct. The patient made a prompt recovery.

CASE III.—Mrs. R., aged twenty-five, colored. Referred to me by Dr. Baggett of this city. This patient had been jaundiced for several weeks. She had a tumor in the region of the gall-bladder, extending nearly or quite to the level of the umbilicus. This tumor was sensitive to the touch, fixed in its position, connected with the liver, and, as in the other cases, could be lifted up from behind. A diagnosis of distended gall-bladder due to impacted stone was made, which proved to be correct. At the operation, May 22, 1896, a large number of gall-stones were removed from the gall-bladder, a rubber drain inserted, and the collapsed sac sutured to the peritoneum. The patient was well and left the hospital after two weeks.

CASE IV.—Mrs. McF. W., aged forty-five. Referred to me by Dr. Moran. This patient had been under observation during several months prior to her admission to Columbia Hospital in March, 1896. I had seen her in consultation, and confess to having given rather a gloomy prognosis. She had a tumor which was attached to the lower edge of the liver, and had vomited blood and mucus. In addition, her skin was of a decided icteroid hue, and the clinical picture resembled strongly that of cancer of the liver or stomach, or both. This attack, although quite severe, was recovered from and the woman returned to her work. She gave no distinct history of a sudden cessation of pain, and there was no diminution in the size of the tumor, but she was relieved temporarily by an escape of the contents of the gall-bladder through a fistula into the adjoining bowel, which process may be called a natural cholecystenterostomy. The gall-bladder was firmly contracted around several stones, which were removed through a long incision, and the sac was then inverted and closed throughout its entire length. This treatment of the gall-bladder had the effect of obliterating its cavity, which as it was no longer needed, seemed a desirable result. An attempt was made to separate extensive adhesions between the bowel and under surface of the liver. Nearly two hours were required to complete this very tedious operation and to tie all the bleeding vessels in the adherent surfaces of liver, bowel and mesentery. It may be seen, therefore, that this accidental escape of the infectious contents of a distended and possibly suppurating gall-bladder had nearly cost the patient her life from peritonitis. Iodoform gauze was carefully placed between the raw surfaces of the bowel and liver in order to prevent reformation of adhesions. She promptly recovered from the operation, the gauze was removed on the fourth day, and the wound gave no trouble whatever. She is in good health at the present time.

CASE V.—Mrs. G. W., aged forty-seven. Formerly in care of Dr. Tompkins of Virginia. This patient had all the symptoms of gall-stones, minus the jaundice. Instead, there was a blue color of the skin, due to the long continued use of silver nitrate for chronic diarrhea. It is impossible to say what the diarrhea had to do with the disease of the biliary ducts or of the gall-bladder. The history was too indefinite for clinical report. There was no pronounced enlargement of the gall-bladder, hence the diagnosis was not definite or conclusive. However, when

the bladder was found to be filled with many small stones the operation was completed in the usual manner, the patient making a very quick recovery. She sat up in less than a week, and soon afterward returned to her home. Operation April 4, 1896.

CASE VI.—Mrs. H. W., aged thirty-three. A patient of Dr. Woulhaupter. I had operated upon this woman for rectocele, and lacerated perineum during November, 1895. During her recovery from the operation, she experienced an attack simulating gall-stone colic. After her return home she continued to have pain in the region of the gall-ducts, to which were added indigestion, anorexia, and nausea. She was somewhat constipated and the occurrence of flatulence was so pronounced as to lead her to believe that her distress was due to that alone. The attacks of pain continued until she very reluctantly yielded to my suggestion that an attempt be made to remove the stones. Accordingly she entered my private hospital and the operation was performed on April 28, 1896. Only two stones, the size of buckshot, were removed. A drainage-tube was placed in the sac and kept in position for five days. When it was removed two other stones followed its exit, and as no more could be detected by means of the probe the wound was allowed to close. In this case, as in all of the others, the discharge of bile was very abundant until after the removal of the drainage tube, when it ceased spontaneously. This patient has not had the least discomfort since her recovery from the operation. She is now in perfect health.

CASE VII.—Mrs. W., aged forty-one. This patient, an intelligent colored woman, came to the hospital for the removal of a tumor occupying the space between the umbilicus and pubis, and supposed to be connected with the uterus. It did not descend into the pelvis and could not be moved above the umbilicus, although there was free lateral motion. She had lost at least eighty pounds in weight since the beginning of her illness, two years before. During this period, in addition to the symptoms clearly due to the presence of the tumor, she had almost entire loss of appetite and frequent attacks of nausea and vomiting. The clinical history pointed so strongly to the presence of disease of the stomach that a careful examination was made for cancer, but with a negative result. She had pain, but it was not clearly shown to be like that produced by the passage of gall-stones.

On November 21, 1896, I opened the abdomen and removed a dermoid cyst of the left ovary, containing thirty-two ounces of fluid, which was covered over its entire anterior, lateral, and superior surfaces by omentum. Nearly all of the omentum was removed with the tumor. Careful inspection of the stomach failed to disclose any organic change. There was no thickening, no dilatation or other change in form or appearance which indicated disease of the organ. On examination, the gall-bladder was found to be distended with calculi which were so firmly packed that the sensation imparted to the finger was that of polished ivory or marble. A second incision was made in the abdominal wall over the gall-bladder and after surrounding the bladder with sponges an incision was made into it and the stones removed. As a result of the im-

paction of the gall-stones, many of them had become imbedded in the mucous lining of the bladder, which necessitated enucleation and removal. With some difficulty the empty sac was sutured to the peritoneum, a drain inserted, and the wound closed.

My intention in this case was to cause the entire obliteration of the sac, as in Case IV. The plan has suggested itself in these cases as being preferable to a cholecystectomy, which would, perhaps, add some additional risk. This patient made a very rapid recovery. She had no nausea after the operation, nor has she had any return of the gastric symptoms. It is impossible to say that the reflex vomiting was entirely due to the presence of gall-stones, as the extensive omental adhesions to the ovarian cyst may have caused a displacement of the stomach downward, or in some unknown way have contributed to the general result.

Five of these patients were white, and two were negroes. One of the negroes was very black, the other a mulatto. The very black negress was not more than twenty-five years of age, while the other cases occurred in women from thirty to forty-seven years of age. All were married and had borne two or more children. With perhaps one exception, all had gastric distress, nausea or vomiting, or both. Only two had previously presented decided symptoms of gall-stone colic. Only one had the characteristic icteroid tint due to obstruction of the biliary ducts; consequently cholemia was not present except in two cases (III. and IV.). The woman described in Case IV. had previously suffered from cholemia, but it had disappeared after the formation of a fistula between the cystic duct and adjoining intestine. The presence of the bile in the urine, and its absence in fecal discharges, therefore, is not a reliable test for the presence of gall-stones, or even for occlusion of the cystic duct, having the same value as a symptom, and may be placed in the same category as jaundice, a result of obstruction of the hepatic or common ducts.

These cases are undoubtedly more frequent than was formerly thought, and probably many occur without their presence being discovered. In addition to the above-mentioned cases, others have been seen in consultation by the writer. Some of the patients refused operation, or afterward were treated by other surgeons. Two have died, and the diagnosis of gall-stones was confirmed *post-mortem*. Several had cancer in connection with the gall-stones. In one of these, in fact my first case, which occurred several years ago, I removed the stones from the gall-bladder, found that the cholemia was due to cancer, and sent the patient home two weeks later relieved of pain, but she died soon afterward as a result of hemorrhage from the liver through the track of the drainage-tube.

In six of these cases a correct diagnosis was made before operation. The seventh case required an investigation, the result of which shows the importance of careful examination of other organs than those suspected.

Perfect candor, however, demands mention of one recent case in which the diagnosis was incorrect. A woman had been sick for six weeks only, and had developed a tumor in the region of the pancreas, or between that organ and the gall-bladder, in the epigastric region. She had

slight pigmentation of the skin, and while there was a doubt expressed, a diagnosis was made of distended gall-bladder. It proved to be a solid tumor, located behind the peritoneum, attached to the aorta, encapsulated, and quite impossible of removal. It is a spindle-celled sarcoma of the aorta itself, or of a gland near it, a rare growth which in a comparatively short time must prove fatal to its possessor.

ALARMING SYMPTOMS IN A CHILD AFTER INGESTION OF KEROSENE OIL.

By T. EDGAR HOFFMAN, M.D.,
OF ROCHESTER, INDIANA.

ON the evening of July 10, 1897, Mrs. T. B. gave from twenty to thirty drops of kerosene oil to her fifteen-months-old son, who had a cold. When I saw the child, about twenty minutes later, it was limp and pallid, the pupils were contracted, the pulse 140 and of fair quality, and temperature in the groin 101° F. The respirations were slow and there was no perceptible movement of the chest. The inspiratory murmur was blowing, loud, and quickened, the expiratory murmur prolonged and diminished over the left side and entirely absent over the right side.

From the incoherent statements of the excited mother, I inferred that the child strangled and coughed immediately after taking the oil. I was undecided whether the condition I found was due to inspiration of the oil or to susceptibility to its toxic properties, or to both.

Immediately aromatic spirits of ammonia was administered and this was followed by repeated small doses of belladonna until all symptoms disappeared, leaving no bad results.

The accessible works on toxicology do not treat of petroleum poisoning, though cases are not rare, since the oil is in almost universal domestic use and is a popular local and internal remedy as an antiparasitic, antiseptic, counter-irritant, anthelmintic, antispasmodic, expectorant and diaphoretic. Frese (*American Text-book of Therapeutics*, page 72) says it is also used as an intoxicant, producing hallucinations and emaciation.

According to Schmiedeberg, petroleum belongs pharmacologically to the alcohol group. "Inhalation of the vapor induces hallucinations, heaviness of the head, vertigo, unconsciousness, and anesthetic stupor; cyanosis, vomiting and contracted pupils occur; one fatal case has been observed." Anemia and chronic bronchitis have followed long exposure to the vapor.

Two sets of symptoms have been observed from its internal use, according to Johanssen: (1) vomiting, with irritation of the mouth and throat, diarrhea and colic, involvement of the kidneys, albumin and formed elements in the urine, which gives off the odor of petroleum or violets; (2) headache, anxiety, vertigo, small and infrequent pulse, collapse, sometimes tetanic convulsions. According to the *National Dispensatory*, vomiting does not occur, nor usually diarrhea. Its application to the skin has resulted in severe inflammation; it may also produce general intoxication.

In the *Therapeutic Gazette* for September, 1895, page 604, Dr. Cheves Bevil reported a case of a child, two and one-half years' old, who drank coal-oil. The resulting symptoms were stupor, contracted pupils (eyes closed), cold extremities, pulse 135, and very weak, respirations 35 to 40 per minute, temperature 97° F., and odor of oil on the breath. Later, the throat became red and scalded-looking, and there was purging, photophobia, slight suppression of urine and albuminuria. The patient recovered. The *Medical Record* for January 2, 1897, printed an abstract from the *Berliner klinische Wochenschrift* of the report of a case by Dr. Johanssen. A rachitic child, who had had diarrhea, swallowed an unknown amount of the oil. This was followed by vomiting and unconsciousness, and death in coma occurred three hours after the patient was admitted to the hospital. Frequent pulse, difficult breathing, and comparatively low temperature were observed. He refers to two other cases in children, both of whom recovered.

These cases, with the one reported in THE MEDICAL NEWS, August 14, 1897, are the only ones occurring in children I have been able to find. I have found articles upon the subject in the National and United States Dispensatories, Schmiedeberg's "Pharmacology," and the "American Text-book of Therapeutics." I have examined, in addition, without result, Hamilton and Godkin's "Legal Medicine," vol. i, Witthaus and Beckers' "Medical Jurisprudence," vol. iv, "Twentieth-Century Practice," vol. iii, Allbutt's "System Intoxications," Ziemssen's "Cyclopaedia," vol. xvii, and the files of THE MEDICAL NEWS, *American Journal of the Medical Sciences*, *University Medical Magazine* and *Therapeutic Gazette*, for the last three years, and those of the *Medical Record* and the *Journal of the American Medical Association* for last year.

MEDICAL PROGRESS.

Curettage as a Routine Measure after Abortion.—In the *Buffalo Medical Journal*, August, 1897, GOLDBERG makes a plea for the routine treatment of abortion by curettage of the uterus. Although deaths after abortion are rare, yet subinvolution and displacement, and diseases of the endometrium and connective tissue often enough follow it. The bad results are in most instances traceable to the retention of parts of the ovum or membranes. It is most difficult to determine whether or not the uterus has completely emptied itself after an abortion during the early months of pregnancy, and by making use of a curette in every case, the patient is given the best chance of complete recovery. Goldberg has not found it necessary always to tell his patients that a curettage was to be performed, and does not employ an anesthetic. In all cases he uses a Sims' sharp curette, and has never seen any accident result from it.

The Woodbridge Treatment of Typhoid Fever.—In the *Jour. Amer. Med. Assn.*, July 10, 1897, WOODBRIDGE gives a few brief quotations from the reports of 193 physicians who have treated according to his method 2078

cases of typhoid fever, with forty-five deaths. He has now collected data of nearly 8000 cases, having a death-rate of 1.91 per cent. This includes every death known to have occurred under the treatment, or any modification of it. Several deaths in which the treatment was known not to have been properly applied, a large number in which the treatment was not commenced until after the patient was moribund or practically so, and a few cases in which death was not due to typhoid fever, or its sequelæ, are included. In only seven of the fatal cases do the reports show that the proper treatment was instituted on or before the eighth day of the disease. In the case of 4935 patients who recovered, and in whom the duration of illness was given, it was 12.7 days.

The Minute Anatomy of Intussusception.—POWER (*Jour. of Path. and Bact.*, June, 1897) contributes a most interesting report upon the minute anatomy of intussusception based upon an examination of thirty-one specimens. Some of these were very old, but were so well preserved as to be excellently fitted for microscopic examination. One of them, taken from the cecum of a child, is of especial interest, as it was shown by John Hunter to a medical society in the year 1789.

From the examination of these specimens it is clear that any part of the intestinal wall may be affected, though the stress of the infection falls most often upon the submucous tissue and upon the circular layer of muscle. The mucous membrane may also be seriously injured. The amount of extravasated blood as well as its seat varies greatly. The extravasation is followed by inflammatory changes, in which the submucous tissue and the circular layer of muscle are chiefly involved. These changes terminate in hyperplasia of the connective tissue, leading to sclerosis; in a tryptic digestion, leading to the disappearance of every element in the wall of the bowel, and the conversion of its connective tissue into reticulin, or in diffuse suppuration and sloughing of the inflamed bowel, which is then separated and cast off by the ordinary process of ulceration.

Bad Results Following the Use of Petrolatum.—MILLARD (*The Reporter*, June 26, 1897) mentions a number of instances in which the use of the solid products of petroleum has produced most unpleasant effects. These were usually of the nature of eczema, but ulcers and abscesses have also been met with. Since the author's attention has been directed to this subject, he has found these cases to be much commoner than is usually stated. Apparently some persons have a peculiar susceptibility to this remedy, which unfortunately is so popular that it has supplanted better bases for ointments. One of the best of these is benzoated lard, which Millard recommends in place of vaselin.

The Frequency of Contracted Pelves.—DOBBIN (*Amer. Jour. of Obstetr.*, August, 1897) calls attention to the fact that the percentage of contracted pelves among American women is probably very much greater than is usually supposed. In Germany, where it is customary to take accurate measurements, the rate of occurrence varies from

eight to twenty-four per cent. In France it has been reported as five per cent., while in America it has been given by Reynolds as 1.7 per cent. Dobbin took accurate measurements in 350 obstetric cases occurring in Baltimore, and found that 12.18 per cent. of the pelvis were contracted. About one-third of these were in negroes, the percentage among them being eighteen, while that among Americans were 7.7, and among the foreign-born women 5.5. As these figures are very close to those obtained in German and other clinics where exact measurements are taken, it is reasonable to suppose that Americans do not materially differ in this respect from European nations, but that the apparent difference is due to the lack of exact measurements in this country.

Ovariectomy in a Child Thirty-three Months Old.—HOFFMAN (*Am. Jour. of Obstetr.*, September, 1897) reports on ovariectomy performed for the removal of a cystic sarcoma in a child thirty-three months old. The tumor was discovered about five months before operation, and was at that time of considerable size. At the time of its removal it contained from three to four quarts of fluid, and a fleshy mass weighing $2\frac{1}{2}$ pounds. An ovariectomy for a tumor of this character has rarely, if ever, been performed on so young a patient. Unfortunately, death followed thirty-three hours after the operation.

Sun-Heated Sand as a Therapeutic Measure.—The value of the sand-bath has been known for many generations, but although frequently employed by the laity in one way or another, it receives at present very little professional attention. The ease with which a hot sand-bath may be carried out at most ocean resorts, and the benefit which follows its use in cases of obstinate joint affections of rheumatic, gouty, or syphilitic origin, as well as in chronic troubles of the liver, spleen, kidney, and pelvic organs, has satisfied PARKER (*Medical Times*, September, 1897) that it ought to be more frequently employed. A temperature of 120° to 130° F. is readily borne, and the best costume for the treatment is the ordinary bathing-suit. The patient should be directed to change his position and location every ten or twenty minutes, and the bath should be continued for two or three hours. Parker has also found it of value in the wasting diseases of childhood.

THERAPEUTIC NOTES.

A Harmless Cure for Obesity.—In the *Maryland Med. Journal*, June 19, 1897, CATHELL gives rules for the reduction of obesity which have been successful in his practice for many years.

"Over-fatness" is commonly due, he says, to one of the following causes: Congenitally small lungs with a defective oxygenating capacity; eating excessively of all kinds of food; want of lung-expanding exercise; using alcoholic drinks to excess.

Many of the drugs which have a known fat-reducing power exert an injurious action on the other tissues of the body, and if used persistently for any length of time, or in efficient doses become dangerous to health. While the

various obesity cures are so rigorous that few carry them out conscientiously, the treatment of the author is very simple:

The patient has only to drink after each meal a glass of the artificial Kissingen water to be found at drug-stores and soda-water fountains, and on the succeeding day, a glass of artificial Vichy water also half an hour after each meal. This is to be continued week after week until the patient comes down to a normal degree of stoutness, and the waters are then discontinued.

While taking the waters the person should keep a weekly record of his weight, always using the same scales, and wearing the same clothing, and should also, for his own satisfaction, record his chest, waist, and hip measurements. If the loss in weight exceeds two pounds a week, the amount of each water should be made smaller; and if the loss has not equalled two pounds a week, a few teaspoonfuls of lemon juice should be added to each glass of the Kissingen water to increase its acidity, and a teaspoonful of aromatic spirits of ammonia to the Vichy to increase its alkalinity. The diet should be light and contain only small amounts of fat, starch, sugar, and alcohol. Moderate out-door exercise should be included in the day's program.

The mode of action of these waters taken in the manner described, is not clear, but their efficiency is too well established to admit of doubt.

Sprains and Their Treatment.—In the *Boston Med. and Surg. Jour.*, June 17 and 24, 1897, GRAHAM emphasizes what he has called attention to before, *viz.*, the advantages to be derived from the treatment of a sprain with almost immediate massage and passive or active motion. Applied intelligently massage is allowable from the first, the presence of, or increase in the pain being the surest guide to an excessive or faulty use of this method of treatment. From study and a large and continued experience, the writer draws the following conclusions:

1. A sprain is a wrench or twist of a joint, a sudden, partial displacement of two articulating surfaces, followed by immediate replacement.

2. The symptoms are pain, swelling, discoloration, and usually heat and impaired motion.

3. Its diagnosis may be obscured by the swelling which may conceal a fracture.

4. Whatever will quickly reduce the heat, pain, and swelling—such as massage, snug bandaging, and elevated position of the joint—will proportionately make the diagnosis easier.

5. The means just mentioned are, therefore, not only valuable for diagnosis but also for treatment; and their use in many cases of sprains of all degrees of severity, show that they recover in one-third of the time required under absolute rest and fixed dressings without massage.

6. Even the sprain of a joint previously weakened by malignant disease may be rapidly ameliorated by massage.

Other articles by LOVETT and MUMFORD in the same numbers of this journal substantiate these claims, and give details of treatment.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, SEPTEMBER 18, 1897.

A COLLECTIVE INVESTIGATION OF INFANTILE SCURVY.

It will be remembered that the collective investigation of the use of antitoxin in diphtheria, which was undertaken two years ago by the American Pediatric Society, was productive of exceptionally good results, inasmuch as it added greatly to our knowledge of the action of the new therapeutic agent. This Society now proposes to make similar researches into the domain of infantile scurvy, and it is hoped that the cordial cooperation of physicians throughout the country will again be forthcoming, thus assuring the ultimate success of the investigation.

Unfortunately, this curious disease is one about which we know but little. Attention was called to it a few years ago by Cheadle and by Gee, who pointed out the fact that it is of much more frequent occurrence than is generally supposed. Subsequently, Barlow also described it at considerable length, including the *post-mortem* findings. Among the Germans, especially, it is known as "Barlow's disease," and in certain other countries as "scurvy-rickets." Its etiology is practically unknown, for although it appears to depend upon some long-continued dietetic

error, just what this may be, or in what manner it operates to produce this rather than some other affection, are matters regarding which there is no definite knowledge.

The solution of the problem is to be brought about in two ways: first, by careful chemic and physiologic study of the secretions and excretions of the body, and, second, by a collective investigation of the apparent causes, symptoms, complicating diseases, course, and treatment, combined with painstaking records of autopsies in as many instances as possible, providing the cases have been carefully observed.

YELLOW FEVER.

THE outbreak of yellow fever in Mississippi is of such serious portent to the people of the Southern States that it is a matter of sincere congratulation that the sanitary branch of the Federal government is so fully alive to the dangers of the disease and has taken decisive steps toward preventing its spread. A cordon has been established about Ocean Springs, the village in which the scourge first made its appearance, the houses have been fumigated, and, as far as possible, the streets disinfected. Representatives of the United States Marine Hospital Service are on the ground, and those already afflicted with the disease have been segregated. At the present writing eighteen cases of the disease have made their appearance at New Orleans, and although every effort is being made by the Board of Health to thoroughly clean and disinfect the city, and to impress upon the minds of all the absolute necessity of observing every sanitary precaution, the feeling of alarm is general. Other cities have declared a quarantine against the infected district, and great anxiety is felt along the entire Gulf Coast, for the reason that several hundred persons who had been at Ocean Springs, and consequently exposed to the danger of infection, left there during the few days previous to the edict of the authorities and scattered in all directions, going to Mobile, Montgomery, Jackson, and other places.

It appears that an outbreak of fever, which was declared by the local physicians to be dengue, occurred at Ocean Springs during last July. It spread rapidly, and at one time fully 600 persons, or one-fourth of the entire population, were ill with the

disease. It prevailed during the entire month of August, but was not regarded as of serious consequence until ten deaths had occurred—an unprecedented number in such an ordinarily mild disease as dengue fever. A commission of experts from New Orleans made a careful investigation, and coincided in the opinion of the character of the affection. Soon afterward the disease assumed a virulent form, and one of the examining physicians himself died, with evidence of black vomit. A second conference with experts was then called for, which resulted in the announcement that the disease undoubtedly was the much-dreaded yellow fever.

Many efforts have been made during the past few years to isolate the specific germ of yellow fever, notably by Freire of Rio Janeiro, Finlay of Havana, and Sternberg of Washington; but to Sanarelli, a young Italian residing in South America, who, during several years, studied and worked under the direction of Roux at the Pasteur Institute, Paris, undoubtedly belongs the credit of its discovery. In a lecture delivered at the University of Montevideo on June 10, 1897, a translation of which was published in the *British Medical Journal* of July 3d, he embodied the result of his investigations, and described the germ under the name of *bacillus icteroides*, as “at first sight presenting nothing morphologically characteristic. It is a little bacillus with rounded extremities, for the most part united in pairs in the culture, and in small groups in the tissues, from two to four thousandths of a millimeter in length, and, as a rule, two or three times longer than broad. It is very pleomorphic.”

Contrary to the generally accepted theory, this organism, which can be rarely demonstrated in pure culture, being associated with the coli bacillus, staphylococcus, or streptococcus, especially affects the blood and connective tissue, and is never found in the gastro-intestinal contents. “Its poison, therefore, instead of being absorbed through the intestinal walls, is manufactured in the interior of the organs and in the blood itself.” The toxin produced is an exceedingly active one, and appears to have a special action upon the parenchymatous cells of the organs of secretion. In addition, it produces degenerative changes in the gastric and intestinal mucous membrane, and in the walls of the blood-vessels, thus giving rise to the condition known as black vomit.

Sternberg, in an exceedingly interesting paper read at the Twelfth International Congress at Moscow, which was published in the *American Journal of the Medical Sciences* for September, 1897, draws a parallel between the so-called bacillus *x* of Sternberg and the bacillus *icteroides* described by Sanarelli, and calls attention to their striking similarity of action.

The present outbreak recalls vividly to mind the epidemic of 1888, when the disease made its appearance at Tampa, Fla., and quickly spread to Plant City, Manatee, Palmetto, and finally to Jacksonville. It will be remembered how subscriptions from all parts of the country poured into the stricken district, more than \$200,000 being contributed within two weeks. The epidemic was not stamped out until the middle of October, by which time there had been 4704 cases and 412 deaths. At Fernandina the record was 1200 cases and 38 deaths; at McClenney, 200 cases and 22 deaths, and at Gainesville, 100 cases and 12 deaths. At Decatur, Ala., there were 123 cases and 30 deaths, and sporadic cases occurred in other parts of the State. It would seem from this record that about ten per cent. of yellow fever cases are fatal in the Southern States.

The origin of the disease in this country has always been directly traced to importation from abroad. The epidemic which raged at Pensacola during 1873 and 1874 was introduced from Havana, as was that which decimated Fernandina in 1877 and Jacksonville in 1888. The present outbreak undoubtedly will be traced to a similar cause.

In a paper on “The Pathological Anatomy of Yellow Fever,” read at the First Pan-American Medical Congress, Washington, D. C., in 1893, by Dr. Joseph Jones of New Orleans, the statement is made that in the United States the disease is limited to certain months of the year, and never prevails during the winter. The great epidemics, notably those of 1847, 1849, 1853, 1854, 1855, 1858, 1867, and 1878, commenced early in the hot months (May, June, and July), and obtained their maximum intensity during August and September. Thus, during the period of thirty-two years the deaths from yellow fever in New Orleans were as follows: January, 6; February, 0; March, 2; April, 0; May, 5; June, 49; July, 2248; August, 10,639; September, 11,346; October, 5714; November, 1777; December, 119. The curve of the disease, therefore, corresponds, to

a certain extent, with the curve of temperature. Unfortunately, the prevailing weather throughout the South during the past week has been warm and rainy—ideal conditions for the development of fever—and the advent of colder weather in the vicinity of the Gulf is hardly to be expected until the end of October.

Dr. F. Peyre Porcher of Charleston, S. C., in a paper, entitled "Yellow Fever; Its Pathology and Treatment," also read at this Congress, claimed that "in fair cases and temperate individuals, treated early, there is no need for any violent third stage, for any black vomit, albuminuria, or suppression of the urine." He says, furthermore: "It is a mistake to suppose that yellow fever is necessarily a fatal malady, that epidemics vary greatly in malignity, and that we must fold our hands supinely. Belot, of Havana, claims that 95 out of 100 fair cases seen early may be cured, and I fully agree with him."

This author, as a result of large experience, recommends the following treatment: The head, hands, and arms of the patient should be sponged assiduously with ice-cold water at the very commencement of the attack, this being repeated whenever the temperature shows a tendency to rise. Twenty grains of calomel and 25 grains of quinin should be administered at once, followed, after an interval, by sulphate of magnesia. Mustard plasters should be applied to the entire abdomen, and mustard foot-baths given frequently. After the saline has acted, a dessertspoonful every two or three hours of the following mixture should be given:

Potassii acetatis	3 i-ii
Potassii citratis	3 i
Morphiæ sulph.	gr. i
Aquæ	℥ vi.

He claims that no other treatment is necessary, but suggests that a few drops of tincture of aconite added to the mixture might prove of service.

ECHOES AND NEWS.

Congress of Hygiene and Demography.—The Ninth International Congress of Hygiene and Demography will be held at Madrid from the 10th to the 17th of April of next year.

American Academy of Railway Surgeons.—The next regular annual meeting of the American Academy of Railway Surgeons will be held at Chicago, October 6, 7, and 8, 1897.

The American Electro-Therapeutic Association.—The next meeting of this Association will occur at Harrisburg, Pa., September 21, 22, and 23, 1897. An interesting program has been provided.

Floating Hospitals for Japan.—According to the *British Medical Journal*, the Japan Red Cross Society is about to build two vessels of 2600 tons each for the use of patients in time of war.

Tonsorial Asepsis.—An enterprising barber in Baltimore is to conduct an aseptic barber-shop, in which the barbers' arms will be bare to the elbow and all the tools will have frequent aseptic baths.

Honor for Sanarelli.—The news comes from Rome that a memorial tablet is to be placed on the walls of the Siennese University to commemorate the discovery of the yellow-fever germ by its pupil, Giuseppe Sanarelli.

A Hospital for Epileptics at Moscow.—A number of wealthy merchants of Moscow propose to endow an infirmary for epileptics and the weak-minded of both sexes in commemoration of the International Congress recently held there.

Precautions against Yellow Fever.—As precautionary measures against yellow fever, it is said that South Americans usually recommend four things: Avoidance of bananas, mangoes, and other fruits; avoidance of whisky and other strong liquors; scant exposure to the night air, and all the quinin pills one can swallow.

A Patient Fined for Leaving a Hospital.—A man was fined recently in London for leaving a hospital without permission while suffering from typhoid fever. He had been a patient in the institution for some time, and was convalescent, but it was held that he endangered the lives of other persons by leaving before it was considered safe for him to do so.

Doctors in Argentina.—In Buenos Ayres there are 805 practitioners of medicine—a proportion of 1 to something less than 1000 inhabitants. The number of students of medicine has doubled during the last ten years, and it has been proposed that the medical schools be closed for five years, in order to prevent overcrowding of the ranks of the profession.

Meeting of the Tri-State Medical Society.—The ninth annual meeting of the Tri-State Medical Society of Alabama, Georgia, and Tennessee will be held in the Senate chamber at Nashville, Tenn., October 12, 13, and 14, 1897. Dr. W. F. Westmoreland of Atlanta, Ga., is president, and Dr. F. Tester Smith of Chattanooga, Tenn., is secretary of the Society. Dr. W. D. Haggard, Jr., of Nashville has been appointed chairman of the Committee of Arrangements.

A New Form of Insurance.—In this column last week was noted the offer by a landlord of a premium for the appearance of twins and triplets among his tenants. That these events are not regarded by all with the same high appreciation is made evident by a letter received by the

New York State Superintendent of Insurance. In this communication a certain enterprising insurance man enquires if it would be legal to form a benefit society, to insure women against childbirth, death by childbirth, twins or triplets.

Lustig's Antibubonic Serum.—Professor Lustig, Dr. Malenchini, and Dr. Galeotti, the bacteriologists sent by the Italian Government to Bombay to investigate the merits of the former's prophylactic serum against the bubonic plague, have returned, and report themselves satisfied with the results of their mission. The Lustig serum differs from that of Yersin in that it is curative as well as preventive, and is much more easily prepared. It is absolutely free from bacteria, and no bad results have been reported from its use.

Oxygen in the Treatment of Chronic Ulcers.—A method has been suggested by Dr. George Stoker of London, by which he believes chronic ulcers and delayed repair in the tissues may be stimulated by the direct application of nascent oxygen. His reasoning has induced the British Government to purchase twenty complete equipments for the production of the necessary gas for use in Monibasa (Uganda) upon the workmen employed in building the military railroad, many of whom are incapacitated by chronic ulcers of the leg.

Winter Recreation Piers in New York.—It has occurred to the architect who drew the plans for certain of the recreation piers which, by order of the New York Dock Board, are now in course of construction, that by providing glass sides and a heating apparatus at a small additional expense the piers might be made available during the winter as well as the summer. The idea is truly a capital one, and should receive serious consideration. With the flowers and plants already in possession of the city it would easily be possible to convert the piers into winter-gardens of great beauty.

Anticholeraic Serum.—On behalf of Dr. Ferran of Barcelona, M. Gautier has laid before the Academy of Medicine, Paris, a claim of priority in connection with the treatment of cholera by anticholeraic inoculations. Dr. Ferran's method of treatment dates back to 1885, at which time a commission of French medical men visited him for the purpose of investigating it. He refused, however, to give the formula of his vaccine, and still persists in this refusal. Under these circumstances the Academy has declared that it can neither give any decision as to the curative virtues of a preparation of which it knows nothing, nor give support to his claim for priority.

American Medical Students in Germany.—The report comes from Berlin that the governments of Prussia and all the other German States having universities have altered the conditions under which medical students in the future will be admitted to the clinics. Under the new rules many Americans will be barred, and the Board of Physicians of Berlin and Brandenburg has asked the Government to draw the lines still closer, so as not to admit students from the average American medical school unless they

pass a preliminary examination. Mr. Andrew D. White, the United States Ambassador, has been notified by the American students in Berlin of these new developments, and he is inquiring into the matter.

Essays and Addresses of Sir J. Russell Reynolds.—The friends of the late Dr. Reynolds have done well in perpetuating the memory of the great London physician by publishing his essays and addresses in book form. Although for more than forty years he occupied the same residence, and steadfastly confined himself to the daily performance of professional duties, at the same time he unerringly won his way to every English heart, and by his pen placed himself in helpful sympathy with his professional brethren in every quarter of the globe. These essays present the progressive unfolding of his rich life, for he was in every sense a man of progress. Such a monument to his memory is in perfect keeping with his well-known literary taste.

Obituary.—John Braxton Hicks, M.D., London, F.R.C.P., F.R.S. This eminent obstetrician and gynecologist died on August 28th, at his residence in Lymington, England. He was a son of Mr. Edward Hicks, M.P., and was seventy-two years of age at the time of his death. He studied medicine at Guy's Hospital, and was for many years connected with that institution, having been appointed Assistant Obstetric Physician in 1865, Obstetric Physician in 1870, and Consulting Obstetric Physician in 1882. He retired from active practice about three years ago. Braxton Hicks played a prominent part in the history of obstetrics and gynecology in Great Britain, and his writings on these subjects have become classic. He was an Honorary Fellow of the Royal Society, of the Obstetric Societies of Edinburgh, Berlin, and Philadelphia, and of the American Gynecological Society.

Russian Antipathy for Jews.—It will be remembered that when the time arrived for the foreign delegates and visitors to the recent International Medical Congress at Moscow to arrange their plans for the journey it was discovered that Hebrews are excluded by law from Russian territory. Although the Government removed this impediment, its royal ukase could not so readily dislodge the personal prejudice from the minds of the people, and in spite of the more than regal hospitality met with on all sides this unmastered racial antipathy cropped out at least once during the meeting, the occasion being a dinner given in honor of the Congress, when a heated discussion arose between one of the Russian members and a prominent German professor, and unnecessary personalities were indulged in. The affair resulted in considerable hard feeling and it was only by the intervention of friends of both parties to the discussion that amicable relations were restored.

A False Charge Against Johns Hopkins Hospital.—During the past week a London daily newspaper sharply criticized a report which appeared in the July number of the *Johns Hopkins Hospital Bulletin* relative to certain experiments which had been made in the treatment of the insane with preparations of the thyroid gland. Accord-

ing to the London journal, one patient was reported to have died as a result of the treatment, and the comment is made that such procedures in England would quickly end in the halting of the experimenters before a court of law to answer for the patient's death. In reply, Dr. Berkley, who wrote the report, states that the brief tests made were upon insane persons not in any way connected with Johns Hopkins Hospital, and that, although they demonstrated the toxic properties of the thyroid extracts, they did not hasten the fatal termination in the case of the only patient who died, as death was due to acute miliary tuberculosis nearly two months subsequent to the date of the experiments. The employment of the thyroid gland in cases of melancholia and dementia had been suggested by the mental improvement resulting from its use in cretinism. The method is not a new one, as it has been experimented with by English therapeutists.

CORRESPONDENCE.

A CORRECTION.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: In THE MEDICAL NEWS of August 21st, a report of a discussion of Dr. Potter's paper on Eclampsia, read at the recent Niagara-Falls meeting of the American Association of Obstetricians and Gynecologists, is at fault in stating that I referred in figures to the excretion of urea. What I did mention, however, was the amount of total urinary solids—a quite different matter.

I said nothing about Paget, but I did emphasize the very valuable work of Etheridge in applying Haine's modification of Häser's process for estimating the total urinary solids per diem, claiming that it was more easily applied than the Doremus test for urea, and quite as valuable as an early sign of renal inadequacy.

CHARLES STOVER, M.D.

AMSTERDAM, N. Y., August 26, 1897.

THE HAHNEMANN MEDICAL SCHOOL OF CALIFORNIA ASKS AFFILIATION WITH THE CALIFORNIA STATE UNIVERSITY.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: At the last meeting of the Regents of the University of California, a petition from the Hahnemann Medical School asking for affiliation with the State institution was presented. At the same time a counter-petition was offered by the members of the regular profession, comprising the Faculty of the Medical Department. The subject was postponed by the Regents until the date of their next monthly meeting, September 7th. We think that the proposed measure will be defeated, but no one can foretell the result of the final vote cast by laymen who are not thoroughly posted about medical matters. To save our University from the ignominy cast on those of Michigan and Iowa, we are using every effort to prevent the favorable acceptance of the petition.

In the petition appears the following, which seems to be the only claim deserving of consideration: "As the patrons of homeopathy are among the well-to-do class of

citizens and not so much among the masses as the patrons of other schools of practice, it is undoubtedly a fact that such patrons pay at least one-third of the taxes of the State."

Can you show that no such condition exists in the Eastern States? We expect to dispose of this claim effectually before next month. In our counter-petition we have clearly shown that homeopathy is dead in its birthplace, Germany, and waning elsewhere; that it is denied recognition by all of the great European universities, governments, steamships, railroads, life-insurance companies; that none of the great blessings, as vaccination, anesthesia, antiseptic surgery, etc., have come from it; that bacteriology, serum-therapy, the discoveries of the germs of disease, surgical methods and appliances, are not indebted to it in any manner.

Trusting that you may be able to serve us, as well as the entire profession, and thanking you in advance for what you may do, I am,

Yours sincerely,

CEPHAS L. BARD, M.D.

VENTURA, CAL., August 15, 1897.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

THE OPENING OF THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA—A NEW CLINICAL LABORATORY FOR THE MEDICO-CHIRURGICAL HOSPITAL—PHILADELPHIA COUNTY MEDICAL SOCIETY—PATHOLOGICAL SOCIETY OF PHILADELPHIA—VITAL STATISTICS FOR THE WEEK ENDING SEPTEMBER 11TH.

PHILADELPHIA, September 11, 1897.

COMPETITIVE examinations for medical scholarships at the University of Pennsylvania will be held on Saturday, September 25th, and entrance examinations for the Department of Medicine will take place on the following Monday. Owing to the largely increased number of students of medicine at the University this year, it has been found necessary to turn over to the medical school the building formerly occupied and recently vacated by the Dental Department, to meet the needs of the Medical Department of an additional building for laboratory purposes. The building has been altered and thoroughly equipped for the purposes of practical physiologic work. Another building, which will be at the disposal of the Medical Department during the coming year, will be the D. Hayes Agnew Memorial Pavilion, which constitutes one of the wings of the University Hospital. This structure has now been completed, and contains, in addition to apartments used for dispensary purposes, operating-rooms for gynecologic and orthopedic work.

A new clinical laboratory will shortly be erected by the Medico-Chirurgical Hospital on the ground adjoining the hospital, which has been recently acquired by the institution. During the past summer members of the hospital staff and of the faculty of the Medico-Chirurgical College have visited the prominent Continental and British clinical laboratories, to gather new ideas to be incorporated in their new building. It is anticipated that the

structure will be completed during the coming college year.

At a stated meeting of the Philadelphia County Medical Society, held on September 8th, Dr. Joseph Price made a presentation of specimens removed by abdominal section, and reported a series of cases of various pelvic disorders for which abdominal section was the operative procedure indicated. This paper, together with the demonstration by Dr. Price of the specimens presented, and the ensuing discussion of the topics by various members of the Society, fully occupied the time allotted to scientific business at the disposal of the evening's meeting.

A stated meeting of the Pathological Society of Philadelphia was held on September 9th. An interesting instance of endothelioma of the spinal dura was presented by Drs. S. W. Morton and A. F. Witmer. The patient, a woman of advanced years, prior to the appearance of the cord lesion, had suffered removal of the left breast for malignant disease. Following this operation, a marked projection of the twelfth thoracic vertebra was noticed, and later a train of symptoms, such as radiating pain in the right leg, obstinate constipation, bladder involvement, and many trophic disturbances set in. Shortly before the patient's death new growths in the right humerus and the left tibia were noted, and bed-sores made their appearance over the sacrum. Autopsy showed, in addition to other lesions, caries of the twelfth dorsal vertebra, and the presence of a new growth measuring 33x25x19 mm., attached to the spinal dura, and compressing to a considerable extent the substance of the cord. Upon microscopic section, the tumor was found to be an endothelioma, which was considered by the reporters to be of primary nature. Following this paper, Dr. A. A. Eshner made a communication relating to a case of uremia, presenting atypical clinical manifestations, and drew attention to the unreliability of a subnormal temperature as a symptom of the condition under discussion.

At the conclusion of Dr. Eshner's paper, nominations for officers for the ensuing year were made. For president, Dr. William E. Hughes was nominated; for vice-president, Drs. F. A. Packard, C. W. Burr, Alfred Stengel, and John Guiteras; for secretary, Dr. David Riesman; for treasurer, Dr. T. S. Westcott; for curator, Dr. J. Dutton Steele, and for recorder, Dr. W. S. Carter. The above candidates will be balloted for at the next meeting of the Society.

The number of deaths in this city for the week ending September 11, was 389, a decrease of 10 over the preceding week, and an increase of 4 from the corresponding week of last year. Of the whole number of deaths 139 were in children under five years of age. The returns of new cases of contagious diseases for the week showed a decrease of 22. There were 68 cases of diphtheria; 33 cases of scarlet fever, and 60 cases of enteric fever.

Mr. Vanderbilt Denies It.—Mr. George W. Vanderbilt denies the report that he proposes to build a hospital for consumptives at Asheville, N. C.

OUR VIENNA LETTER.

[From our Special Correspondent]

THE MEDICAL COUNCIL AND THE ATTEMPT TO REGULATE RELATIONS BETWEEN PHYSICIANS—THE VIENNA SCHOOL AND THE SUPRARENAL CAPSULES—ANATOMIC RELATIONS, DIAGNOSIS, THERAPY AND PHYSIOLOGY—EXERCISES IN HEARING FOR DEAF-MUTES AND THE HARD-OF-HEARING, AND THEIR RESULTS.

VIENNA, August 29, 1897.

OCCASIONALLY one finds in certain of the Viennese medical journals a notice somewhat to the following effect: "Dr. So-and-So, having been duly warned that he is transgressing the regulations made by the Medical Council, and having neglected to heed such warnings, members of the profession are hereby requested to have no further professional relations with him. By order of the Medical Council (Arzt Kammer)." Such notices are usually directed against physicians whose advertisements in the daily political press have been called to the attention of the Medical Council. It pronounces, as it were, a modern medical excommunication, or interdict, but from what I hear, it produces about as little effect upon the delinquent doctors as would the corresponding spiritual decrees if employed in our day. The advertising doctor goes on his way, perhaps gathering a little additional publicity from what he will not fail to point out to his patients as professional jealousy on the part of the regular physicians because of his wonderful success.

While the Arzt Kammer here is a legally constituted body for the regulation of professional relations, its decrees practically carry no more weight than do those of our medical societies in America because there is no sanction attached to them. Sometime it will be recognized that when a body of physicians decides that a doctor has by unprofessional conduct rendered himself unworthy to practice his profession, then the public will have a right to demand that such a man shall not be allowed to practice. Meantime, however, the work of swindling the public goes bravely on, and quacks and advertising specialists find it almost as profitable here as in America. When there has been question of allowing more power to be given to the Medical Council the old feeling that makes the general public suspicious of doctors in general has shown itself ready to oppose any innovation which will put the public health any more directly into the doctor's hands. This curious relic of medieval feeling remains despite all that the profession has done during these last fifty years to decrease the amount of disease and eradicate epidemics, and it will remain until the realization comes that the medical profession as a body is disinterestedly engaged in the prevention of disease, notwithstanding traditional feeling to the contrary.

The Vienna school has of late interested itself a good deal in the study of the suprarenals. The pathology of these glands has been illustrated by Professor Kollisko, who has also pointed out some of their interestingly intimate relations with the circulatory and nervous systems. At one of his last pathologic demonstrations of the year, he exhibited an encephalic fetus, the so-called frog-faced infant, in whom the cerebrum was totally deficient. Be-

fore dissecting the abdomen, he remarked that the suprarenals would, almost without doubt, be lacking or, at most, only traces of them would be found. Examination of the viscera and comparison with those of a normal fetus showed that this was the case. This interesting observation, the result of a series of sections in such cases, is but another proof of the intimate relations which exist between the central nervous system and the suprarenals.

In one of the last clinics of the semester Professor Neusser discussed the possibility of diagnosing Addison's disease when the characteristic discoloration of the skin and mucous membranes is absent. While it is an extremely difficult problem, Neusser does not consider it impossible. Several interesting cases, which have come to autopsy during the past year, though with lesions of the suprarenals, and without the pigmentary deposits, seem to indicate the points on which the diagnosis can be based. The last one which occurred was a characteristic one and may be taken as a type. A comparatively young man was brought to the hospital in a state of coma. There was no edema and no signs of any ever having existed, but there was an extremely high-tension pulse and thickened arteries. There was no albumin and no casts in his urine. He died without coming out of his lethargy, and the only clinical diagnosis that seemed possible to make was that of Bright's disease. The autopsy showed extensive degeneration of the suprarenals. The changes in the arteries were such as are often found in Addison's disease, and such as Kollisko considers as due to the effect upon the vascular system of the absence of the secretion of the suprarenals in the organism and the consequent interference through the sympathetic with the peripheral vasomotor mechanism. It is on these changes in the arterial system with the high-tension pulse, or a very striking difference in tension between the peripheral pulse and that in the abdominal aorta, for instance, when other causes may be excluded, that a diagnosis of Addison's disease may be made even in the absence of characteristic pigmentation.

From a therapeutic standpoint, suprarenal extract has met with some favor here, internally and locally. It seems to have caused a distinct amelioration of the symptoms in at least one case of Addison's disease within the last few months, and when applied locally has been found to act as a good hemostatic preparation. Its power of contracting the peripheral vessels is such that it produces very satisfactory local anesthesia, and one reporter considers it better than cocain for this purpose in operations upon the nose. Its use is not followed by the great reactive relaxation of blood-vessels which occurs after the use of cocain, and which so often gives rise to troublesome bleeding.

Dr. Arthur Biedl, Professor Stricker's assistant in the Department of Experimental Pathology, has been studying the secretion of the suprarenals as it occurs in the circulation. He thinks that he has demonstrated that the splanchnics carry vasodilator and secretory fibers to these glands. He has studied especially the venous blood coming from them, and has observed that after irritation of the splanchnic nerves in the thorax the number of minute

granules of protoplasm in the blood coming from the glands are diminished. These granular masses have long been thought to have their origin in the suprarenal capsules, though no definite proof could be advanced. The number of leucocytes in the venous blood is also diminished, and Biedl suggests that, owing to widening of the blood-paths and decrease of function in the glands, they are retained. This part of the subject is of striking interest, because the clinician and the therapist have so far outstripped the physiologist in the acquisition of knowledge of the suprarenals that additions to the physiology are welcome as affording a solid basis for scientific work in a matter which is otherwise liable to drift into the veriest empiricism.

One of the features of the study of ear diseases in Vienna (and where has more been done for the specialty than in Vienna?) is Professor Urbantschitsch's exercises in hearing for deaf-mutes or for those who have acquired deafness. The words seem almost a contradiction in terms, but the exercises are a very practical mechanic method of bringing out powers of hearing which were so latent that they were thought to be absent. For the outer world, Urbantschitsch's name is so overshadowed by those of his two great Vienna colleagues in ear diseases, Gruber and Politzer, that it is quite unfamiliar. To his colleagues here, how much he is one may judge from his recent election to the presidency of the Austrian Association of Otolologists. His success with the methodification of hearing-exercises will yet make him well and widely known.

The idea of hearing-exercises for the deaf is not a new one, but its practical systematic application has only shown in recent years how much it may accomplish. The deaf are usually not completely without hearing, but never having heard sounds because always uttered in the usual tone of voice, have never learned to distinguish them. If, however, sounds are uttered in a very loud tone close to their ears they learn to catch them, and after a time to distinguish between different sounds. After a certain amount of such exercises, the sounds need not be uttered in so loud a tone, yet they are heard. Just why it should be so is a question which divides the otologists, but it would seem that even a minimum amount of nerve conduction becomes by practice more used to produce the reflexes necessary for the completion of a function. Whatever the explanation may be, after a few weeks, though sometimes it takes months of patient exercises (not for longer than five-minute intervals, for it is very tiresome, but frequently during the day), patients improve wonderfully in their hearing powers. Absolutely deaf-mutes learn to catch words uttered just above the ordinary tone of voice. After a few exercises the noises in the street easily become distinguishable and the dangers of street crossing greatly decreased. Deaf-mutes who could only catch expressions by lip-reading, but who found it difficult to obtain positions in business because of the inconveniences attached to this method, have learned in the course of six or eight weeks to hear enough for certain business purposes.

In a large proportion of the cases of deaf-mutism no nervous or aural lesion can be demonstrated *post-mortem*

to account for the condition. It is probable that it is in many cases due to a congenital paucity of auditory nerve-fibers rather than an absolute absence of any important nervous element that constitutes the etiology of the condition. Under these circumstances, the advisability of training the hypoplastic nervous elements to their highest possible functional capability, and the probability that such training will be followed by distinct improvement of function seems clear. Meantime, it is a step forward distinctly in line with much that is best in modern therapeutics—the use of even Nature's weakened forces to the best possible advantage.

TWELFTH INTERNATIONAL MEDICAL CONGRESS.

[From our Special Correspondent.]

MOSCOW, August 23, 1897.

THE second general session of the Congress was extremely interesting. Professor Krafft-Ebing's discourse was a very able one and some of its material strikingly new. His subject was "The Etiology of General Paralysis," and his argument was as near a demonstration of its syphilitic origin as it is possible to have in the inductive sciences. He adds two things to what has been said so far on the subject. All statistics collected with any care during recent years have shown that in a large proportion of the cases there was syphilis in the history of patients suffering from progressive paralysis. Krafft-Ebing's own statistics show about sixty per cent. of syphilitics among his general paralytics during ten years. There remained always, in all statistics, however, a notable number of cases without any syphilis in the history. Krafft-Ebing's assistant in Vienna during last winter went to the clinic of Professor Lang, and obtained the histories of the patients suffering from what were undoubted tertiary lesions of syphilis. He found that there was a larger percentage of cases of general paralysis among those patients in whom not the slightest syphilitic history was obtainable than among the general paralytics in Professor Krafft-Ebing's service. One of the great objections which has been made to the theory of the syphilitic origin of general paralysis and tabes would seem to go down before these striking statistics. It is possible then for patients to have had syphilis and yet know nothing of it, at least in as large a proportion of cases as those in which a syphilitic history is wanting in general paralysis.

After Krafft-Ebing came Dr. N. Senn of Chicago who read a paper on "The Classification and Surgical Treatment of Acute Peritonitis." His discourse was a masterly review, and I am sure that the Americans present were proud to think that we were so well represented. The work of American surgeons has entitled them to teach the medical world something on the subject of acute peritonitis, especially the acute septic form, to which part of his subject Dr. Senn limited himself in his address, and the ripe experience of our great surgeon, gathered not alone from personal observations but from contact with brother American surgeons, stood out clearly and magnificently.

Professor Metchnikoff in a paper, entitled "The Pest,"

explained the reason for the failure of plague-serums to fulfil expectations in India after the wonderful success that had been reported from its use in China. When it was resolved to manufacture large quantities of the serum for India, a very difficult question presented itself at the Pasteur Institute in Paris. Up to that time the serum had been obtained from one immunized animal, but now it became necessary to inoculate at least thirty horses with the plague in order to obtain the serum. This could not be done at the Institute itself, but would have had to be carried out in one of the suburbs. The slightest error of the attendants in handling the virulent cultures, and there necessarily was a number of them, would perhaps precipitate an epidemic of plague in Paris itself. Professor Roux, taking this into consideration and knowing from experience in the manufacture of other serums that dead cultures often act almost as well in producing immunization, resolved to employ these cultures. As is clear from the issue this was a serious error. The dead cultures produced a reaction in the animals and a protective serum was obtained, but as events showed, it was an extremely weak one. It was this serum which was shipped to Yersin and employed by him in India. The death-rate in China from twenty-eight virulent cases treated had been about seven per cent.; that in India with this serum was forty-seven per cent. According to the statistics of some observers, this is about the normal mortality of the plague. Yersin, however, who collected statistics very carefully in the hospitals, found that the death-rate from genuine plague was eighty-five per cent. In epidemics numbers of other diseases—pneumonia, typhoid, etc.,—are confounded with plague and treated in the hospitals and so lower the death-rate. Yersin's statistics are the results of bacteriologic examination, the only absolutely diagnostic method in many cases, and they have been confirmed by the Russian Government Plague Commission.

The use of the serums lowered the death-rate by nearly one-half, but Yersin realized very soon how different the agent was from that which he had used in China. He began the manufacture of serum from living cultures himself. But he had only gotten his laboratory in working order and had gone to a distance to continue his studies in the pathology and therapeutics of the disease when the veterinarian whom he had left in charge was carried off by pernicious malaria. The assistants at the laboratory had not as yet been sufficiently drilled in their work, and so the quality of the serum suffered a second time. However, at the Pasteur Institute they have now produced an extremely strong serum, and there is no doubt that it will do the work claimed for it therapeutically. It is not alone curative, but is vaccinal in its properties; that is, it produces temporary passive immunity from the disease. The latter property will be especially useful for the protection of countries in which passengers from infected places land. An immunizing vaccination with the serum will assure the non-conveyance of contagion. The principle of the serum, according to Metchnikoff, is much better than that of Hoffkin, who uses heated virulent cultures. There is always a certain amount of

organic reaction to this, which never occurs with the serum and there is an element of danger attached to its use.

Professor Robert of Barcelona treated us to an extremely scholarly address on "The Characteristics of Human Pathology in its Relations to Therapeutics." While completely conceding that the cell is the unit of life, he insisted that man is much more than an aggregation of cells; he is a composite whole and must be so treated. He is much more even than a composite of organs, any one of which may become diseased and need special treatment. Here is the danger in modern therapeutics from specialism without just recognition of the interaction of all the parts. There are three grand indications of therapeutics essentially connected with the pathology and physiology of man whose pointings must ever be followed: (1) Support cellular energies and encourage proper cellular nutrition, which is accomplished best by (2) regulation of all the organs so that the functions of nutrition are properly carried out; (3) support of the nervous system on whose functional coordination depends so much of internal regulation. Causal therapeutics may have its dangers because of interference in the effort to remove the cause by Nature's own protective effort. It is the assistance of Nature's effort that now, more than ever, is on the therapeutic horizon in triumphant serum-therapy.

SOCIETY PROCEEDINGS.

THE BRITISH MEDICAL ASSOCIATION.

Sixty-fifth Annual Meeting, Held at Montreal, August 31 to September 3, 1897.

[Special Report to THE MEDICAL NEWS.]

SECTION IN GENERAL MEDICINE.

THIRD DAY—SEPTEMBER 3D.

CHOLELITHIASIS; ITS CAUSATION, SYMPTOMATOLOGY, DIAGNOSIS, AND TREATMENT.

DR. WILLIAM HUNTER of London, England, opened the discussion. He said that seven per cent. of all recorded *post-mortem* examinations have revealed the existence of biliary calculi—a fact which of itself emphasizes the importance of the subject. Until within the last four or five years medical science has, during fifty years, contributed but little that is new in the study of the etiology of cholelithiasis. His statements on this occasion would but have the weight of his own authority, as he purposed simply giving the results of his own investigations upon the subject, particularly in the course of the past two years. He found gall-stones practically to consist of only two constituents, *viz.*, cholesterin and bilirubin-cassium. A stone may be composed of either or both of these constituents. If a compound of both, the cholesterin will be found to constitute the outer layers, the bilirubin-cassium forming the nucleus.

Cholesterin is formed from the degeneration of liver-cells, especially that of mucous epithelium. It is found in limited quantity in other pathologic products of mucous

membranes, as in the sputum of chronic bronchitis and phthisis, while in pus it exists in as large a proportion as in bile itself, *e.g.*, seven per cent. This substance may be deposited in crystalline form with the aid of acetic acid. It is invariably present in degenerated epithelial cells of the hepatic ducts.

Whenever inflammatory action in the hepatic ducts is attended by the formation of free albumen, the action of the latter product upon degenerated hepatic cells gives rise to bilirubin-cassium. Cholelithiasis, then, is of local, and not general, origin. Anything which causes stagnation of bile, and consequent catarrhal inflammation, will tend to its formation. Among such causes may be mentioned extraneous pressure upon the bile-ducts interfering with the flow of the bile, such as might be caused by tight lacing and pregnancy. The potency of these two causes may, in part, account for the fact that the disease occurs five times as frequently among women as men.

The bacillus coli communis has so frequently been found associated with gall-stones that it would appear to bear a causative relation to its existence. Typhoid organisms have also been found in gall-bladders containing calculi. The question of the relation of infection to formation of stone is worthy of further investigation. Welch, in 1891, found typhoid bacilli in the gall-bladder three months after injection of that organism.

The formation of stone in the intrahepatic ducts is explained as due to the excretion of irritating substances by the hepatic cells. Only one known artificial product will excite a direct catarrh of the bile-ducts, *viz.*, toluenediamin, an agent with which a most violent inflammation of these ducts may be set up at will.

The low pressure in the bile-ducts, gall-bladder, cystic and common ducts affords but little force for the expulsion of inflammatory products (inspissated bile), and, in addition, the dependent position of the gall-bladder necessitates the emptying of its contents against the force of gravity. These conditions beget a natural tendency to the retention of the contents of the gall-bladder.

The indications for treatment are simple. Regulate excretion of bile by flushing the bile passages with abundance of water. Avoid too long fasting, as food stimulates excretion. In cases of infected bile the writer knew of no drug equal to salicylate of soda as a biliary antiseptic. There can be no hope of effecting solution of concretions, as olive oil, the only agent possessing this power, cannot by any physiologic means be conveyed to the seat of the disease.

DR. J. E. GRAHAM of Toronto continued the discussion, dealing chiefly with the symptomatology and diagnosis. Cases might be classified as (1) those without jaundice and (2) those with jaundice. In the former cases the symptoms are often very obscure, and an examination of the urine for the presence of bilirubin may prove helpful. There will be no colic unless the cystic or common duct is occluded. The seat of pain is so variable that the writer on more than one occasion mistook biliary colic for appendicitis. Elevation of temperature may exist without suppuration. He believed that biliary colic sometimes exists without the presence of calculi. The differentiation

of a distended gall-bladder from a movable kidney is often well-nigh impossible. Cirrhosis of the liver, suppuration, and abscess are frequent sequelæ of cholelithiasis. Malignant disease and diabetes are so frequently associated with this affection as to point to the probability of some causal relation.

DR. OSLER of Baltimore said he believed that typhoid infection is a much more common cause of cholelithiasis than is commonly supposed. It has been demonstrated experimentally that typhoid bacilli may be present in the system without causing typhoid fever, and in many such cases it is the undoubted cause of cholelithiasis. He believed cases of biliary colic without calculi are due to attacks caused by infective organisms, usually the bacilli coli communis or typhoid bacilli.

DR. HANDFORD of Nottingham, England, although practising in a district where typhoid is endemic, treating as many as 300 cases in private practice during a single year, has never found cholelithiasis as a sequel of a single case, and the claims as to their causal relation is something entirely new to him. He has found gall-stones in young patients much more frequently than the statistics of many writers would appear to indicate is usual. He also believes in the existence of biliary colic without stone.

DR. JOHN A. MULLIN of Hamilton, Ont., in a rather extensive experience with typhoid fever, has never found cholelithiasis to follow that disease in a single instance.

DR. BAUMGARTEN of St. Louis referred to the frequent association of cholelithiasis and malignancy, and thought in such cases that the latter is the cause of the former, although his observations have led him to believe that this etiologic order is sometimes reversed.

DR. PASTEUR of Montreal cited a case in which the surgeon could find no gall-stone, and yet the patient speedily recovered after the operation.

DR. RUERS of Denver, Col., related the history of a case in which no stone could be found, but in which the *post-mortem* examination disclosed obstruction of the small intestine from an impacted gall-stone.

DR. ACHESON of Galt, Ont., asked Dr. Hunter whether, in his opinion, the use of lime-water in limestone districts had any part in the formation of gall-stone.

DR. HUNTER, in closing the discussion, replied that he believed the causes to be local, and that the drinking of lime-water, or any other general constitutional cause, cannot have any direct part in the formation of biliary calculi.

THE EMPYEMA OF PNEUMONIA

was the subject of a paper read by DR. ANGUS MCKINNON of Guelph, Ont. He stated that he believed empyema to be a more frequent sequel of pneumonia than of pleurisy; in fact, he was of the opinion that empyema is very frequently concurrent with the pneumonia. So-called cases of abscess or gangrene of the lung in reality are cases of empyema. He urged the importance of examining critically for empyema every case of pneumonia which does not undergo resolution in the usual time. A continued cough and fever after pneumonia is significant, and its import should not be overlooked. He advised early testing with the aspirating-needle. Aspiration may

suffice in the early stage, but, later, opening the pleura and drainage must be resorted to. Free perspiration is another suspicious symptom of the formation of pus in the pleural cavity. The treatment is entirely surgical.

SOME OF THE MEDICAL USES OF THE ROENTGEN RAYS

was the subject of a most interesting paper by DR. F. H. WILLIAMS of Boston. He has employed the fluoroscope for diagnosis of chest diseases in some 500 cases. He showed by diagrams the differences which he has noted in health and in several chest diseases, in the position of the diaphragm line in inspiration and expiration; also, the differentiation of diseased conditions from the shadows varying in intensity, which he procured by diseased organs. He has employed the fluoroscope most successfully in the examination of cases of tuberculosis, emphysema, pleurisy, pneumo- and pyothorax, cardiac, and other diseases, obtaining in many cases information at a stage when physical examination gave only negative results. He has found no untoward effects in any of his cases from the use of the rays, and believes with due care and avoidance of too long exposures that this method of examination is entirely free from any danger whatever.

THE PRESIDENT congratulated Dr. Williams upon his paper, and the brilliant results of his work, and expressed the belief that there is a great future in store for his method of investigation. He was glad to see that Dr. Williams has succeeded in utilizing the X-rays in the domain of medicine, its use hitherto having been confined to surgical conditions.

DR. C. L. GREENE of St. Paul, Minn., read a paper on the feasibility of controlling pernicious vomiting by intubation of the larynx with a modified tube. The tube is of the ordinary form, with a linear opening in its upper part for the admission of air. Dr. Greene cited his experience with its use, and only asked that his claims made for the device be substantiated by a fair trial.

A hearty vote of thanks to the Chairman closed the meeting.

SECTION IN SURGERY.

THIRD DAY—SEPTEMBER 3D.

DR. F. J. SHEPHERD of Montreal reported a case of abdominal fibrosarcoma growing from the mesentery of the small intestine in a man aged thirty years. Owing to the extent of mesentery involved, it was necessary to remove eight feet of small intestine, three feet because of its intimate relation with the tumor, and the remainder because its blood supply was cut off by the removal of the growth. The lower cut end of intestine was six inches from the ileocecal valve. Union was established by an end-to-end suture.

The patient was much depressed by the operation, but made a complete recovery. At first there was occasional attacks of diarrhea, but later the stools became normal. The tumor weighed thirteen pounds.

DR. T. MUNIZ of Mexico discussed

THE DIAGNOSIS AND TREATMENT OF PENETRATING WOUNDS OF THE ABDOMINAL CAVITY.

DR. B. F. CURTIS of New York read a paper report-

ing a case of partial resection of the mucous membrane of the bladder for ulceration caused by the eggs of distomatohematobium (Bilharz). The patient was twenty-nine years of age, and eight years previously had served in the British army at Cairo. For two years he had had hematuria and had been suffering intensely for three weeks with vesical irritation in addition. He was anemic and exhausted. Suprapubic cystotomy revealed an area about the right ureteral orifice $1\frac{1}{2}$ inches in diameter which was the seat of a nodular infiltration with some ulceration closely resembling a sarcoma. The diseased area was excised, the ureter being slit upward to guard against contraction. The patient made an ideal recovery and was discharged cured in thirty-eight days. The correct diagnosis was not made until the tissue removed was examined microscopically, on account of the great rarity of the disease in North America. The patient has had no hematuria or vesical symptoms since the operation. For two years after the operation he was troubled by attacks of blocking of the right ureter by a thick jelly-like mucus secreted in the kidney probably on account of the presence of the parasite, but they gradually became less frequent and for over a year he has enjoyed perfect health. The author recommends similar treatment for those cases of the disease which are intractable to ordinary medical and local treatment, because of the sufferings of the patient and the liability to the secondary formation of calculus or of a malignant tumor in the bladder.

DR. A. H. FERGUSON of Chicago read a paper, entitled

PERSONAL OBSERVATIONS ON THE SURGERY OF THE GALL-BLADDER AND BILE-DUCT,

mentioning a number of instructive cases. If there is an enlarged gall-bladder the perpendicular incision is preferred. The gall-bladder should be stitched to the parietal peritoneum in the *upper angle of the wound*. It is then ready to be opened. Water may be forced into it, to determine whether the common bile-duct is patulous.

DR. A. B. ATHERTON of Frederickton, N. B., reported

A CASE OF REPEATED ATTACKS OF ABDOMINAL PAIN AND VOMITING.

The patient, a boy, was finally seized with an unusually severe attack, and upon opening the abdomen, the appendix was found and removed. Through a second incision a Meckel's diverticulum, containing fecal masses, was found, and as it was twisted and half strangulated, was removed and the abdomen closed. The operator noticed that the loop to which the diverticulum was attached was drawn up into the wound with difficulty, but no great thought was given it. At autopsy, three days later, it was found that this same loop of small intestine was strangulated through an opening in the mesentery, the loop passing through from above downward, and from right to left.

DR. W. W. KEEN of Philadelphia congratulated the reader upon his bravery in reporting an unsuccessful case, as it is only by such records that others can avoid the same errors.

DR. J. LLOYD of Montreal reported

A CASE OF STONE IN THE URETER.

Such a condition may present all the symptoms of renal calculus except that there is wanting local tenderness in the loin on deep palpation. If a stone exists in the kidney, a deep, hard punch in the loin will invariably elicit the characteristic stabbing pain of renal calculus.

The symptoms of stone in the ureter are attacks of paroxysmal pain and possibly hematuria. If blocking of the ureter is continuous the kidney atrophies in a few months. If the blockage is intermittent, there follows distension of the kidney.

The uremic symptoms of abdominal distention, vomiting, and depression of the heart, with a rapid small pulse, are more marked if the stone is in the ureter than when it is in the kidney. In only one of six cases could local tenderness be elicited by pressure on the ureter. In most cases the stone is impacted in the pelvic portion of the ureter, not immediately at the mouth of the ureter, but still so low down that it can usually be felt per rectum.

If the presence of a stone is made clear it should be removed. If it is very low down it may be reached by suprapubic cystotomy. If it is higher, but still in the pelvic portion, a short abdominal incision should be made, the finger introduced, and placed upon the common iliac artery, and the ureter felt. If a stone is found the ureter can be approached outside of the peritoneum through an iliac incision, and with a little patience the ureter may be opened outside of the peritoneal cavity and the stone removed.

In women a stone in the ureter has been removed through the vagina. If the stone is high up an oblique lumbar incision is made as for stone in the kidney.

Although the ureter cannot usually be closed on account of its small size, the speaker had never had any leakage of urine through the wound in an operation of this sort.

DR. W. W. KEEN reported having opened the abdomen of a man who had had recurrent attacks of pain thought to be due to appendicitis. No appendix existed. The man recovered. Some months later a small stone was removed from the bladder, which undoubtedly while lying in the ureter had caused the previous attacks of pain.

After every attack of renal colic not followed by the passage of a stone, the bladder should be evacuated by Bigelow's instrument.

DR. A. L. SMITH of Montreal called attention to

THE FREQUENT ASSOCIATION OF APPENDICITIS WITH PUS-TUBES,

a condition which he had observed eight times. He regarded the affection of the appendix as secondary. The common method of cutting off and tying an appendix is a bad one. Frequently a fecal fistula develops some months after the patient is supposed to be entirely well. In one case there followed a pelvic abscess containing a quart of pus. Mucous surfaces will not unite. In all cases, therefore, the appendix should be cut off flush with the cecum and a Lembert suture applied.

DR. H. O. MARCY of Boston advocated peeling down the peritoneum, tying and cutting off the mucous mem-

brane, and sewing and inverting the peritoneal surfaces of the appendix.

DR. F. J. SHEPHERD objected to being told by a gynecologist how to cut off an appendix. He had tried the various complicated methods for dealing with the stump and has abandoned them all for a simple ligature and cauterization which has uniformly given him good results.

SECTION IN OBSTETRICS AND GYNECOLOGY.

THIRD DAY—SEPTEMBER 3D.

The session convened at 9:40 A.M.

In the absence of DR. J. LIPPE of St. Ambroise de Kildare, his paper on

OBLITERATION DU COL UTERIN

was read by the Secretary, Dr. Giles of London.

DR. J. F. W. ROSS of Toronto presented a paper upon THE DIAGNOSIS AND TREATMENT OF INTRAPELVIC TUBERCULAR DISEASE,

in which he dealt simply upon the early form of the disease. When a cure follows celiotomy revealing fibroid nodular disease of the peritoneum, it is impossible to say positively that the disease was tuberculosis. If death follows from secondary involvement of the lungs or other organ, the primary disease may be recognized positively as tuberculous in nature. He reported five cases, one of which revealed a tuberculous ulceration of the uterosacral ligaments without involvement of the tubes and ovaries which were not removed. Cheesy pus was found in one case in the tubes, which were undeveloped. Tuberculous disease of the tube may be mistaken for salpingitis of other origin, hysteric neuralgia and salpingalia, or for subacute peritonitis due to fibroids or other tumors. The clinical thermometer is the best means of making the diagnosis. Of the five cases reported, two were cured without treatment before the diagnosis was made. In the majority of the cases that appear in the hospitals, the disease is so far advanced that surgery offers but little chance of recovery. Early operation is advisable since it stops congestion and prevents propagation of the disease. In late cases the patient suffers from menorrhagia and metrorrhagia.

The paper of DR. T. MORE MADDEN of Dublin ON THE CONSERVATIVE TREATMENT OF FALLOPIAN-TUBE DISEASE.

was read in abstract by the Secretary. He stated that he has for many years used aspiration in the treatment of pyo- or hydrosalpinx. Successful results may thus be secured in many cases, and if the method fails, operation may be done later. The patient is anesthetized and placed in the left lateral position. The index-finger is then passed up the vagina posterior to the uterus and the tubes and ovaries are palpated, an assistant pressing the fundus downward. The position of the tumor being determined, a long fine needle is introduced into the retrovaginal fossa and carried to the most prominent part of the tumor into which it is plunged. The tap is then turned and the fluid allowed to flow out. The cavity is then washed out with an antiseptic fluid. If the tube refills, the process may be repeated.

DR. A. P. DUDLEY of New York opened the discussion on the two foregoing papers. He believes that we have become so expert in removing from women the important organs of generation that we are apt to operate unnecessarily. To what extent can we do conservative surgery on the uterine appendages with safety to the woman? If their organs are removed the uterus becomes a useless organ, and may also be removed as the gynecologists claim. This proves that the appendages are the important organs. He has seen many fat healthy ovaries removed. The French government is now offering a pension to mothers who will rear children, and thus prevent a diminution in the native population. It would be better, he thinks, if it would pension the doctor and cut off his work. Ten years ago he began his conservative work on a patient who desired to have the ovaries left. He removed from her one-half of one ovary, tapped cysts in the other, and did some necessary plastic work. In three-months' time she became pregnant, but herself induced abortion. Since then he has the records of sixty-eight such cases removing portions of the ovaries and tubes, one ovary and one tube, the ovary of one side and the tube of the other, and of these, twelve women became pregnant, and eight of them mothers. He has invaded the ovary in all directions, split it in two, removed cysts and cross-sections, and sewed the rest together. He has left only a piece as large as a pea and has yet to record one case in which inflammation has followed to a sufficient extent for detection by bimanual palpation. He has punctured the ovary with a needle through and through without bad results. He has never used Apostoli's method of electrocautery, for he thinks it unnecessary. He never uses catgut, but the finest silk and a cambric needle. He would remove tuberculous tubes and ovaries together with the uterus, because the endometrium is also generally infected. Conservative surgery upon the tube has been done as follows: He has cut the tube in two and removed one-half many times. He has washed non-fetid pus from the tube, divided the structure and replaced the tube without subsequent peritonitis; if the pus is fetid, he removes the tube. He has removed half the tube and half the ovary, and then makes an artificial fimbriated extremity by splitting up the retained end and suturing the mucous lining to the outer peritoneal surface, the cilia taking the place of the fimbria. Saving the ovary, the woman menstruates, escapes the hot flushes, and does not suffer from estranged domestic relations.

DR. BERRY HART of Edinburgh believes that conservative surgery will be done more and more. The danger is that in incomplete operations we may leave the diseased portion and have secondary trouble.

DR. SETH GORDEN of Portland believes in all that Dr. Dudley had said, and that it is only a question as to how far a man will go; but he does protest against the extreme conservatism which does not conserve the woman's health. Many of the so-called conservative operations do not restore the woman's health. Painful menstruation is not so dear to women as is supposed. If it were not for the fact that many women desire children, they would be willing to be freed from the monthly trouble. In all cases of

tubal disease, it is not conservative to leave the uterus; we will do more good when we remove all.

DR. JENKS of Detroit endorsed Dr. Dudley's stand. He has never seen bad results follow his conservative work.

DR. GILES of London remarked that the trouble in conservative surgery is the difficulty in tracing out the ultimate history of the patient, and it is only by the ultimate history that we can determine the value of the method. The primary duty of the surgeon is to retain for a patient her natural functions irrespective of her desires or likes.

DR. WILLIAM GARDNER of Montreal said that in his experience pain has been absent in tuberculosis of the pelvic organs; hence, it is not a symptom of value. The presence of pus is suggestive only but not absolute proof of tuberculosis. The gonococcus or other agent must first be excluded. We cannot place much dependence upon elevation of temperature here as in tuberculosis elsewhere.

DR. D. BERRY HART of Edinburgh read a paper, entitled

THE MORPHOLOGY OF THE VAGINA.

The urogenital sinus, he said, is now not believed to participate in the formation of the vagina. From a study of a two-months' fetus in section he found that the Wolffian bodies and ducts of Müller are formed, the latter ending blindly while the Wolffian ducts entered the urogenital sinus. At the fourteenth week important changes occur. The lower end of the sinus becomes distended to aid in the formation of the hymen. The urogenital sinus and Wolffian bulbs by coalescing form the lower third of the vagina, while the upper two-thirds only are Müllerian. The lymphatic supply of the lower third of the vagina goes with that of the external genitals. The hymen is formed by a union of the Wolffian bulbs. In marsupials the lateral canals represent the Wolffian ducts, while the center blind pouch is Müllerian. The subject, he claimed, has important practical bearings.

DR. A. LAPHORN SMITH of Montreal read a paper on the

DIAGNOSIS AND TREATMENT OF RETROVERSION OF THE UTERUS WITH FIXATION.

He believes that most of the cases of uterine displacement may be relieved by palliative measures. If the uterus is subinvolted, he treats that by amputating the cervix, curetting, etc., with treatment by glycerin tampons. If after a reasonable time these measures fail, he falls back upon pessaries. The mistake is often made of putting in pessaries when there are diseased ovaries. They should not be used in such cases. Stem pessaries are dangerous. The general condition of the patient must be considered. The round ligaments are round muscles and must be nourished. A useful treatment is exercise of the vaginal muscles by coarse wire faradism. If cases cannot be cured by such measures Alexander's operation or ventrofixation must be performed. Ventrofixation is indicated when there is retroversion with fixation or disease of the tubes and ovaries. Alexander's operation is

of service only when such complications do not exist. The results of the two operations are very satisfactory. He had done fifty-three Alexander operations and ninety-four ventrofixations with good results. There is no death-rate attached to either operation. In neither operation should we have hernia. The inguinal ring is more solid after than before Alexander's operation. In fastening the uterus to the abdominal wall, silkworm-gut thoroughly sterilized is, in his opinion, the best material to use. In ten per cent. of his cases these give rise to trouble and must be removed. He also uses fine silkworm-gut in the Alexander operation.

The paper of DR. INGLIS PARSONS of London on A NEW METHOD OF TREATMENT FOR PROLAPSE OF THE UTERUS

was read by the Secretary. The most important factor in the production of prolapse is the erect position. The treatment is to remove the organ or fasten it to the anterior abdominal wall. Another method would be to produce a limited pelvic cellulitis, and thereby fix the organ. Pelvic perimetritis must be avoided. It is only the cellular tissue around the cervix which is involved in pelvic cellulitis. Quinin is the best agent with which to produce the local irritation. It is injected subcutaneously under antiseptic precautions without anesthesia—15 minims of a solution of quinin (15 grains in one dram of water, dissolved by the aid of sulphuric acid) are injected on each side of the cervix. The needle is introduced only three-fourths of an inch, the site of the puncture being half an inch from the cervix, the needle pointing outward to avoid the uterine artery. The patients make satisfactory recoveries with but slight rise of temperature. A small slough occurs at the point of injection.

In discussing the two foregoing papers, DR. J. RIDDLE GOFFE of New York said that it was a hard subject—the dynamics of the female pelvis. What are the forces that produce the displacements, and what means have we to overcome these forces? When a woman is on her feet the displacing forces are the most effective. The illustrations in the best books give a wrong impression of the relations of the uterus to the other pelvic organs. In the erect posture the symphysis pubis is lower than the tip of the coccyx and about in the axis of gravity. The uterus then lies on its anterior face. He believes that the uterus is retained in place by ligaments and not by the perineum. Nature always adopts the plan of suspension and does not prop from behind. Even the liver and brain are suspended. The perineum is not the support of the uterus. This organ weighs $1\frac{1}{2}$ to two ounces and should be easy to hold in place. If we can retain the cervix high up in the hollow of the sacrum, the fundus will be anterior from gravity. Anteversion is so uncommon pathologically that he now no longer recognizes it as pathologic. Antelexion means a lack of development. The uterus in the fetus is slightly antelexed and remains so till puberty. Then, if health is up to par, the blood is determined to the uterus, and it gradually straightens out and becomes normal in shape. Anything which prevents this normal development will result in antelexion, as in over-cramming in school, and the improper hygiene of shop-

girls. This uterus must be stimulated to develop, and this is done by dilating the cervix and applying carbolic acid, following with a cotton tampon. This treatment must be persisted in for three months. Intra-uterine gauze produces uterine contraction, and these gymnastic exercises stimulate the growth of the uterine muscle. *Retroversion* and *retroflexion* are usually combined. He would urge the importance of preventive measures. They are almost invariably due to a lack of involution following pregnancy. The ligaments are involved as well as the uterine muscle. The majority of chronic cases are complicated by inflammation. Operative treatment through the anterior vaginal wall will give good results.

DR. MURRAY of New York believes that if good midwifery were done we would have very little uterine displacement posteriorly. Curetting and removal of the septic endometrium favor involution.

DR. GARDNER of Montreal is a strong advocate of minor measures in the treatment of displacements of the uterus, before proceeding to surgical measures. He would emphasize the importance of improved nutrition of the genital organs. There is a layer of muscle between the layers of the broad ligaments which has been called the uterine platysma (?). This requires tearing up. His limited experience in the inguinal operation has not been satisfactory.

SECTION IN PUBLIC MEDICINE.

SECOND DAY—SEPTEMBER 2D.

Before opening the session, DR. MONTIZAMBERT begged to inform the members of the exact state of affairs in regard to the smallpox "outbreak" in the city. There had been since July 2d but thirteen cases with five deaths, the remaining eight being still in the smallpox hospital with four others from a neighboring town, making twelve in all. Not a single case had occurred or was now known of in Montreal outside of the hospital, so that they believed they had the disease practically stamped out.

DR. JAMES MCLEOD of Prince Edward's Island read a paper on

THE POLLUTION OF GROUND AIR,

which was discussed by Dr. Oldwright of Toronto.

The formal discussion upon

THE UTILITY OF QUARANTINE AS NOW CONDUCTED was opened by DR. F. MONTIZAMBERT, General Superintendent of the Canadian Quarantine System. He rapidly described the Canadian system and especially the points in which it differed from that of England, the most important ones being that it includes the detention of healthy passengers arriving in infected or even suspected ships, while the English detain only those persons or ship actually infected, and the latter for the briefest possible time in which disinfection can be carried out. In fact, in England there is no "quarantine" in the strict etymologic sense of the term. This he thought might be safe for England, but certainly not for Canada. In England there are scores of ports; in Canada practically but four. In England journeys inland are very short, suspected passengers can readily be isolated if desired in one of

those much-abused compartments in the railway-cars; health officers are on guard in every town, who visit them at once upon their arrival and keep them under close observation till all possible danger is past, and isolation hospitals are everywhere available. None of these things are found in Canada with its magnificent distances and sparse population. Of course, the modern quarantine included only such detention of uninfected ships as was necessary to inspect their bills of health, and of suspected or infected ones, as was needed for the prompt isolation of cases, observation of the uninfected till past the danger period, and disinfection of the vessel and of cargo, if necessary. It had nothing whatever in common with the "forty-day" (quarantine) system of detention, except its unfortunate and misleading name.

DR. WALTER WYMAN, Surgeon-General of the Marine Hospital Service, described our American system and defended quarantine as still absolutely necessary at times, although he admitted, a necessary evil.

DR. J. A. DUNCAN, Secretary of the Board of Health of British Columbia, described the system in use against Chinese infections upon the Pacific coast. He urged that Chinese immigrants should not be received on board British or American ships in Chinese ports without a certificate of successful vaccination and a certificate of health for fourteen days past from some qualified European physician. Also that the whole Pacific coast be put under the control of a joint International Board of Health.

The subject was then thrown open for discussion.

DR. J. R. KAYE, Health Officer of West Riding of Yorkshire, said that the English system now simply consisted of thorough inspection, isolation of infected or suspicious cases, and notification of the health officers at the destinations of the other passengers, who visited them at once on their arrival and kept watch of them as long as deemed advisable, removing to isolation hospital on the appearance of any suspicious symptoms.

SIR JAMES GRANT of Ottawa spoke of the effectiveness of the Canadian system and its great importance in view of the huge shipments of food-products from Canada to Europe.

DR. MONCKTON COPEMAN of the English Local Government Board said that England had practically abandoned quarantine in 1893, and the records since had amply justified the step. The cholera record since was better than ever before in spite of the epidemic in Asia, reaching over to Germany, and the enormous traffic poured in from all the infected countries. They regard it as safer than the old method and in every other way vastly preferable to it:

DRS. REYNOLDS of Chicago, OLDWRIGHT of Toronto, and HARVEY LITTLEJOHN of Edinburgh spoke briefly.

DRS. FELIX FORMENTO of New Orleans and WOLFRED NELSON of New York (late of Panama) paid a high tribute to the services of quarantine with steam and sulphur disinfection of ships in excluding yellow fever, which had been absolutely kept out of New Orleans since 1878 solely by this means. Before that, cases occurred every year and epidemics every three or four years.

DR. BRYCE of Toronto dropped a most innocent-look-

ing little question into the English camp by asking what England was doing, or was prepared to do in her "inspection and notification" system for the examination of those swarms of emigrants from European ports who crossed from the east coast to Liverpool or Glasgow on their way to Canada. None of the English health officers appeared to want to play with the torpedo, but Dr. Bryce insisted, and after nearly everyone present had referred the question to somebody else and one official suavely suggested amid audible Canadian smiles that Dr. Bryce write to the Local Government Branch of the Circumlocution Office, which would be most happy, etc., it was pumped out somehow that they were doing nothing at all and had no idea when they would.

DR. MONCKTON COPEMAN of Hull then read a paper on

SOME ALLEGED DANGERS OF VACCINATION,

which he declared were solely due to uncleanly habits on the part of the patient, as germs could now be excluded by using glycerinized lymph.

DR. WYATT JOHNSTON of Montreal reported the admirable results of house-disinfection by formaldehyde gas, illustrated by the apparatus used.

DR. KAYE of Yorkshire read a paper on

THE RELATION OF THE HEALTH OFFICER TO THE REGISTRATION AND CERTIFICATION OF DEATHS, and Dr. Bryce commented briefly.

THIRD DAY—SEPTEMBER 3D.

The paper and discussion of the morning were by DR. GEORGE JANIN of Montreal (formerly of the *Corps des Ponts et Chaussées* of Paris) on

METHODS OF SEWAGE PURIFICATION.

He began by complimenting England upon being the first country to take legal action against the pollution of rooms by sewage, and this example had been followed fully by France and Germany, but not yet so completely as he could wish in this country. The river method was, of course, now practically condemned absolutely by all sanitarians of standing. This leaves four chief methods—separation processes, mechanic (filtration, etc.), chemic, and soil methods, of which the last was greatly to be preferred on all grounds. In this the sewage is poured out over large tracts of porous soil carefully underdrained, in intermittent flow. The land so treated becomes extremely fertile and produces such huge crops of vegetables as to defray quite a share of the expense of the process. Its advantages are, first, that it is the only absolutely sure method, the sewage being completely sterilized in passing through three feet of such soil by mechanic filtration, oxidation by ground air and above all the activity of ground-microbes. At Gennevilliers, the water running away in the escape drains may be drunk with perfect safety and even pleasure. Second, that the soil and vegetables grown upon it are absolutely free from odor or pollution of any sort and the latter will pay half the running expenses of the plant.

DR. H. LITTLEJOHN of Edinburgh agreed thoroughly

with Dr. Janin (Chanin) as to the perfection and admirable results of soil-purification, but thought the question of the expense of the necessary acreage a serious obstacle in many large towns. Certainly no other known method was so adequate.

DR. OLDWRIGHT of Toronto followed in the same strain, and DR. BRYCE related a most interesting result from an experiment with this method at the asylum at London, Ontario. It was not only completely effective both winter and summer, but the past year under cultivation by the patients, the field of three acres had produced \$1200 worth of vegetables, and they were going to double the acreage on the agricultural grounds next year.

DR. H. PROBST of Ohio endorsed the system, and said we should soon be driven to it everywhere as scarcely a river in his State was now fit for water supply.

DRS. SHRADER of Iowa and HERRICK of Cleveland expressed their appreciation of the plan.

DR. WOODS HUTCHINSON of Buffalo called attention to the fact that the chief and most essential factor in this method of purification was the life-activity of the bacteria of the soil, the nitrifying organisms. Experiment had shown that soil was deprived of two-thirds of its purifying effects simply by being sterilized, and that the "ventilation" of the soil by periods of intermission in the flow, was to enable these organisms to get their supply of oxygen. The researches of Floyd Davis had shown that the familiar "scum" which choked the ordinary sand-charcoal filter, was a mass of the mycelia of these organisms, and that such water as succeeded in passing through was absolutely sterilized. And as sanitarians had so constantly denounced bacteria in other fields, he thought it only fair for this section to "give the Devil his due" and recognize them as the chief of the bacteria family.

DR. MOULTON said that it was now proposed to pour sewage into "vat-cultures" of these organisms.

DR. LACHAPPELLE of Montreal raised the question of the drains freezing up in winter.

DR. JOHNSTON of Gloucester admitted the superiority of the method, but thought it impracticable in many places. In Gloucester they used chemic precipitation by alum and salt filtration, with good results.

DR. JANIN, in closing the discussion, said that although the first cost of the land was great, yet this was almost off-set later by the income which could be derived from the land, several European cities receiving heavy rents per acre for their sewage-fields. As to the blocking in winter, it was in active operation the year round in Dantzic, where the mean temperature was lower than in Montreal and the ground frozen a foot deeper. Break the surface ice in the ditches and the warm sewage sinks right into the soil almost as rapidly as in summer.

The next paper was by DR. J. J. MACKENZIE of Ontario upon

RESULTS FROM MECHANICAL FILTRATION IN ONTARIO,

who spoke highly of alum, which produced a very effective layer of slime upon the filter-beds.

DR. WESTBROOK, bacteriologist of the Minnesota State Board of Health, reported his investigations of

EPIDEMICS OF DIPHTHERIA IN A STATE INSTITUTION.

He found typical cultures of Loeffler's bacillus from the throats of perfectly healthy children, and in those of convalescents as long as six months after recovery. Consequently he regarded the present customary time of isolation as much too short, and that convalescents should be kept in separate rooms, if possible.

DRS. OLDRIGHT, LITTLEJOHN, and others objected to the difficulty of carrying out such suggestions, to which DR. WESTBROOK replied that that was a problem for physicians to solve, not for bacteriologists. They had enough of their own and when they had demonstrated a proposition it was for the physicians to carry it out without bothering them with objections on mere practical grounds.

The papers of DRS. SHUTTLEWORTH, HEWITT, and WOLFORD NELSON were read by title, and the section adjourned with the usual vote of thanks to the Chairman.

SECTION IN PATHOLOGY.

FIRST DAY—SEPTEMBER 1ST.

MR. W. WATSON CHEYNE of London, England, the President of the section, delivered the annual address, entitled

ON THE PROGRESS AND RESULTS OF PATHOLOGICAL WORK.

He referred to the time when he was first introduced to pathology—some twenty-five years ago, and described the condition of this branch of medicine at that period of its existence; when it consisted almost entirely of long descriptions of naked-eye appearances. In contrast, he pictured the science as it is to-day when we are so much occupied with the etiologic side of pathology, and, in his opinion, deservedly so, for, so far as practical results in the treatment of disease are concerned, the knowledge of the changes produced is of comparatively little importance as compared with the reasons underlying the existence of abnormal processes. The more accurately we can trace the etiologic factors in disease, the more likely we are to arrive at a rational method of treatment.

He spoke at length of the work of Lord Lister in the field of bacteriology, and of the many difficulties in the paths of early investigators. Lord Lister's great research on the bacterium *lactis*, in which he devised the method of fractional cultivation, was a great advance, and resulted in the separation of the bacterium which causes lactic fermentation from other organisms. This was a great step in the proof of the specificity of a particular bacterium, both as regards morphologic characters and chemical action.

Then came Koch's foundation researches on infective diseases of wounds, and the publication of his methods of straining and examining bacteria and of cultivating them on solid media. From this period the investigations have branched off in two directions: (1) Almost all infectious diseases have been studied for parasitic organisms; and (2) researches have been directed toward the tracing of the life history and functional activity of bacteria, and of ascertaining what occurs when bacteria, or their products,

are introduced into the body. From the latter has been derived Metchnikoff's work on phagocytosis.

He called attention to the fact that in spite of all that has been accomplished many problems still remain to be solved. This is particularly true of tuberculosis—for instance the remarkable results which sometimes follow free incisions into tuberculous tissues are as yet obscure. Again, what is the meaning of a chronic abscess? How is it that the tubercle bacilli at one time produce a quantity of tuberculous tissue, at another a cheesy mass, and at another, a chronic abscess? He does not accept the view that we have to do, in the latter case, with a mixed infection. In connection with pyogenic organisms there are still other problems awaiting solution.

Although the greatest advance has been in bacteriology, great progress has also been made in pathology generally. Inflammation has been further studied, but, to the speaker's mind, it has not been made any clearer. There now appears to be a tendency to regard inflammation as a natural effort at repair after an injury, though the speaker does not subscribe to this view—in spite of the able arguments adduced in its support. He considers inflammation as the mechanism which eliminates noxious agents or neutralizes their effects, and the healing process, as that which repairs defects, whether caused by injury and associated with inflammation or not.

He called attention to the fact that the advances in experimental pathology had resulted in immense benefit to the human race, a sufficient answer to the antivivisectionists. If no other practical advantage had resulted from bacteriologic work, the possibility of establishing a definite diagnosis in obscure cases is surely a gain of the utmost importance; for it permits the institution of a rational prophylaxis and treatment. The speaker places Lord Lister's discovery of aseptic and antiseptic surgery among the greatest results of experimental pathology. In conclusion he referred to the serum treatment of disease and the brilliant prospect which lies before it.

MR. ALEXIS H. THOMSON then read a paper on

EPITHELIOMA OF THE PENIS.

He referred to the penis as the commonest site of the disease, the dorsum of the glans being the most frequent. The richness of the blood supply offers considerable resistance to deep extension. Extension takes place by continuous infection, by outlying or secondary nodules, or by the lymphatics along the dorsum. This last point is important in regard to amputation by the dorsal flap. Fortunately the disease is generally confined to the region near its origin.

Professor Boyce asked if endothelioma had been seen in the same locality. Mr. Thomson could not say that it had.

THE PRESIDENT presented Professor Goldman's paper on

EARLY INFECTION OF THE BLOOD-VESSELS IN CARCINOMA AND SARCOMA.

Eosin was used in staining the vessel walls. Sections were shown of infection of the vessel wall with elevation of the endothelium by cancer-cells, going on to rupture

through the vessel wall and extension. The President said that he had seen similar appearances in sarcomata.

Dr. A. A. Kanthack's paper on

CANCER OF THE TESTICLE

was presented by DR. HUNTER. The drawings had been made by Sir James Paget. Dr. Hunter showed sections of carcinoma of the testicle, carcinomatous masses attached to the inferior vena cava, and carcinomatous masses in the lung. The tumor had been taken for enchondroma, but was shown to be columnar-celled epithelioma. The case has been accepted by Virchow as malignant enchondroma, but has now been proved to be epithelioma with cartilaginous growth about the cancer, a form recognized by Ziegler and others.

Dr. Barker asked if it could not be a teratoma, and Professor Boyce whether cartilage or cancer predominated. Dr. Hunter remarked that the main value of the specimen and paper was historic, and that he could not, in the absence of the author, answer the questions.

THE PRESIDENT read a paper by Mr. H. J. Stiles on

EVOLUTION OF CANCER BODIES,

which sought to prove that the well-known bodies are nothing but degenerative forms of cancer-cells, especially of the nucleus. Discussions have been numerous on this question. Those holding that these bodies are parasitic claim that they stain quite differently from cancer cells, and therefore are probably not cancerous. He claimed to have seen closely allied transitional forms, from the ordinary cancer cells to the cancer bodies. Sections of cancer cells were shown with a nucleus swelling and losing its chromatin. The capsule of the so-called parasite was mainly perinuclear protoplasm. The nucleolus persisting formed the nucleus of the parasite, so-called. The bodies were not endogenous cell forms. Ruffer's bodies have been seen in meningitis, and proved to be degenerated leucocytes. The sections were all from carcinoma of the breast.

Dr. Wm. H. Welch of Baltimore said he had always thought that the resemblance between cancer bodies and genuine parasites is very slight, and he had come to the same conclusion as Dr. Stiles. Besides, there is always the difficulty of explaining the dissimilarity between primary and secondary nodules.

Dr. S. E. HODENPYLE read a paper on

THE OCCURRENCE OF TYPHOID FEVER WITHOUT LESIONS OF THE SMALL INTESTINE.

Cases were cited of death from typhoid fever without lesions in the small intestine or only swelling of Peyer's patches, others with lesions in the colon only, and cases with no intestinal lesion whatsoever, the diagnosis being made by the presence of bacilli in the spleen.

Dr. Welch mentioned a case of typhoid fever without any intestinal lesions, but the bile revealed typhoid bacilli. The bacilli could probably exist in the bile for months. Dr. Hunter observed that it was interesting to learn that the bacilli had been found in the gall-bladder; a number of such cases were on record. Dr. Martin mentioned a case in the Royal Victoria Hospital, Montreal, with ex-

ceedingly slight lesions in the intestine, but with bacilli in the bile.

PROFESSOR BOYCE read Dr. Patrick Manson's paper on

FILARIA SANGUINIS HOMINIS NOCTURNA,

a new species seen in Demerara.

Dr. H. B. ANDERSON read a paper on

MULTIPLE CYSTS OF THE STOMACH AND INTESTINE.

Dr. VAN GIESSEN of New York read a paper on
HEMATOMYELOPORE IN CONNECTION WITH SYRINGOMYELIA.

He reported several cases of trauma to the spinal cord, followed by the production of tubular canals starting at the site of the trauma. These he explained as the result of hemorrhage into the cord. He recorded also one case of spontaneous hemorrhage. This was often mistaken for syringomyelia and described as a case of sudden onset. Professor Boyce questioned the hemorrhagic origin.

Dr. LEWELLYS F. BARKER of Baltimore read a paper on

CHANGES IN THE NERVE-CELLS IN EPIDEMIC CEREBROSPINAL MENINGITIS.

Degenerative changes were shown (in sections) in the anterior horn-cells in cerebrospinal meningitis very similar to cell changes seen after section of the facial nerve.

SECOND DAY—SEPTEMBER 2D.

Dr. J. G. ADAMI of Montreal introduced the discussion on

SERUM DIAGNOSIS AND THE AGGLUTINATING ACTION OF THE SERUMS,

and referred to the work done by Welch and Wyatt Johnston. He said that Grüber, in April, 1896, showed that the reaction could be obtained on the eleventh day of typhoid fever, but Widal emphasized the clinical value of it. Rouget and Metschnikoff had done work on the subject earlier.

Dr. A. S. GRUNBAUM of Liverpool spoke of the various ways of making the test, and alluded to the application of serum diagnosis in other diseases.

Dr. C. P. MARTIN presented a paper by Dr. Wyatt Johnston of Montreal explaining methods for quantitative work, and emphasizing the importance of making sure that the culture is alkaline.

Dr. J. J. MCKENZIE added some experience gained in Ontario.

Dr. JOHN H. MUSSER of Philadelphia related his clinical experience with the test, and said that the reaction had been obtained on the seventh day; blood from a case occurring ten years previously had given the reaction; cold baths had not influenced the test.

Dr. E. B. BLOCK spoke in detail of the the technic, insisting on the importance of the most scrupulous care in making the tests.

Dr. ADAMI then gave a summary of a paper by Widal, and Dr. R. W. Boyce of Liverpool stated that in Liverpool the distinction between typhus and typhoid fever had

been made by the serum method. He preferred using fluid rather than dried blood.

DR. GILMAN THOMPSON of New York summarized clinical experience in five of the largest New York hospitals. He stated that the reaction had been seen on the fourth day of typhoid fever. Attempts to distinguish between typhus and typhoid fevers by this method had failed. Of cases of typhoid fever 75 per cent. were readily diagnosed without this test, 23 per cent. of cases could not be certainly diagnosed by serum methods, and misleading results had been obtained; he therefore claimed that at present this test, like the diazo reaction, is not of great clinical value.

DR. WILLIAM H. PARK of New York then read a paper on

ISOLATION AND IDENTIFICATION OF THE BACILLUS TYPHOSUS,

showing cultures of bacillus typhosus and of bacillus coli communis. He summarized the methods of obtaining serum in New York, the moist method being preferred. He attached no value to negative results.

DR. F. F. WESTBROOK referred to the methods adopted in Minneapolis. DR. WILSON went more into details of the experience in Minneapolis, stating that acute mania and puerperal septicemia had each given genuine positive results; malaria gave negative results. Cases of typhoid fever had given positive results, but on later examinations repeatedly lost or regained their power to give positive results. DR. RICHARDSON also read a paper on the same subject.

THIRD DAY—SEPTEMBER 3D.

DR. V. A. MOORE of Ithaca, N. Y., presented a communication on

THE NATURE AND DIFFERENTIATION OF INFECTIVE SWINE DISEASES IN THE UNITED STATES.

He spoke also of the swine diseases in Europe, seeking to group the varieties under one head. Dr. W. H. Welch of Baltimore maintained that Metschnikoff's bacillus of hog cholera is not that of American hog cholera. He referred to the extreme difficulty of differentiating the pathogenic organisms in hog disease.

DR. J. G. ADAMI of Montreal read a paper on

PICTOU CATTLE DISEASE,

speaking of the methods of extension of the disease, the predisposing causes, the symptomatology, and the morbid anatomy. The liver and the lymphatic glands are the organs affected primarily. He described the micro-organism and showed cultures.

DR. MCEACHRAN said the disease had existed at Pictou for forty years.

DR. R. BOYCE read a paper on

THE TUBERCLE BACILLUS IN MILK,

and discussed the communicability of tuberculosis from lower animals to man. Tubercle bacilli had been found in milk of cows with and without disease of the udder. Milk from tuberculous cows had been proved to be infectious. Of 111 specimens of milk examined at Liver-

pool only four showed tubercle bacilli. Dr. Abbott and Dr. McEachran dwelt on the extreme difficulty of making a thorough microscopic examination of the udder.

A discussion on

PLEUROPNEUMONIA IN CATTLE

was opened by Dr. Adami, who claimed that it had been well proved by experts that Canada is and had long been free from the disease; but the Imperial Government still declined to recognize this. The imperial veterinarians, with the exception of one man who reserved his opinion, are not men who had done work of the highest class, and are not capable of judging thoroughly of the question. Canada's experts had agreed with the experts from England and the United States in stating that Canada is free from the disease. Canada felt that in giving superiority to the opinions of her government veterinarians the Imperial Government was unjust to Canada and to scientific men. Dr. Welch confirmed Dr. Adami's remarks.

DR. MCEACHRAN spoke as a representative of the Canadian Government, and the discussion was closed by the President.

DR. WELCH expressed hearty thanks for the reception given to guests from the United States, and moved a vote of thanks to the President for his able conduct of the meetings. Dr. Boyce, in seconding the motion, said that the President had won the thanks and affection of all. The motion was carried with enthusiasm. The President acknowledged the kindness shown him and the meeting came to an end.

SECTION IN ANATOMY AND PHYSIOLOGY.

SECOND DAY—SEPTEMBER 2D.

The chief business of this section was the discussion on

ANESTHETICS,

which was opened by PRESIDENT A. WALLER of London, PROFESSOR MACCALLUM being in the chair. Dr. Waller's remarks were illustrated by experiments and lantern-slides. The chief point was that chloroform acts upon the nervous system seven times more powerfully than ether, the clinical inference being that chloroform is not a safe anesthetic. The paper was discussed by Professor Richet of Paris, who was strongly of the opinion that deaths under chloroform are due to cardiac and not to respiratory failure, and that, therefore, the heart is the thing to watch.

SURGEON-COLONEL LAWRIE of Hyderabad followed, and stated his well-known views as to the inferences to be drawn from the experiments at Hyderabad, arguing that over-dosage alone is to be feared, that such over-dosage commonly results from irregular and gasping respiration.

DR. SHORE then described the results of experiment by himself and Dr. Easkell which went to show that chloroform has a direct and primary depressing influence upon the heart. Dr. Easkell corroborated the views of Dr. Shaw and an animated discussion arose between Surgeon-Colonel Lawrie and Dr. Shore, which was cut short by the President who called on Professor S. N. Stewart to

speak. The latter took a middle position on the question but was inclined to side with those who were in favor of ether. He thought, however, that many of the classic experiments should be repeated. Dr. Waller then replied on the whole discussion and described some more of his results, contending that the views of the majority concurred with the conclusions he had drawn from his experiments. Owing to the time occupied by the discussion, it being one o'clock, the reading of the remaining papers was postponed and the meeting adjourned.

THIRD DAY—SEPTEMBER 3D.

DR. GASKELL opened the discussion on the heart-beat. He gave a very lucid account of the history of the investigation of the subject and said that he had seen no reason to alter the views which he had published fourteen years ago, which attributed no power of rhythmic stimulation to the ganglionic cells in the heart.

The discussion was continued by DR. PORTER of Boston and DR. HOWELL of Baltimore, who agreed with the views of Dr. Gaskell. DR. MELTZER of New York then stated a theory he had formed as to the cause of the heart-beat, and was followed by DR. MACCALLUM of Toronto and DR. HUBER of Ann Arbor. DR. MILLS of Montreal criticised some of the views of previous speakers, and was surprised that reference to nerves had been so much left out of the discussion. He was inclined to regard some of Dr. Gaskell's views as rather "poetic." He was disposed to attribute the heart-beat to the coöperation of various factors which differ quantitatively in different animals. Dr. Gaskell replied and emphasized the fact to which Dr. Mills had drawn attention; namely, the variability of different hearts. The meeting closed with a demonstration of Hill and Barnardo's new sphygmometer by DR. HUTCHISON.

SECTION IN PSYCHOLOGY.

FIRST DAY—SEPTEMBER 1ST.

DR. R. M. BUCKE of London, Ontario, the President of the Section, delivered an address, entitled

MENTAL EVOLUTION IN MAN.

The speaker said that psychology ought to be the most interesting of studies, and as a matter of fact it undoubtedly is so, though it has been greatly discredited by the imperfection of the method by which it has until very lately been studied, *viz.*, the introspective.

He then referred to the necessity of researches in comparative psychology as an aid in the study of human mental evolution, and finally of the study of mental growth in the individual and in the race.

In regard to the future of the human intellect it was said that by slow and dubious steps taken in darkness our remote ancestors climbed wearily to simple consciousness. After another immense interval they reached self-consciousness. But that cannot be the end—the cosmic process cannot stop there—cannot, indeed, stop anywhere. Evolution, as far as we can see, has always gone on, is going on to-day, and will always continue. Our old mental faculties are some of them fading out, others

advancing toward greater perfection, and alongside of them new ones are springing up, some of which will, without doubt, be of overshadowing importance in the future.

So-called telepathy and clairvoyance seem to be specimens of such nascent faculties. He placed in the same class the phenomena of what is often called spiritualism. The labors of the Society of Psychical Research have made it plain that these phenomena really exist. These are instances of faculties which are not commonly possessed. Whether any such faculty will grow, become common, and finally universal in the race, or wither and disappear, will depend upon the general laws of natural selection, and upon whether the possession of the nascent faculty is advantageous or not to the individual and to the race.

The speaker said that of infinitely more importance than the faculties just mentioned is that superimposed upon self-consciousness, as is that faculty upon simple consciousness, a third and higher form of consciousness, which is at present making its appearance in our race. This higher form of consciousness when it appears occurs, as it must, at the full maturity of the individual, at about the age of thirty-five, but almost always between the ages of thirty and forty. There have been occasional instances of it for the last 2000 years, and it is becoming more and more common. In fact, in all respects, as far as observed, it obeys the laws to which every nascent faculty is subject. In the course of a few more millenniums there should be born from the present race a higher type of man possessing this higher consciousness. This new race, as it may well be called, would occupy, as toward us, a position such as that occupied by us toward the simple conscious *alalus homo*. The advent of this higher, better, and happier race would amply justify the long agony of its birth through the countless ages of our past.

REVIEWS.

THE MEDICAL AND SURGICAL USES OF ELECTRICITY.

By A. D. ROCKWELL, A.M., M.D., Formerly Professor of Electrotherapeutics in the New York Post-Graduate Medical School and Hospital; Fellow of the New York Academy of Medicine. Illustrated with two hundred engravings. New York: William Wood & Co., 1896.

THIS work is practically the ninth edition of Beard & Rockwell's well-known "Treatise on the Medical and Surgical Uses of Electricity," revised and enlarged by the present writer. The arrangement of the material is practically the same as in the older work. Part I. contains six chapters devoted to electrophysics, and enters very thoroughly into the purely physical principles of the various forms of electricity. In part II., the action of electricity on the various organs of the body is discussed in great detail; one chapter is devoted to the influence of electricity upon the general nutrition, a favorite subject with the writer. Part III., on electrotherapeutics is the most elaborate of the book, containing more than half of the reading matter of the entire volume. It reflects through-

out the author's well-known enthusiastic belief in the efficacy of electrotherapeutics, a belief which is hardly shared to any such degree by the younger school of neurologists. The methods of application for therapeutic purposes are given in detail and with such clearness that the general practitioner desiring to employ this method of treatment will find the book a useful and practical guide.

Part IV., the last of the book, deals very completely with electrosurgery, and includes an up-to-date addition in the shape of a chapter on the Roentgen Rays and their application in medicine.

In a future edition of the book we would suggest the advisability of describing the reaction of degeneration in greater detail, especially in its relations to the degenerative changes in the muscles and nerves; if we consider the great practical importance of electrodiagnosis we may well expect a very thorough discussion of the subject in a book otherwise complete.

PROCEEDINGS OF THE AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION, AT THE FIFTY-SECOND ANNUAL MEETING, HELD IN BOSTON, MAY 26-29, 1897.

THIS volume contains a number of interesting papers on subjects of the day. Among the most notable may be mentioned the annual address by G. Stanley Hall on "Psychological Education," in which the writer outlines the consensus of instruction required for a thorough equipment of the modern student of psychology. The standard aimed at is high, and it is hoped that it will be attained within a reasonable time.

A short paper by Henry J. Berkley on "The Intracortical End-apparatus of the Nerve Fibers" is in line with the rest of the author's valuable work on the minute histology of the central nervous system in health and in disease.

Dr. Frederick Peterson contributes an interesting paper in which the "Psychology of the Idiot" is discussed at length, and Dr. Hoch furnishes a valuable article on "General Paralysis in Two Sisters, Commencing at the Age of Ten and Fifteen Respectively—Autopsy in One Case."

DIE FÄRBLINDHEIT UND IHRE DIAGNOSE. VON DR. M. OHLEMANN. Brannschweig: Joh. Heind. Meyer, 1897.

IN this little pamphlet, the author describes the different methods by which the diagnosis of color-blindness can be made. Without entering into any theoretic discussion, he simply relates the facts in a clear and condensed manner, so that the book will be of service to those who have to examine a great number of people for this affection.

CHIRURGIE DES VOIES URINAIRES. By DR. E. LOUMEAU. 2d Vol. Bordeaux: Feret et Fils, 1897.

THIS work is a collection of clinical observations which have appeared at intervals in current French periodicals. The twenty-seven articles embrace the surgical diseases of the urethra, but in a few instances only are the cases or the treatment extraordinary or unusual.

The author favors immediate suture in rupture of the

urethra. In treatment of urethral fistulæ, he resorts to suprapubic drainage, when plastic measures fail. His experiences in hypertrophy of the prostate give a more favorable showing for double castration, than resection of the vas deferens. The unique cases are: "Congenital Stricture with Urethral Calculus," and "A Large Cicatrix of the Vault of the Bladder."

"The Morphology of Balanitic Hypospadias," is a lucid explanation of the various types as determined by embryologic development and which the accompanying illustration clearly shows. The other cuts depict a urinal for use in cases of permanent suprapubic drainage, and a new form of urethral sound.

THERAPEUTIC HINTS.

An Efficient Remedy for Round Worms.—WARD (*Pediatrics*, September, 1897) gives the following prescription for use against round worms, which he heartily recommends, having used it successfully many hundreds of times:

℞	Santonin	.	.	.	.	.	gr. iii
	Hydrarg. chlor. mitis	.	.	.	.	.	gr. x
	Sacchr. alb.	.	.	.	.	.	q. s.

M. Ft. chart. No. 2. Sig. For a child, three to six years old, one powder on retiring, and the other in the morning, fasting.

For Erysipelas.—Externally, to the inflamed surface, a 10-per cent. ichthyol ointment, applied daily; internally, a teaspoonful every two hours of the following:

℞	Tr. ferri chlor.	.	.	.	.	3 iv
	Glycerini	.	.	.	.	3 iss.

For Acute or Subacute Cystitis.—

℞	Ext. buchu fl.	.	.	.	.	3 i
	Potassii citratis	.	.	.	.	3 iii
	Spt. etheris nitrosi	.	.	.	.	3 ss
	Syr. limonis, q. s. ad.	.	.	.	.	3 iii.

M. Sig. Teaspoonful in water every three hours.

For Advanced Syphilis and Anemia.—

℞	Hydrargyri chlor. corros.	.	.	.	.	gr. iss
	Tr. ferri chlor.	.	.	.	.	3 v
	Glycerini	.	.	.	.	3 ii
	Aquæ, q. s. ad.	.	.	.	.	3 iv.

M. Sig. Teaspoonful in water every three hours.

An Astringent Gargle.—

℞	Ext. rhus glabræ	} aa	.	.	.	3 i
	Ext. hydrastin. fl.		.	.	.	
	Potassii chlor.	.	.	.	.	3 iss
	Glycerini	.	.	.	.	3 i
	Aquæ, q. s. ad.	.	.	.	.	3 vi.

M. Sig. Dessertspoonful to a tablespoonful in small quantity of water as a gargle.

For Acute Rheumatism.—The following combination has been highly recommended:

℞	Ammonii salicylatis	.	.	.	.	3 iii
	Liq. pepsini	.	.	.	.	3 iv.

M. Sig. Teaspoonful in water every two or three hours.

THE EARLIEST POSSIBLE RECOGNITION OF TUBERCULOSIS.¹

By JAMES T. WHITTAKER, M.D.,
OF CINCINNATI, OHIO.

It is now established that pulmonary tuberculosis develops in consequence of the inhalation of the tubercle bacillus from the sputum of other tuberculous individuals. The ignorance of this fact and indifference to it hitherto, with the neglect of the simplest precautions, satisfactorily accounts for the appalling number of cases of the disease, and accounts, also, for the insidiousness of the infection. In most cases the source of contamination may be discovered in long and close association with the patient. But the infection may lie latent for years. Childhood is the period of most frequent infection, puberty of most frequent manifestation. Experience with the diseases of children based upon *post-mortem* examination shows that the first tuberculous deposits occur in the lungs, remain latent, and manifest themselves by physical signs and symptoms only after puberty. (Penzoldt.) During this long interval the disease may show itself only in general impairment of health, with headache, earache, otitis media, nervous dyspepsia, neurasthenia, rheumatoid pains, amenorrhea, etc. Children who suffer from frequent or more or less continuous malaise, who feel more than others the confinement of the schoolroom, who are said to be delicate and disposed to phthisis, should be tested for tuberculosis.

The following are a few of the earliest signs of tuberculosis:

Odor of Breath.—Rosenbach speaks of an odor of the expired air peculiar to phthisical patients. This odor, he says, is like that of bronchitis, but is distinguished by a kind of faint sweetness, probably due to the action of protozoa.

Red Line on the Gums.—The occurrence of a red line on the gums, the so-called Frederick-Thompson line is well-known. I attach no importance to it. It is said to be observed most frequently in the young. I have looked for it, but found it only exceptionally.

Clubbed Fingers.—Of clubbed fingers I will say nothing, save that they are also seen in certain forms

of heart disease. In phthisis they belong to the phthisical habitus, which is interpreted in our day as an already existing infection.

Local Signs.—Every obstinate local affection of bones, joints, skin, testis, or Fallopian tubes, should excite suspicion. Adenitis is extremely suspicious.

Fever.—The importance of anything like a continued or frequently recurring fever, without known cause, is now universally appreciated. The elevation of temperature may be only a fraction of a degree, but it shows itself every evening and during a period of several weeks or months. This sign has now become so significant as to at once excite the suspicion of tuberculosis. Absolutely reliable conclusions may be drawn only when the temperature is taken *per rectum*. The temperature should be observed three times a day. The evening records are most desirable. Malaise and increase of temperature contribute all the more directly to the diagnosis if they are associated with impairment of nutrition, anorexia, blood changes, or anemia, and especially with chlorosis. The younger Klebs, who tests every such patient without exception with tuberculin, has never yet failed to get the reaction of tuberculosis in chlorosis.

Night-sweats.—Night-sweats usually belong to a later period in the history of the disease, in fact, to the septic period; but they sometimes show themselves early, in exceptional cases preceding even cough or any pronounced change in nutrition.

Albuminuria.—Albuminuria is wont to show itself to a slight degree in the earliest stages of phthisis. Tissier speaks of an albuminuria as pretuberculous, which he noticed mostly in the morning, with a concomitant phosphaturia, in a regular intermittent cycle, preceding all other symptoms of pulmonary tuberculosis. The albuminuria disappeared as soon as the tuberculosis had become definitely established. I have seen the albuminuria disappear in this way, but I have never observed phosphaturia in these cases. This albuminuria is not a symptom of nephritis; it is a toxic alteration of the albumen, whereby it becomes more dialyzable. Erythremus cordis, palpitation, and early dyspnea are symptoms of this same toxemia.

The Diazo Reaction.—The diazo reaction, in my experience, is much less common, and is less reliable, though it may indicate the tuberculosis which often follows measles. This reaction is absent at first, but

¹Abstract of a paper read at the Twelfth Annual Meeting of the Association of American Physicians, held at Washington, D. C., May 5, 1897.

shows itself suddenly and continuously up to the time of death in the typical miliary tuberculosis of children.

In miliary tuberculosis the tubercle bacillus may be demonstrated in the blood. Krönig withdraws a few drops of blood, dilutes it with 10 c.cm. of acidulated distilled water, subjects it to the centrifuge for two minutes, and examines the sediment in the usual way for tubercle bacilli.

Cough.—Cough, which is the commonest symptom of phthisis, sometimes leads us astray in making a diagnosis from chronic bronchitis, chronic pneumonia, and chronic influenza, which may all be independent of tuberculosis. It is the morning and evening cough which is most suspicious, but any cough which continues for more than three weeks should lead to further exploration. There may be no cough at all in acute miliary tuberculosis. Latent deposits do not excite cough.

The Tubercle Bacillus in the Sputum.—Much depends upon the source of the specimen of sputum, and the patient must be instructed to bring up secretion from the lungs. The use of the centrifuge after the fluidification of the sputum by soda or potash shortens the examination and increases the value of the test.

Hemorrhage.—Sometimes the occurrence of hemoptysis is the first positive indication of the existence of phthisis. Under all circumstances the spitting of blood is suspicious, premising, of course, that the blood comes from the lungs. It is not too sweeping an assertion that when hemoptysis occurs in a person apparently enjoying perfect health, it is a sure indication of tuberculosis.

Tuberculin.—The first test dose of tuberculin for the cases of lightest infection (suspected) should be 5 mg., the second 10 mg., or 1 cg., the third 2 cg. These doses may be given on succeeding days, or better, every other day, preferably in the evening, that the temperature records may be properly observed on the following day. Failure to obtain reaction after three tests excludes the presence of tuberculosis.

The most serious objection to the use of tuberculin, and that which limited its general use in the beginning, was the one first urged by Virchow, that it awakened tuberculosis from latent sources and disseminated the disease. This statement was eagerly caught up and echoed on all sides. Baumgarten believed that under its influence a more rapid and abundant colonization of bacilli occurred in the lungs. Fürbringer went so far as to declare that miliary tuberculosis was found oftener in patients treated by tuberculin than in the non-injected. This authority invoked the aid of statistics in the statement that miliary tuberculosis was found in the lungs after the

use of tuberculin in forty-three per cent. against six per cent. in the non-injected, and a general tuberculosis was found after the use of tuberculin in twenty-one per cent. against ten per cent. of the non-injected. But these objections are now matters of mere historic interest, for competent observers everywhere, following the footsteps of Guttman and Ehrlich in Germany, and Trudeau, Dennison, and Klebs in this country, bear testimony to the fallacy of these views, and to the unquestionable efficacy of the agent as a diagnostic medium.

It was in vain that the advocates of tuberculin, especially Guttman and Ehrlich, protested that these results were observed only when the agent was used in too large doses or in too advanced stages of the disease. I have used tuberculin every day in hospital and private practice for six years, now in more than 1000 cases, and have never seen evil result from it.

Koch, April 1, 1897, declared that the fear of the tubercle bacilli being rendered mobile in consequence of the reaction produced by the administration of tuberculin, and therefore being transmitted to healthy animals, has been shown, in many thousands of injections made in cattle, to be perfectly groundless. "My own individual experience in the use of tuberculin in the early diagnosis of tuberculosis in man coincides with and supports this view. In all these cases there was never the slightest intimation of anything like a mobilization or transmission of tubercle bacilli. This experience should entirely annul the foolish prejudice which exists regarding the causing of mobility of tubercle bacilli, and it should put the diagnostic value of tuberculin in the recognition of tuberculosis in man upon the same plane as in animals."

The following cases of positive and negative evidence, selected from a large number of cases, illustrate the value of tuberculin as a means of diagnosis:

Neurasthenia. Positive Evidence.—Miss M., aged eighteen years, a tall, fragile, delicate-looking girl, complained of languor, palpitation upon exercise, and fatigue. The menses were sometimes delayed. No other anomaly was observed. There was no cough and no fever. I had treated the mother of this girl for incipient tuberculosis, the diagnosis having been established by the discovery of the tubercle bacillus in the sputum in the absence of physical signs, and felt sure that the patient had some local deposit in consequence of having lived so long in the atmosphere of infection. A test-dose of tuberculin, 1 mg., was given at 2 P.M. Reaction set in the following morning at 8 o'clock, with chill, fever, temperature of 103° F. during the course of the day, pain in the bones, headache, etc., the symptoms all subsiding the same night.

Negative Evidence.—Miss H., aged twenty-two years. History of tuberculosis in family of both

father and mother. Patient very tall, exceedingly slender, and emaciated, extremely elongated, cylinder-shaped thorax. Confined to bed for several months. No cough; no fever; good appetite. Test-injections of tuberculin, 0.005, 0.01, and 0.02, negative. This patient is improving rapidly under a pneumatic and general tonic treatment.

Night-sweats. Positive Evidence.—J. M., aged twenty-eight years, had had slight cough, morning and evening, during several months, with night-sweats every night. No other sign of illness. Examination in every way negative. No cough; no bacilli in what sputum he could raise. Complete reaction to tuberculin, the use of which twice a week in gradually increasing doses, completely arrested the night-sweats after three weeks.

Sister of Charity, aged twenty-six years. Brought to the hospital to be treated for night-sweats, with which she had been affected for more than a month, and which proved refractory to the use of atropin, agaricin, and quinin, but which ceased entirely after three weeks under the use of gradually increasing doses of tuberculin.

Negative Evidence.—A. M., aged twenty-two years. Melancholia, sexual neurasthenia, prostatorrhea. Night-sweats for several weeks, occasionally profuse. Test-injections of tuberculin, 0.001, 0.005, 0.01, negative. The night sweats ceased and the patient improved in every way under the use of quinin and aromatic sulphuric acid, together with urethral injections of lactate of silver, two per cent., with the Ultzmann catheter.

Joint Disease. Positive Evidence.—Mrs. W. C. S., aged twenty-nine years, tall, delicate, pallid. Lived in a house several months with an uncle who died of tuberculosis. Had one miscarriage one year ago at two months. Complained of general weakness and pains in the trunk, especially on turning. There was some stiffness of the right wrist. No cough, but short-breathing on exercise. Temperature 99° F. No physical signs save perhaps a slightly defective expansion of the right lung. Test-injection of tuberculin increased the temperature two degrees.

This patient subsequently developed tuberculosis of the right carpus, which finally necessitated amputation of the forearm. Notwithstanding this extreme measure, the patient succumbed to acute tuberculosis three months later.

Negative Evidence.—Miss F., aged thirty years. March 18, 1897. Diagnosis, chronic rheumatism. Right elbow swollen; hand and arm cold, blue, and anesthetic. The disease proving refractory to salicylates, iodine, and external applications; test-injections of tuberculin were given, one on April 17th, and one on April 19th, 0.01 and 0.02, respectively. No reaction.

Pulmonary Tuberculosis. Positive Evidence.—W. V., aged thirty-eight years; four children, two tuberculous. Had "lung disease" as a child seven or eight years old, and pneumonia three years ago. Gained in weight since, from 130 to 150 pounds. Cough during seven or eight months with considerable catarrh. Expecterated tough, white mucus. Physical

examination entirely negative. Lungs clear, with good expansion. Examination of sputum showed presence of one or two bacilli, not absolutely certain. Injection of tuberculin, 0.01 at noon, produced elevation of temperature one and one-half degrees the next morning.

Negative Evidence.—A physician brought his daughter, aged sixteen years, to me, a diagnosis of Bright's disease having been made, because during three months she had had headache, lassitude, and slight albuminuria. Her temperature for the most part was subnormal, but showed occasional elevations of one-half to one degree. There was nothing in the condition of the urine to indicate Bright's disease. The specific gravity was normal. There were no casts. The diazo-reaction was constant. I felt sure that the albuminuria depended upon a change in the albumin from a toxemia. Although there was no cough, I suspected a latent tuberculosis, but after a thorough test with tuberculin, I had to abandon this suspicion. I then tested the blood with a typhoid culture and found the typical agglutination and arrest of motion of bacilli described by Widal. Having fortified this observation on two subsequent occasions, at intervals of a week, I felt justified in attributing the condition to typhoid fever.

Abdominal Tuberculosis. Positive Evidence.—Mrs. A. P.; pain and swelling of the abdomen during three months, with gradually increasing weakness and loss of flesh. Temperature subnormal. No cough. No evidence of disease of the lungs; abdomen somewhat distended; obstipation. Palpation revealed nodulation, as from agglutination of the intestine. Satisfactory reaction to tuberculin. Subsequent laparotomy, with recovery.

Negative Evidence.—Mrs. P., aged forty years; membranous enteritis. No history of tuberculosis, but had had anal fistula, which excited a suspicion of the presence of tuberculosis. Test-injections of tuberculin were negative. Treated subsequently with euphoron suppositories. Condition much improved.

Sore Throat. Positive Evidence.—K. T., female, aged twenty years; incipient tuberculosis. Had been treated with tuberculin and sustained by it for two years, the disease having made no advance in that time except when the patient interrupted the treatment for several months. Sore throat appeared occasionally, apparently being of catarrhal origin, but upon one occasion, under maximum dosage, a crop of ulcers marked by grayish-white deposit appeared about the larynx, with edematous infiltration of the interarachnoid mucosa. The treatment was interrupted for one week, after which the dose was resumed in less amount, and under gradually increasing dosage the ulcers disappeared.

C. P., aged twenty years, in perfect health "until upon one occasion he was shaved by a barber and had hairs pulled out of a pimple, which had become sore, by means of hair-forceps. The barber dug under the skin with his pincers." Two weeks later the glands became affected and the general health began to suffer. The throat became sore. Two months later the patient came to me with the glands swollen un-

der the right jaw, the arm, and in the right groin. In the course of a week sore throat developed, with uniform redness and swelling, and with the formation of one ulcer on the side of the veil of the palate. I first suspected an accidental inoculation of syphilis, and treated the patient with mercurial inunctions and iodine. There was no material improvement under this treatment. As I had previously treated a member of his family for pulmonary tuberculosis, it occurred to me to make a test-injection of tuberculin. This injection was followed by a typical reaction. I then commenced the regular treatment, finding that every increase in the dose was attended by manifestations of tuberculous deposits in the throat. It appeared as if colonies of bacilli under the mucosa had been brought to the surface by the tuberculin. They were always soon destroyed by local applications of nitrate of silver in stick form, and the patient made a good recovery after three-months' treatment with tuberculin.

Negative Evidence.—Miss H. had been aphonic for several weeks. The voice was husky for months. The general health was poor. There was considerable pallor and apparent weakness, but no fever or sweats. The patient expressed herself in whispers. There was no cough and no sputum. The examination of the chest was entirely negative. The larynx was catarrhal throughout. The epiglottis was heavy and concealed the interior. At times, however, a glance could be obtained within the throat, revealing a thickened, reddish, gelatinous-looking mass, at the middle of the left vocal cord.

A test-injection of 1 mg. of tuberculin gave no reaction. A second injection of 5 mg. gave no reaction; a third injection of 10 mg.—i.e., 1 cg., gave no reaction. I then excluded tuberculosis, cocaineized the throat, and touched the gelatinous mass twice with nitrate of silver melted upon the end of a laryngeal probe. The mass melted away, and the patient recovered the use of her voice in two weeks.

The importance of an early diagnosis no more requires mention here than a repetition of the well-known fact that the disease, at all times amenable to arrest at this stage, has now, under the use of the perfected tuberculin, probably become subject to absolute cure.

The examination of the sputum should include a search for the influenza bacillus, for the diplococcus of pneumonia, and for the streptococcus and other pyogenic micro-organisms. The exclusive presence or predominance of these micro-organisms determines the complications of tuberculosis. The majority of these patients, as we now know, succumb not to tuberculosis but to sepsis. The failures in the treatment of the disease in man with the specific remedies hitherto employed, are largely due to the fact that tuberculosis in man becomes in the later stages a mixed infection. These are the cases which are benefited to the greatest extent by creosote, climato-therapy, etc. Jakowski developed pyogenic bacteria

nine times in seven patients from the blood of hectic fever. But, as Hewelke concludes, negative findings in the blood do not justify negation of mixed infection in pulmonary tuberculosis.

These studies will give us new subdivisions and new names—streptomycosis, staphylomycosis, etc.—but in the meantime will tend to reinstate the old term, phthisis, by the demonstration that pulmonary tuberculosis is only one of the forms of this disease. This observation does not under rate the gravity of tuberculosis, because it is the tubercle bacillus which prepares the way for the invasion of the secondary or pyogenic micro-organisms. We may now distinguish uncomplicated tuberculosis, which marks only a small percentage of all cases of lung disease, runs a course without fever, or, if fever exists, is unfavorable because the disease is then so far advanced. These uncomplicated cases are especially suitable for tuberculin treatment. Most cases of later course represent infection with the streptococcus, and these are to be separated into those of active course with fever, and passive without fever. The distinction chiefly lies in the fact, that in the first case the parenchyma of the lungs is attacked with the streptococci, while in the second, the streptococci lie only in superficial colonies in the bronchi, etc. (Spengler.) Rarer cases are mixed infections with the pneumococcus, micrococcus tetragonus, staphylococcus, influenza, and pseudo-influenza bacillus. All these forms, associated with fever, are to be treated only tentatively with tuberculin until the complicating affections have been subdued, if they can be, by the open-air treatment, by creosote, cognac, climate, etc. Ten years ago I reported some remarkable arrests of this kind of sepsis by means of the administration of pure oil of garlic.

Most of the cases of phthisis are readily recognized as such, and need no test-injections, but the diagnosis in our day demands a differentiation of cases. Moreover, the diagnosis should be declared sooner, for it is plain now that the earliest possible appreciation will lead to the extinction of the disease.

Preservative Power of Glaciers.—In October, 1866, Capt. Henry Arkwright and three companions were killed by an avalanche on the Grand Plateau of Mt. Blanc. The bodies of the three companions were recovered a week after the accident, but that of Captain Arkwright could not be found. During the present summer, however, the melting glacier presented it to view 9000 feet below where he was killed thirty-one years ago, and it was recovered. The head and feet were missing, but otherwise the body was perfectly preserved. The right hand was especially life-like, even the red tint of the blood having been preserved. All of his personal ornaments were intact, and the white handkerchief in his pocket still retained his name.

NOTES ON THE ETIOLOGY OF INFLAMMATION OF THE ACCESSORY SINUSES OF THE NOSE.¹

BY W. T. HOWARD, JR., M.D.,

OF CLEVELAND, OHIO;

PROFESSOR OF PATHOLOGY OF THE WESTERN RESERVE UNIVERSITY;
AND

J. M. INGERSOLL, M.D.,

OF CLEVELAND, OHIO;

LECTURER ON OTOTOLOGY, RHINOLOGY, AND LARYNGOLOGY IN THE
MEDICAL DEPARTMENT OF THE WESTERN RESERVE UNIVERSITY.

(From the Pathological Laboratory of the Western Reserve University.)

In the present paper we wish to make a preliminary report on the results of our studies of eighteen cases of inflammation of the accessory sinuses of the nose. The material for the most part has been derived from the private practice and dispensary service of one of the writers (Ingersoll), but to the courtesy of Drs. Hamann, Bunts, Sherman, Stephan, and Wenner we are indebted for the opportunity of making cultures in the cases of several patients on our list. The cases were both acute and chronic, some dating, according to the histories, from twenty to thirty years.

We shall limit ourselves in the present report to a statement of the results of our studies, and leave the details of the cases and cultures for a later article. Our cases include suppurations of the antra, and the ethmoidal and frontal sinuses. We have not met with inflammation of the sphenoidal sinuses. The methods employed for obtaining the material for study were several. From the antra the material was obtained in one of three ways: (1) By exploratory puncture with a straight trocar well up under the middle third of the inferior turbinal in the majority of cases; (2) through an opening in the alveolar border of the superior maxilla, after the extraction of a tooth; and (3), in two cases in which neither of the first methods could be adopted, pus was obtained by means of a platinum needle, or a cotton swab, from or near the orifice of the maxillary opening. In all cases the utmost care was used to cleanse the nose and to avoid contamination of the pus and infection of the patient. Pus from the frontal and ethmoidal sinuses was usually obtained at the time of operation; in one case, however, it was obtained by puncture, and in two through spontaneous openings.

The methods of examination of material obtained from the sinuses was as follows: Both stained and unstained coverslip preparations were studied, and the kinds and relative number of the cells were

noted. Tubercle bacilli and protozoa were looked for, but always with negative results.

Cultures were made on coagulated blood-serum, and on agar-agar plates.

The pathogenesis of nearly all the organisms found was determined by inoculation of rabbits or guinea-pigs.

The antrum of Highmore was involved in fifteen cases, with a total of seventeen antra; the right antrum in five cases (VII., X., XI., XVII., XVIII.), in three cases alone, and in one case with the ethmoidal sinuses (VII.); and in one case with the frontal and ethmoidal sinuses (XVII.). The left antrum was involved eight times alone (Cases I., II., III., IV., VIII., IX., XIII., XVI.). Both antra were affected in two cases (VI. and XIV.), and in each of these the ethmoidal sinuses were involved. In these cases the process was chronic. Three of the cases of antral disease were acute (IV., VII., XI.), and twelve were chronic. Two of the acute cases followed influenza (IV. and VII.). In the first the streptococcus pyogenes was found in pure culture, and in the second, the influenza bacillus and the staphylococcus pyogenes aureus; the third case followed a severe coryza, and the diplococcus lanceolatus and the pseudodiphtheria bacillus were found. Of the twelve chronic cases, two followed influenza (I., XIII.), the first being associated with hypertrophy of the inferior turbinal, and was complicated with facial erysipelas, an abscess of the alveolar process of the superior maxilla, and a fatal secondary septicemia, due to the streptococcus pyogenes. There was found in the antrum of this patient, who came to autopsy, a polypos, and the walls were swollen, deeply congested, and edematous. In the second patient the nose was normal, and cultures from the antral contents gave the bacillus mucosus capsulatus.

Case II. was secondary to a syphilitic ulceration of the alveolar and palatal processes of the superior maxilla. In the pus from the antral cavity the streptococcus pyogenes, the staphylococcus pyogenes aureus, and the bacillus mucosus capsulatus were found. In this case nasal polypi were also present.

Case XVII. followed an acute coryza subsequent to exposure after pneumonia, and was apparently of thirty-years' standing. There is no record of the condition of the nose. The frontal and ethmoidal sinuses were involved with the right antrum. In the cultures from the antrum, the streptococcus pyogenes, and the staphylococcus pyogenes aureus were found.

In Case XVIII. the *atrium infectionis* was apparently through a decayed bicuspid tooth. In the cultures from the pus the diplococcus lanceolatus was found in pure culture. There is no record of the condition of the nose. In Case VIII. there was

¹ Read at the Fifty-second Annual Meeting of the Ohio State Medical Society, Cleveland, May 31, 1897.

tenderness and swelling about the first and second bicuspid of the affected (left) side, but there was nothing wrong with the teeth themselves. There was hypertrophy of the left inferior and middle turbinals. Cultures in this case gave the staphylococcus pyogenes albus and a thread fungus which was not pathogenic for guinea-pigs or rabbits. In Case XVI. there had been a purulent discharge from the right nostril for a year, and there was pain and swelling about the second left bicuspid tooth. The tooth was badly decayed and an abscess extending from it was found. The streptococcus pyogenes and the staphylococcus pyogenes aureus grew in the cultures. In Cases IX. and X. there was a long-standing atrophic rhinitis. In Case IX. there was anemia and neurasthenia. Cultures from this patient gave the staphylococcus pyogenes albus and an unidentified bacillus. In Case X. the streptococcus pyogenes and the staphylococcus pyogenes aureus were found.

Of the two cases of bilateral empyema of the antrum, Case VI. had had a purulent discharge from the left nostril for twenty-two years, and from the right nostril for twelve years. Twelve years before coming under observation all the upper teeth had been extracted and a plate inserted. About five years ago there was an otitis media acuta sinistra. Since then both nasal fossæ have been occluded and the sense of smell lost. On examination both nasal fossæ were found to be filled with polypi, and one large polypus filled the nasopharynx. From the right antrum a pure culture of the streptococcus pyogenes was obtained. From the left, the streptococcus pyogenes and bacillus mucosus capsulatus. In Case XIV. the streptococcus pyogenes was obtained from both antra. There is no note of the condition of the nose, or of antecedent acute infectious disease in this case. In both cases (VI. and XIV.) the ethmoidal and frontal sinuses were involved.

Of the chronic cases, three followed acute infectious diseases (influenza, coryza, and pneumonia), one was due to syphilitic ulceration of the hard palate and alveolar process; two were clearly, and another possibly, secondary to dental decay, and two were associated with atrophic rhinitis; in three cases there were nasal polypi present, and in three there were hypertrophies of the turbinals.

In the seventeen antra examined, the streptococcus pyogenes was found in eleven, five times alone, four times with the staphylococcus pyogenes aureus, once with the bacillus mucosus capsulatus, and once with the pneumococcus and the bacillus mucosus capsulatus. The staphylococcus pyogenes aureus was never found alone, but with the streptococcus pyogenes four times (III., X., XVI., XVII.), and with the influenza bacillus once (Case VII.). The ba-

cillus mucosus capsulatus was found alone in one case (XIII.), with the streptococcus in the left antrum of Case VI., and with the diplococcus lanceolatus and the streptococcus pyogenes in Case II. The diplococcus lanceolatus occurred alone in one case (XVIII.), once with the pseudodiphtheria bacillus (II.), and once with the streptococcus and the bacillus mucosus capsulatus (VI.). The staphylococcus pyogenes albus was found once with a non-pathogenic thread fungus (VIII.), and once with an unidentified bacillus (IX.).

In three cases the frontal sinuses were alone affected, the right sinus twice (V., XII.), and the left once (XV.). In one case (XVII.) the right antrum and the ethmoidal sinuses were also involved. In the first case (V.) the process followed a severe coryza. Twenty years ago there was intense frontal headache, most marked on the right side. After a few days spontaneous rupture occurred, and there has been a continuous discharge of creamy pus ever since. Several cubic centimeters of pus were obtained by aspiration through the fistulous tract. The right middle turbinal was hypertrophied at its anterior end, and the septum deviated slightly. There was no discharge of pus from the nostril. The other sinuses appeared normal. Cultures gave the staphylococcus pyogenes aureus and an unidentified non-pathogenic bacillus.

In the second case (XIII.) the patient, a girl aged eleven years, eighteen months ago had a severe attack of coryza. Since then there has been frontal headache, most marked on the right side, and a purulent discharge from the right nostril. Pus from the right frontal sinus contained the diplococcus lanceolatus in pure culture. In Case XV. the left frontal sinus was alone affected. The process was of long duration, and the abscess ruptured spontaneously. Pus obtained from the sinus contained the staphylococcus pyogenes aureus and the bacillus mucosus capsulatus. In Case XVII. with empyema of the right antrum there was inflammation of both the frontal and ethmoidal sinuses. From the antrum and the frontal sinuses the streptococcus pyogenes and the staphylococcus pyogenes aureus were obtained.

In Case XIV. there was empyema of both antra, and of the ethmoidal and frontal sinuses. The frontal sinuses contained pus and polypi. In the pus from the frontal sinuses, as well as from the other cavities, obtained several times, there was always found a streptococcus growing in short chains which slowly liquefied gelatin. This organism was not pathogenic for animals. The first three cases were instances of chronic empyema of the frontal sinuses, two of them following acute coryza. The ethmoidal sinuses were never found alone affected, but always in association

with antral empyema, and, with one exception, with empyema of the frontal sinuses as well. In Case VI. both of the antra and the frontal sinuses were involved (see above). In the material from the ethmoidal sinuses the streptococcus pyogenes was found. In Case XIV. both antra and the frontal sinuses were involved, and there again the streptococcus pyogenes was found in the ethmoidal scrapings. In Case VII. the process was associated with empyema of the right antrum following influenza, and in the pus the staphylococcus pyogenes aureus and the influenza bacillus were found. In the last case (XVII.) there was also empyema of both antra and frontal sinuses as well as of the ethmoidal sinuses. In the material obtained from the latter the staphylococcus pyogenes aureus and the bacillus pyocyaneus were found.

While in our experience primary inflammation of the frontal sinuses is not uncommon, we have never met with inflammation of the ethmoidal sinuses, except when secondary to, and accompanying inflammation of the antra either alone or in combination with inflammation of the frontal sinuses. Our material, except in the first case, which came to autopsy, has been derived from the living. The inflammatory process was well established in every case. In the affected antrum of Case I. there was a polypus, the cavity was filled with a thick pus, and the walls were congested and edematous. In the other cases the character of the pus varied. Usually, however, it was mucopurulent; not infrequently it contained fibrin, and in some cases it was thick and of a creamy appearance. As previously stated, tubercle bacilli and protozoa were never found. Besides bacteria and polymorphous nuclear leucocytes, which were present in varying numbers, in nearly every case large, swollen, flat, sometimes round, sometimes ovoid or even polygonal cells, epithelial in appearance, were seen. These cells varied in size, had oval or round vesicular nuclei, with finely granular protoplasm, and often contained large or small fat droplets. Occasionally they contained bacteria. These cells were found in the material from the antra and from the frontal and ethmoidal sinuses. Columnar epithelial cells were never seen. These swollen epithelial cells must have been changed and desquamated cells from the walls of the various cavities. In some cases these cells were very much more numerous than in others. Cases in which these cells are numerous, we are disposed to call catarrhal.

Death from Chloroform.—Professor Ryle, D.D., President of Queen's College, Cambridge, England, lost a child of eight years recently from the administration of chloroform.

YEAST NUCLEINIC ACID IN THE TREATMENT OF SEPTICEMIA, WITH REPORT OF CASES.¹

By WALTER COURTNEY, M.D.,
OF BRAINERD, MINN.;
CHIEF SURGEON, EASTERN DIVISION, NORTHERN PACIFIC R. R.

FOR the purposes of this article we will define septicemia as a general systemic invasion by one or more varieties of the pyogenic or putrefactive bacteria, their products, or both. There are but few forms of infectious disease which we dread more to meet, or fear more when met, than septicemia. The rapidity with which it proves so frequently fatal, and the fruitlessness, in such cases, of the most faithful, assiduous, and often heroic treatment, are enough to move our minds to anxiety and fear in the presence of such a relentless disease.

It has been my fortune during a good many years to be placed in a position which has compelled me to meet and treat many of these most undesirable cases. Railway men are peculiarly liable to badly lacerated and contused wounds, and in too many instances there occurs every opportunity for early infection. Often, time and distance and, necessarily, imperfect operations and dressings are elements of mischief which have accomplished much harm by the time the patient reaches the hospital. Treatment as laid down in text-books is often unsatisfactory; even though the patient recovers, the tissues around and about the wound where infection occurred may be left in an indolent and sluggish condition, rendering healing slow and difficult.

A year ago last winter I had the privilege of working in Dr. Vaughan's private laboratory at the University of Michigan, and while there observed his experiments with yeast nucleinic acid on rabbits and guinea-pigs which had been inoculated with the bacillus tuberculosis, bacillus tetani, and bacillus anthracis, each in different animals. The marked inhibitory, and frequently curative, effect of the nuclein treatment of these various infections, well measured in all by careful controls, made a deep impression upon my mind. After resuming my regular duties it was not long before I was confronted with the task of treating a severe case of septicemia. In considering the treatment I should pursue, I remembered the striking effects I had observed from the use of yeast nucleinic acid, and determined to try it, in conjunction with other remedies, in the treatment of my patient.

Nuclein is said to be distinctly germicidal, for certain bacteria at least. Whether its germicidal properties, when introduced into the living body, are wholly due to the promotion of leucocytosis, and

¹ Read before the St. Paul (Minn.) Academy of Medicine.

consequent phagocytosis or not, I am at this time unable to say. One thing seems to be certain, and that is that nuclein has no antitoxic properties. This has been demonstrated by Vaughan and McClintock in their series of experiments on rabbits and guinea-pigs with yeast nucleic acid and the toxins of diphtheria and tetanus.¹

The outcome of the case above referred to was most satisfactory, and I was inclined to believe the nuclein was deserving of some credit, and determined, when opportunity offered, to give it further trial. Up to the termination of my fourth case I was not aware that any one else had used yeast nucleic acid in the treatment of septicemia. At this time I wrote to Dr. Vaughan inquiring if he had knowledge of any such application of the remedy, and asking him, if he had, to kindly refer me to the literature of the subject. His reply to my question was: "I am just sending to the publishers an article on nuclein in which is contained the following paragraph concerning its use in septicemia:

"Boise and Hofbauer have reported good results from the treatment of puerperal septicemia with nuclein, the former using my preparation, and the latter that of Horbaczewsky. Hofbauer states: 'Among the clinical symptoms which were observed during the course of treatment, the following may be mentioned:

"'1. *Effect upon the General Condition.*—This was manifested in a very marked and even surprising manner. Patients who previously lay apathetic and half asleep now gave a clear and satisfactory answer when questioned as to their condition. Though the temperature remained above the normal, nevertheless, the improved appearance and the calm expression of countenance offered a decided contrast to what had been previously observed. At the same time the icteric tint of the skin disappeared and the appetite was improved.

"'1. *Influence on the Local Condition.*—The puerperal ulcers soon took on a healthy appearance and healed. The discharges from the septic uterus rapidly lost their odor and purulent character, and lessened in quantity. The first dose increased the temperature, followed by a gradual decrease. The remissions were longer and more pronounced and the exacerbations slighter, until restoration to the normal resulted."

Following are the cases which I wish to report:

CASE I.—Nicola J., Italian, aged thirty-six years, laborer, of healthy appearance and well-nourished, was admitted to the Northern Pacific Hospital,

Brainerd, Minn., at 5.30 P. M., May 31, 1896, for a severe gunshot wound of the arm which had been received twenty-four hours previously. At that time the wound had been cleansed and an antiseptic dressing applied. Our examination showed a large, ragged, and septic wound on the inner aspect of the middle portion of the left arm. Nearly two-thirds of the biceps had been destroyed, about two inches of the brachial artery and vein had been shot away, and the median and ulnar nerves were lacerated. The patient was somewhat exsanguinated and had a rapid and weak pulse, and his general condition was poor. The vitality of the hand and forearm was quite uncertain. Whisky and strychnin were given hypodermically. Under chloroform anesthesia, we tied the vessels, removed all dead and doubtful tissue, also a large quantity of bird shot, drained thoroughly, packed loosely with iodoform gauze, and enveloped the whole limb in a voluminous dressing. His temperature the same evening was 100° F. and pulse 140. The bowels were moved. Stimulants, in the form of strychnin, digitalis, and whisky, were freely given, and milk, egg-nog, and beef tea were taken frequently.

June 1st. Highest temperature, 100.4° F.; pulse, 140; systemic intoxication becoming quite marked. At 8.30 P. M. he was ordered 2 c.cm. of a one-per-cent. nuclein solution (Vaughan's) every fourth hour, hypodermically. Vomited twice during the day. Bowels moved. Administration of stimulants continued. Water and other fluids freely allowed. June 2d. Highest temperature, 100.6° F.; pulse, 120; skin sallow and conjunctivæ stained. Vomited twice. Bowels moved. Wound dressed. Same medication and diet. June 3d. Apparent improvement. Highest temperature, 100.4° F.; pulse, 114 and of improved quality. Face losing its sallow, drawn look. Not so restless. Wound dressed. Bowels moved. Same medication. June 4th. Patient markedly improved. Highest temperature, 100.8° F.; pulse, 108 and of still better quality. Some desire for food. Wound dressed. The use of nuclein discontinued. June 5th. Continued improvement. Highest temperature, 100° F.; pulse, 104.

From this time forward the patient was considered out of danger, but it was not until June 21st that his temperature reached normal and remained there. His pulse ranged between 84 and 100 for some time afterward. The limb was saved, but there was gangrene of the finger-tips. It was greatest on the little finger, destroying it completely as far upward as the last phalanx extended; it did not extend so far on the ring finger, still less on the middle finger, and only involved the skin over a small area of the index finger. This strange condition was doubtless due to the injury sustained by the nerves of the arm. Motor paralysis of these fingers still existed to some extent when the patient was discharged.

CASE II.—Enrico D., Italian, aged twenty years, laborer, of healthy appearance, was admitted at 4 P. M., September 2, 1896. Right leg had been amputated in middle third the day before for car-wheel injury. The whole stump was swollen and boggy.

¹"The Physiological Action and Therapeutic Uses of Yeast Nucleic Acid, with Special Reference to its Employment in Tuberculosis," THE MEDICAL NEWS, February 27, et seq., 1897.

The flaps looked dark and unhealthy, and were distended by blood-clots. All stitches were removed, clots turned out, wound irrigated, packed with iodoform gauze, and an antiseptic dressing applied. Calomel purge. Highest temperature, 100.8° F.; pulse, 96. September 3d. Highest temperature, 101° F.; pulse, 96. Wound dressed. Tissues red and glazed; parts of both flaps looked gangrenous. Patient restless. Saline cathartic. September 4th. Highest temperature, 102° F.; pulse, 94. Patient greatly depressed. Wound dressed twice; dry and glazed; slough black. Serous discharge. Nuclein 20 minims hypodermically, every fourth hour. September 5th. Highest temperature, 102.6° F.; pulse, 90. Wound dressed twice; stump a little less swollen and boggy. General condition slightly improved. Saline cathartic. Nuclein continued. September 6th. Highest temperature, 101.4° F.; pulse, 86. Wound dressed; purulent discharge. Patient more comfortable. Nuclein continued. September 7th. Highest temperature, 103° F.; pulse, 94. Wound dressed; purulent discharge. Nuclein continued. Cathartic given. Patient somewhat more comfortable. September 8th. Highest temperature, 101° F.; pulse, 74.

From this time on the patient did well and made a good recovery, so far as the general systemic results of infection were concerned.

CASE III.—Felix L., French-Canadian, aged twenty-eight years, engine-wiper, strong and well-nourished; good family history; was admitted October 29, 1896, suffering with diseased testicle. He stated that while at work on September 7, 1896, he slipped and fell astride of the hand-rail of a locomotive and injured his right testicle. Had had some medical attention. On examination, the right testicle and cord were found to be greatly enlarged, the former being very dense and hard in its upper portion and soft and fluctuating below, from which there was a sinus discharging thick, cheesy pus, mixed with glandular tissue. Temperature, 99.2° F.; pulse, 80. Urine normal.

On November 2d, the patient having been fully prepared for operation, he was anesthetized with chloroform, followed by ether and, after careful examination, it was decided that castration was indicated, which was done. Every precaution was taken to make the wound aseptic and drainage was provided for in the lower part of the scrotal wound. November 3d. Temperature, 101° F.; pulse, 88. Cathartic given. November 4th. Highest temperature, 103.8° F.; pulse, 100. Patient somewhat restless, but free from pain. Wound dressed; no redness or inflammation, but one or two sutures over inguinal canal removed for better drainage. Bowels active as result of cathartic. November 5th. Patient slept very little during night; is restless, but has no pain; sweating some and seems to be suffering from severe systemic intoxication. Wound dressed and found looking well; considerable serous discharge. Removed all sutures and packed loosely with iodoform gauze. Pilocarpin, hypodermically, and large quantities of water and other fluids were given. Highest temperature, 104.8° F.; pulse, 112. Nuclein, 2

c.cm. of a one-per-cent. solution, hypodermically, every fourth hour, was ordered. November 6th. Highest temperature, 104.8° F.; pulse, 110. Slept very little during previous night. Wound clean, but considerable drainage of serum. Microscopic examination of same was negative. No culture was made. All emunctories kept active. November 7th. Patient a little more comfortable and slept a little more during the night. Wound in good condition. Same medication and treatment. Highest temperature, 104.2° F.; pulse, 100. November 8th. Patient very much the same, except a little more comfortable. Same medication and treatment. Highest temperature, 103.8° F.; pulse, 106. November 9th. Patient passed a fairly comfortable night; general condition greatly improved. His temperature continued to fall all day and by evening was normal, as was the pulse. From this time forward his temperature and pulse never rose above normal, and progress and recovery were uneventful.

CASE IV.—Oscar N., Swede, aged twenty-three years, laborer, well-nourished, was admitted December 7, 1896, for injury of right foot, which had been crushed between a bumper and deadwood two days before. Examination showed injury to four smaller toes, two of which were completely crushed and had to be removed. Plantar surface burst open over ball of foot; lower two-thirds of dorsum badly lacerated and subcutaneous tissues greatly contused. Wound septic and evidence of systemic invasion. Temperature, 102.6° F.; pulse, 100. Wound treated antiseptically. Medication: Calomel, followed by saline; chlorodyn for pain; nuclein, 2 c.cm. of a one-per-cent. solution, every fourth hour, hypodermically. December 8th. Highest temperature, 102.8° F.; pulse, 108. Epistaxis. Wound dressed. Skin gangrenous on dorsal surface of foot to the extent of size of palm of hand. Foot put in continuous warm bath of 1-to-500 carbolic acid solution. Nuclein continued. December 9th. Highest temperature, 102.4° F.; pulse, 98. General condition improved. Nuclein continued. December 10th. Highest temperature, 101° F.; pulse, 100. Epistaxis. Evidence of systemic intoxication less pronounced. Nuclein continued. From this time on there was a daily improvement, and on December 15th the use of the nuclein was discontinued. On this date his temperature reached 100° F., and his pulse 90. The patient made a good recovery.

CASE V.—W. F. F., Welsh, aged twenty-nine years, locomotive fireman, of healthy appearance, was admitted December 27, 1896, for gunshot wound of right forearm, received forty-two hours previously. A 44-caliber ball had entered just above the wrist and shattered the lower end of the ulna into a score or more of pieces and badly fractured the radius at its lower end. A local surgeon had carefully drained and dressed the wound. Soon after admission the wound was examined. The discharge was inclined to be purulent, and the hand and forearm were swollen. Every effort was made to render the wound aseptic. It was drained and loosely packed with iodoform gauze and dressings applied. Cathartic

and light diet ordered. Evening temperature, 98.4° F.; pulse, 84. December 28th. Wound dressed and condition about the same. Evening temperature, 98.8° F.; pulse, 90. December 29th. Wound condition same as day before. Evening temperature, 98.8° F.; pulse, 90. December 30th. Wound dressed; swelling almost gone, but discharge still doubtful. Temperature, 99° F.; pulse 80. December 31st. Wound dressed; not looking well. Highest temperature, 102° F.; pulse, 94. January 1st. Patient had a bad night; wound found very unsatisfactory. Chloroform was administered and wound freely opened. All necrotic tissue was removed. Thorough irrigation with bichlorid and pyrozone. Sterile iodoform was well rubbed in and the wound loosely packed with iodoform gauze and voluminous dressing applied. Highest temperature 103° F.; pulse, 104. Nuclein, 2 c.cm. of a one-per-cent. solution given hypodermically every third hour. Urinalysis yielded negative results. January 2d. Patient fairly comfortable. Very free catharsis. Highest temperature 102° F.; pulse, 90. January 3d. Highest temperature; 101.8° F.; pulse, 100. January 4th. Temperature, 102.2° F.; pulse, 96. January 5th. Highest temperature, 102.6° F.; pulse, 96. Saline cathartic ordered. January 6th. Highest temperature, 102.6° F.; pulse, 100. Blood count gave 10,125 white corpuscles to the c.mm. Nuclein every fourth instead of every third hour. January 7th. Highest temperature, 101.8° F.; pulse, 96. Wound dressed; seropurulent discharge. Forearm and hand somewhat swollen. Appetite poor and some nausea. Cathartic, which was effective. January 8th. Hand and forearm swollen more than day before. Counter opening made on back of hand for evacuation of pus accumulation. Profuse perspiration. Progressive emaciation apparent. Highest temperature, 102.2° F.; pulse, 100. Ordered 10 minims of a five-per-cent. nuclein solution every fourth hour, instead of a one-per-cent. solution. January 9th. Wound dressed twice, dressings being wet with solution of potassium permanganate. Large amount of purulent discharge. Swelling increasing and extending above elbow. Profuse perspiration. Skin sallow. Bowels active from salines. Highest temperature, 104.4° F.; pulse, 120. January 10th. Wound dressed twice. Profuse purulent discharge. Whole limb greatly swollen. Red lines in skin, indicating lymphangitis. Hand and arm placed in 1-to-500 carbolic bath at a temperature of 100° F. Patient vomited. Profuse perspiration. Sallowiness of skin well-marked. Highest temperature, 103.4° F.; pulse, 112. Symptoms of osteomyelitis constantly increasing. Whisky, strychnin, and digitalis, which had been given during previous three days, ordered increased.

January 11th. The degree of systemic poisoning was so great, and the osteomyelitis so well marked, that it was decided that amputation should be performed at once. This was done at about the middle of the forearm. The periosteum was swollen and softened and stripped from the bones in retracting the muscles; the medulla of the ulna was dis-

eased quite up to the point of section. In the radius the internal conditions were more favorable. No sutures were used in the flaps, which were packed with iodoform gauze. No marked shock from anesthetic (chloroform followed by ether) or operation. January 12th. Patient slept fairly during preceding night and was quite comfortable. Highest temperature, 101.8° F.; pulse, 100. Wound not disturbed. January 13th. Patient doing well. Wound dressed; free drainage. Highest temperature, 100.2° F.; pulse, 96. January 14th. Patient doing finely. Wound not dressed. Some appetite. Bowels moved by cathartic. Highest temperature, 100.4° F.; pulse, 88. Nuclein discontinued. From this time forward patient did well. February 1st. Blood count showed white corpuscles 6333 to the c.mm. Patient going about out of doors and general condition is excellent, but stump has not closed on account of a limited necrosis of ends of both bones.

CASE VI.—The following history was furnished by Dr. T. N. McLean of Fergus Falls, Minn.: Merrian A., aged six years, a well-nourished, healthy-looking child of good family history. Was called to see him December 23, 1896, at 11.30 A.M. Found both feet badly crushed and lacerated from freight cars having passed over them. The tissues of the left leg were lacerated and torn half way up to the knee. Fracture of bones of foot but not of leg. Some of the bones of the right foot were fractured. Patient was chloroformed, loose pieces of bone removed, wound thoroughly cleansed with bichlorid solution, sutured, and dressed with iodoform and iodoform gauze. At 4 P.M. the patient was very weak. Temperature, 98° F.; pulse, 150. Extremities cold and bathed in cold sweat. Gave strychnin, $\frac{1}{80}$ gr., and brandy, hypodermically, every third hour. Gave normal saline solution per rectum. December 24th., A. M., patient very restless all night; very delirious; picked bed-clothes constantly; had not rallied from shock. Temperature, 98° F.; pulse, 150. Extremities cold. No vomiting. Eleven P.M. Temperature, 102° F.; pulse, 150. Very restless and delirious. Bowels moved by enema. Would not take nourishment. December 25th. Temperature 103° F.; pulse, 150. Very restless all night; profuse sweating; delirious all the time; would not take nourishment. Removed dressings and reapplied fresh ones. December 26th. Temperature 103.4° F.; pulse, 150. Very restless; marked subsultus; delirious all the time. Took about four ounces of milk during previous twenty-four hours. Moved bowels by enema. Gave purgative. December 27th. Condition same as yesterday. Dressed wounds; found right foot looking fairly well. Left leg looked erysipelatous on inner aspect all the way up to the knee. Outer surface over crushed area was gangrenous. Dressed both limbs with hot bichlorid solution, 1 to 4000, and covered with oiled silk. Six P.M. Temperature, 104° F.; pulse, 150. Reapplied hot bichlorid dressings.

December 28th, 10.30 A.M., Dr. Courtney in consultation. We found patient with a temperature of 103° F., and pulse of 156. Skin yellow and perspiring. There had been diarrhea all of the pre-

vious night. Examination of the wounds showed the left foot and leg to be gangrenous almost halfway to the knee; right foot gangrenous almost to ankle; tissues emphysematous and infiltrated with pus. Dr. Courtney amputated both legs, the left one at the middle of middle third, the right at junction of lower and middle thirds. The vessels were tied, flaps packed with iodoform gauze (no sutures), and voluminous dressings applied. Strychnin $\frac{1}{10}$ of a grain, brandy 1 ounce, and 10 minims of a one-per-cent solution of nuclein given every third hour, hypodermically. Morphin, $\frac{1}{8}$ of a grain, was given whenever necessary.

6 P.M. Patient resting well. Temperature, 101° F.; pulse, 140. December 29th. Temperature 100° F.; pulse, 140. Patient quite rational; taking some nourishment; no subsultus. Slept fairly well. December 30th. Temperature, 100° F.; pulse, 130. No pain, no delirium, no subsultus. Dressed wounds; found them perfectly healthy; very little discharge and no pus. December 31st. Temperature, 99.5° F.; pulse, 130. Had a good night and no pain. Patient took nourishment fairly well. January 1st. Temperature, 99.5° F.; pulse, 130. Dressed wounds and found them quite clean. Stitched right stump. January 7th. Temperature, 98.4° F.; pulse, 120. Right stump practically healed. Stitched left stump. Stopped nuclein solution; continued small doses of strychnin. Appetite good. Bowels regular. January 25th. Temperature, 98.4° F.; pulse, 100. Right stump entirely healed one week ago; left stump practically healed. Patient is gaining in flesh every day. Crawls all over the house.

CASE VII.—E. L. E., American, aged twenty-eight years, laborer, a very strong and healthy man, was admitted February 5, 1897, for severe crushing injury of right hand and wrist; no bones broken. Injury had been received thirty hours previously by having had the hand caught between cars. Soon after injury, hand had been cleansed, drainage introduced, and moist dressing applied to reduce swelling. After admission, temperature was found to be 100.8° F., and pulse 96. The hand was thoroughly cleansed and the wounds irrigated, drained, and dressed antiseptically. Saline cathartic given and free catharsis resulted. February 6th. Patient fairly comfortable; wound dressed. Evening temperature, 99.4° F.; pulse, 80. February 7th. Patient not nearly so well; more swelling in hand and arm; vomited twice. Hand was put in warm bath of 1-to-500 carbolic acid solution. Evening temperature, 103.4° F.; pulse, 120. Yeast nucleinic acid, five-per-cent. solution, was given in 10-minim doses, hypodermically, every third hour. Strychnin, gr. $\frac{3}{12}$ every fourth hour. Calomel, followed by saline purge. February 8th, A.M. Temperature, 101.8° F.; pulse, 110. Hand very painful; swelling extended almost to elbow. Hand taken out of bath and put in dry dressing for few hours. Bowels moved twice. Skin and conjunctivæ but little stained. Nuclein continued. Morphin for relief of pain. Strychnin, whisky, and digitalis, every fourth hour. Evening temperature, 102.8° F.; pulse, 104.

February 9th. Patient grew rapidly worse during the night; became delirious, and temperature went up to 104° F., and pulse to 140. Stimulants were increased. Enteroclysis of normal salt solution at 100° F. Later, intravenous injection of normal salt solution also. Profuse perspiration and severe rigors. All efforts failed to beget improvement. Patient became semi-unconscious and died at 9 P.M., a little more than four days after admission, and a little more than five days after being injured. The arm was never swollen above the elbow, and no pus appeared in the tissues or wounds. No autopsy was obtainable.

CASE VIII.—Allen C., aged eighteen, American, laborer, admitted February 26, 1897, with croupous pneumonia of lower lobe of left lung, from which he had been suffering during three weeks. Evening temperature, 100.4° F.; pulse, 96; respiration, 34. Patient was emaciated and much exhausted. Careful attention directed to the emunctories; stimulants and easily digestible and nourishing food ordered. For about a week there was no improvement. The pulse became somewhat slower but was very irregular, doubtless caused by a greatly dilated stomach. The intestines also were greatly distended with gas, causing very severe colic. After this, for four or five days, the general condition was considerably improved; the temperature was but little above normal, the pulse ranged between 80 and 100, and the respiration between 20 and 28.

About March 9th the patient's condition again became worse. Evening temperature, 102° F.; pulse, 112. Well-marked symptoms of septicæmia present. Stomach irritable; some vomiting. Skin presented a dull and icteric appearance. Nuclein, in $\frac{1}{2}$ -dram doses, of a five-per-cent. solution, by mouth, every third hour, added to other treatment. March 10th. Left pleural cavity aspirated and pus found. March 11th. Resected seventh rib, external to axillary line, and evacuated quite a quantity of pus and coagulated fibrin. March 12th. Temperature normal, pulse, 98. Free perspiration and great prostration. Examination of pus from the pleural cavity showed the presence of the micrococcus pneumoniae crouposæ in abundance. Nuclein discontinued two days later.

For more than a week following, the condition of the patient was extremely critical, then improvement began and was rapid. On April 8th the patient was about the house, and only a small sinus at the site of operation remained, from which there was scarcely any discharge.

CASE IX.—John P., Italian, aged twenty years, laborer, admitted March 17, 1897, three days after injury. Compound fracture of left leg at junction of middle and lower thirds. The leg had been very severely injured between cars. There was a large open wound over and down to the tibia (which alone was fractured) and the tissues were torn and lacerated, mostly subcutaneously, from the malleolus half way to the knee on the outer side of the leg. In addition to these, there were other open wounds of the skin. The ends of the bone had been trimmed

off and placed in good position and an antiseptic dressing applied by the local surgeon. Evening temperature on the day of admission, 100.2° F.; pulse, 130. Patient was plainly suffering from general systemic poisoning. Leg dressed; hematoma evacuated and a voluminous aseptic dressing applied. Cathartic given. Strychnin gr., $\frac{3}{12}$, and 15 minims of a five-per-cent. yeast nucleinic acid solution, given hypodermically every fourth hour. March 18th. Patient very restless and general condition very poor. Wound dressed; very free discharge of serum. Enteroclysis of normal salt solution. Nuclein increased to twenty minims every fourth hour; water given freely and emunctories kept active. Evening temperature, 100.8° F.; pulse, 136. March 19th. Patient more comfortable. Wound dressed; free serous discharge. Vomited once during the day; bowels moved several times. Temperature, 100° F.; pulse, 110. March 20th. Patient passed a comfortable night and was considerably improved. Wound dressed; less discharge. Temperature, 100.8° F.; pulse, 108. March 21st. Patient still improving; appetite returning; wound looking well. Temperature, 100.4° F.; pulse, 102. Nuclein discontinued. From this time on the patient improved very rapidly, and on March 31st his temperature reached normal and his pulse, 70. With the improvement in the general condition the wounds began to heal rapidly and have continued doing so ever since.

CASE X.—V. H. E., American, aged thirty-seven years, bridge foreman, admitted March 26, 1897. While working on a railroad bridge, thirty-one hours previously, the patient fell twenty feet, on to ice and stones, and received a fracture of the tarsal bones of the right foot. There was severe contusion of the foot and lower half of leg, with laceration of the skin and subcutaneous tissues over the outer malleolus as well. There was also some slight contusion of the right chest, but no fractured ribs. Temperature, 101° F.; pulse, 78. Wound was dressed and foot elevated. Cathartic administered. Nuclein was given in 15-minim doses, hypodermically, every fourth hour, and light diet ordered. March 27. Patient feeling quite ill. Bowels moved. Same medication. Temperature, 101.8° F.; pulse, 84. March 28th. Patient about the same. Had some bronchitis, with considerable cough. Temperature, 102.6° F.; pulse, 88. Leg greatly swollen and painful, but no evidence of suppuration. As we were more strongly impressed than before that sepsis was present, the nuclein was continued, hypodermically. No local reaction from its use. Calomel purge. March 29th. Bowels moved. Condition of foot and leg the same. Annoying cough, but no evidence of pneumonia could be found. Temperature, 102° F.; pulse, 96. March 30th. Wound dressed; local condition unchanged; no suppuration. Temperature, 101.8° F.; pulse, 80. Same medication. The patient remained about the same, with an evening temperature of about 102° F., and pulse of 80, until April 5th. At this time both began to improve and within two days were normal. The

swelling disappeared from the foot and leg, and a plaster cast was applied. There was no suppuration at any time. At the present time, April 10th, the patient has a very good appetite and is about the house.

In addition to these cases, I know personally of two others which were successfully treated with nuclein, but I am not in possession of such clinical notes as will enable me to write them up in detail at this time. Both of them occurred in the practice of my late assistant, Dr. S. M. Kirkwood, now of St. Paul. They were very severe and exceedingly dangerous cases, and, for a time, both lives were despaired of. In one, the infection was introduced through face and mouth wounds, and the local lymph-glands were greatly indurated and enlarged. In the other, infection occurred through the avenue of a lacerated wound of the little finger. There was suppurative tenosynovitis, and the hand and forearm had literally to be riddled with drainage openings. The arm, as well as the patient's life, was saved.

The recital of these cases has been lengthy, and perhaps tedious, but to fully weigh and value the results of a new treatment all the principal facts ought to be worthy of consideration. From the histories given there can be no question as to their severity and seriousness, and the imputation of simple surgical fever to any would not be consistent with their clinical manifestations. To say that some may have been cases of sapremia would simply be begging the question, in view of the definition with which this paper was begun. But, in order to avoid argument with the pathologists, we may justly claim that sapremia may be fatally serious.

Passing some of these cases in review, it will be seen that Case VIII. (empyema), on superficial inspection apparently differs rather widely from the others and may seem out of place among them, and, in consequence, that the application of the nuclein treatment might appear rather unwarranted. In answer, I may say we know quite well that the micrococcus pneumoniae crouposa is quite frequently found in other localities than the chest, and in connection with inflammation and suppuration of tissues and other organs elsewhere. It may induce septicemia. Flexner, in his excellent paper on "The Study of Terminal Infections," says, in considering the general infections: "Not infrequently a local lesion, such as erysipelas, acute peritonitis, or acute endocarditis, exists which antedates the general invasion of the body by the infectious agent."¹ In Case VII., which resulted fatally, administration of the yeast nucleinic acid was not begun as early as it should have

¹ "Transactions of the Association of American Physicians," 1896.

been. During the first two days after admission, it was thought the symptoms were due to irritation from the painful contusion and laceration of the hand rather than to serious microbic infection. After this the disease seemed wholly irresistible. That I permitted the proper time to pass before resorting to the use of a remedy, which by this time had gained a place in my confidence, is a matter of deep regret to me.

Among the striking results of the treatment in this list of cases I might mention, first, the promptness with which the general health was restored after convalescence had begun, and, second, the readiness with which the injured tissues, which had furnished the infection atrium, healed, this being very noticeable in all except in Case II. In this case the general health improved very rapidly, but the tissues of the stump remained for a long time sodden and very indolent. These results are in decided contrast to my previous experience in the treatment of septicemia, that is, before using the yeast nucleinic acid. Then convalescence in a great many of the patients who recovered was slow; the pulse would long remain rapid and weak, the skin sallow and dull, and the nervous system considerably shaken. The treatment of the local condition, too, where injury and infection occurred, would often tax one's patience and ingenuity to the utmost.

In regard to the auxiliary treatment of these cases, I presume there will not be wanting those who will ask if this alone would not have accomplished the results obtained. I must in honesty admit that it might possibly have done so. On the other hand, with equal candor, I am compelled to say that no other form of treatment previously employed by me ever yielded, in anything like the same number of cases, such satisfactory results. It is true, of course, that the number of cases treated with yeast nucleinic acid is not convincingly large; still, I am encouraged to persevere with it, and with a considerable feeling of confidence.

In my opinion the most valuable forms of auxiliary treatment are those which will effect free elimination by all of the emunctories that may be pressed into service, so as to rid the system of all the toxins possible. This is important because it not only acts on the direct source of danger (the toxins), but often obviates or mitigates another ever-present danger, *viz.*, auto-intoxication. After this I would place the free but judicious use of stimulants, among the best of which are strychnin and whisky. The proper administration of food will at all times receive attention at the hands of the careful clinician.

As regards the use of yeast nucleinic acid in septicemia, there are several points to which I wish to invite attention:

1. It should be given at the earliest possible moment that septic infection is suspected. One should not wait for the typical and classic symptoms as given by text-books. My observations have taught me to believe that if one waits until rigors, icterus, diarrhea, delirium or apathy, profuse perspiration and a foul-smelling and discharging wound are added to an abnormal increase in temperature and pulse-rate and a restless alertness on the part of the patient, to convince him that it is septicemia that must be dealt with, instead of surgical fever or something else, he has been guilty of a serious waste of most valuable time.

2. The nuclein should always, in septicemia at least, be given hypodermically, if possible, in order to secure prompt action of the given dose. If the one-per-cent. solution is used, at least 30 to 40 minims, undiluted, may be given every three or four hours. If the five-per-cent. solution should be used, from 10 to 15 minims may be given every three or four hours, but ought to be diluted with distilled or at least with sterile water. This is necessary to avoid the local reaction which is sometimes caused when this solution is given undiluted. In my experience, the five-per-cent. solution is preferable, for one reason at least; it is always stable. The one-per-cent. solution is not stable; it sometimes becomes cloudy and unfit for use, even before the bottle containing it is opened.

If it be true, as Wells states,¹ that leucocytosis is to be regarded as a local condition, then injection of the nuclein ought to be, in the early stage, as near to the place of primary infection as possible. I have invariably made the injections into the cellular tissue and muscles of the chest.

3. The injection region should be examined daily in order to determine if local reaction can have anything to do with the patient's increased temperature and pulse-rate. If it has, it is due to one of two things: either to insufficient dilution of the 5-per-cent. nuclein solution, or to imperfect preparation of the skin or syringe.

I wish I could have added the results of thorough laboratory study to each of these most interesting cases, but neither my time nor that of my assistants was available for prolonged work of this kind. Though it is probable that before long the exact status of the remedy, and the *rationale* of its action will be satisfactorily explained. The following simple conclusion is the only one I shall offer at the present time: The results of my work with yeast nucleinic acid in septicemia are sufficiently encouraging to justify a feeling of confidence and a continuance of its use.

CLINICAL MEMORANDUM.

REPORT OF A CASE OF INTRADURAL SPINAL TUMOR EXTENDING THROUGH THE FORAMEN MAGNUM, COMPRESSING THE EXTREME UPPER PORTION OF THE CORD, AND ALMOST COMPLETELY DESTROYING IT AT THE THIRD CERVICAL SEGMENT.¹

By J. T. ESKRIDGE, M.D.,
OF DENVER, COL.;

NEUROLOGIST TO ST. LUKE'S HOSPITAL; PRESIDENT OF THE STATE BOARD OF COMMISSIONERS FOR THE INSANE ASYLUM.

I WISH to express my indebtedness to Dr. Francis McNaught for the privilege of seeing and studying the following interesting case:

G. B. G., male, single, aged fifty-two years, white, born in New York State, a bridge-builder and miner by occupation, was first seen by me in consultation with Dr. McNaught in St. Luke's Hospital, March 2, 1897. His family history was negative, so far as I was able to learn. The patient had suffered from the usual diseases of childhood, from typhoid fever at his seventh year, and from malarial (intermittent) fever for seven months each year, from 1872 to 1879. He had possessed a strong constitution, had worked very hard, lived irregularly, exposed himself a great deal to inclement weather, and at times drank to excess. About twenty years ago he contracted syphilis, but did not suffer from any of the secondary symptoms of this disease. He had suffered from gonorrhea twice. Seven years ago he was "lead" while working in an ore-sampling room. The lead poison developed suddenly, and he was delirious for some time. The blue line was found on the gums, but he did not suffer from colic or constipation.

He enjoyed very good health from 1890 till May, 1896, when his present trouble was first apparent to him. The first thing to attract his attention was his inability to strike a drill firmly and with his accustomed precision. Loss of power and dexterity in his hands and arms gradually became more marked, until, at the end of a month or two from the time when his attention was first attracted to his trouble, he had to change the character of his work. About the time that power was first impaired in his arms and hands he noticed a numb, cold, and full sensation in these parts, beginning first in the hands. At times he suffered from excruciating pains in the shoulders and arms. Soon the legs became affected similarly to the arms, but the right leg was more helpless than the left. He did not remember the order in which the sensory and motor symptoms developed in the arms and legs. Whether early in the disease sensation was more affected on one side and motion on the other, he could not definitely recall. From June to October he was taken from place to place and treated by several physicians for syphilis. When the legs became almost completely paralyzed, which was

some time in September, 1896, he lost all voluntary control of the sphincters of the bladder and bowel. His urine had to be drawn, but he did not soil his clothes if the bladder was regularly emptied by means of a catheter.

In October, 1896, he came to Denver and entered St. Joseph's Hospital. He remained there until February 19, 1897. During this time he was not critically examined by any one, but was treated for syphilis. Dr. Devlin, who saw him a number of times, tells me that his left leg and arm were more helpless than the right, but that sensory disturbance was greater on the right side than on the left.

I made a careful examination of his condition on March 2, 1897. I found him lying in bed, completely helpless. He had to be fed, but could sit for hours at a time if supported in a reclining chair. He had lost all control of the sphincters of the bladder and bowel and was greatly emaciated. He complained of great pain in the region of the bladder. He suffered from pain in the limbs and from spasmodic contraction of the muscles of the arms and legs. The pains started in the shoulders and ran down to his hands, and in the hips and extended downward to the feet. During the attacks of muscular contraction the hands and arms were frequently in forced extension, and the legs, at the hips and knees, in extreme flexion; at other times the legs were rigidly and painfully extended, with well-marked plantar flexion of the feet. The pain and muscular contraction would continue until relieved by a hypodermic injection of morphin, and would return as soon as the influence of the sedative had worn off.

The shoulder, arm, and hand-muscles were completely paralyzed and greatly atrophied. He could slightly flex and extend the legs at the knees and hips. All power of motion was lost at the ankles. The muscles of the legs were not greatly wasted. The neck muscles were very weak. He could rotate the head slightly, but could scarcely raise his head from the pillow. The posterior cervical muscles were a little stronger, so that he had little difficulty in holding his head erect if he were held in a sitting posture. The trunk muscles were almost completely paralyzed. The tongue was protruded in the median line; he could open and shut his mouth with considerable force, and none of the facial or ocular muscles were affected. The knee-jerks were both decidedly increased. All the other deep reflexes, including those of the arms, were absent. All the superficial reflexes were abolished.

Tactile Sense.—Anesthesia to a camel-hair pencil in motion was absent anteriorly from the lower border of the inferior maxillary bone downward; laterally from the lower border of the mastoid bones downward, and posteriorly from the fourth cervical spine downward. There was an area on the posterior surface of the neck, extending about two inches laterally from the spinous processes on either side from the fourth cervical spine upward to the scalp, over which the simple contact of a feather or a camel-hair pencil could readily be felt. Sensation over the entire scalp, face, and ears was normal.

Pain Sensation.—This was present, although perverted and delayed throughout the trunk and legs. It was less acute than normal, and greatly delayed in the legs, fairly

¹ Read by title before the Section on Neurology and Medical Jurisprudence, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1, 2, 3, and 4, 1897.

acute over the trunk, external genitalia, hips, and around the anal region. The increased time required to recognize the prick of a sharp point over these areas was well pronounced. Over the hands, arms, and shoulders it was nearly abolished. Over the extreme upper portion of the chest and over the anterior and lateral aspects of the neck it was very acute, but delayed. In those regions in which tactile sense was normal, the face, scalp, and posterior upper portion of the neck, pain-sensation was normal.

Temperature Sensation.—Cold substances, such as

stances were recognized as such. Over the hands, cold substances gave rise to a sensation of burning pain. Over the arms and shoulders the contact of these was not felt.

Heat.—Anteriorly, a bottle containing water at a temperature of 140° F. gave rise to no sensation until the lower border of the inferior maxillary bone was reached. Posteriorly, heat sensation from the fourth cervical spine downward was lost. Cool substances at a temperature of about 90° F., and warm ones at a temperature of 100° F., gave rise to no sensation in any portion of the body or limbs over which tactile sense was absent. (See

FIG. 1.

Horizontal lines denote loss of tactile and temperature sense. Vertical lines denote partial loss of pain and sensation.

bottles containing water at about the temperature of 60° F., gave rise to a burning sensation in the feet, to no sensation over the legs and external genitalia, to a decided sensation of pain over the abdomen and lower portion of the chest, to almost no sensation over the middle third of the chest, and to a sensation of warmth in the upper third of the chest. Over the neck anteriorly, from the clavicle to the lower border of the inferior maxillary bone, cold substances gave rise sometimes to a sensation of cold, and at other times to a sensation of heat. Posteriorly, over the upper portion of the neck, cold sub-

stances were recognized as such. Over the hands, cold substances gave rise to a sensation of burning pain. Over the arms and shoulders the contact of these was not felt.

Eyes.—Vision, fields, discs, and fundi were normal. Smell and taste were present and equal on the two sides.

Hearing.—Watch: R., $\frac{1}{12}$; L., $\frac{1}{12}$. He thought that he heard the tuning-fork better with the right ear. He had been partially deaf in the left ear for a number of years.

In the legs and abdomen he had a full, dead, and painful sensation. In the chest, up to the clavicle, there was

a drawing or constricted feeling. The skin over the neck anteriorly appeared to him as though it were covered over with collodion, and deeper in there was a sensation of pressure. The arms felt as though they weighed a ton, and were the seat of almost constant pain. The spine was not tender to pressure except in the upper cervical region. Forced movements of the arms or of the head from side to side or forward gave rise to pain in the upper cervical region. Carrying the head backward did not cause him pain. The electric reactions of the muscles of the arms and neck were not tested, on account of his feeble condition and the constant pain from which he suffered.

The bodily temperature was usually about normal or a little below. The pulse varied from 70 to 100. Respiration was entirely diaphragmatic, a little rapid, but no symptoms of dyspnea were observed unless he attempted to talk. In speaking, he had to stop after uttering two or three words and take a long, deep inspiration, during the effort at which his head would involuntarily be completely raised from the pillow.

Diagnosis.—The history that the patient gave of the development of his symptoms served to confuse rather than to enlighten one in the investigation of the case. He stated that the right leg was more affected than the left. Dr. Devlin, on the other hand, is confident that when he saw him in October, 1896, his right leg was much stronger than the left. At the time of my examination, March 2, 1897, a short time before his death, all symptoms were bilateral, and consisted in abolition of nearly all the functions of the entire spinal cord, and in great impairment of those intimately concerned in respiration. The diagnosis lay between myelitis, tumor of the cord, syringomyelia, cervical pachymeningitis, and pressure myelitis, the compression being due to caries of the spine or from tumor arising from the bones or membranes.

Myelitis, focal in character, could not be excluded from the history alone, as this was so indefinite and some portions of it were so conflicting. A chronic myelitis, involving the upper cervical region of the cord and destroying tactile sensation as high as the second cervical nerve, with almost complete paralysis of nearly all the voluntary muscles innervated by the spinal nerves, and attended by marked wasting in the muscles of the hands, is incompatible with life, as the phrenic nerves would be seriously affected.

Tumor of the Cord in the upper cervical region sufficiently large to produce bilateral symptoms as grave as those existing in this case, like myelitis, would rapidly result in death.

Syringomyelia might, and sometimes does, give rise to most of the symptoms found in the case under discussion. The muscular wasting of the arms and hands, the disturbance in sensation as high as the lower border of the inferior maxillary bone, the paralysis and the increased knee-jerks might be produced by syringomyelia. In syringomyelia the pain is rarely as severe as it was in this case, and is much less influenced, if influenced at all, by movements of the limbs or by changing the positions of the body. In this patient's case the pain was so great,

especially in the arms, as to require repeated injections of morphin to make life tolerable, and movements of the arms or head, thus putting the neck muscles on the stretch, as when turning the patient in bed, could not be made without giving rise to great suffering. In addition to the severity of the pain and the manner in which it was increased, the most important evidence against the existence of syringomyelia was the way in which sensation was affected. Tactile sense was abolished throughout the area of the distribution of the spinal nerves, except over a small surface on the back of the neck above the fourth cervical spine, over the posterior portion of the scalp, and over a small area of the face. Pain sensation, although delayed, was present throughout the entire surface of the body except over the hands and arms. In syringomyelia, pain and temperature sensations are abolished to a greater or less extent, and tactile sense is preserved, often to nearly a normal degree.

Cervical Pachymeningitis.—The character of the initial symptoms, loss of power, incoordination, numb and dead sensations in the hands and arms, without much pain, is decidedly different from that of cervical pachymeningitis, in which pain is the most prominent symptom for some time. Paralysis is not an early symptom in meningitis, neither does it become absolute until just before death. Besides, a pachymeningitis causing anesthesia throughout the distribution of all the spinal nerves would be incompatible with life.

Pressure Myelitis from some cause seemed to be the only lesion that would account for the symptoms. Was the pressure due to caries or tumor of the vertebræ, or to tumor of the membranes?

Caries of the Cervical Vertebræ, with deformity and pressure upon the cord, may cause sensory and motor paralysis, but under such circumstances there will be spinal tenderness, rigidity of the neck muscles, and deformity of the spine. Muscular rigidity was present in the case under discussion, but there was no spinal tenderness, and all deformity was absent; in fact, one of the most common symptoms of caries of the cervical spines—thickening of the tissues over the spine—was absent.

Tumor of the Cervical Vertebræ is attended by great pain on movement of the head, and all the symptoms of caries of the bones would be present in an aggravated form, especially the spinal tenderness. After a careful study of the history of the case, so far as it could be obtained, together with an analysis of the symptoms, I felt confident in excluding all lesions except tumor of the membranes, especially of the dura.

Tumor of the Membranes usually gives rise to motor symptoms on the side on which the tumor is located, and to sensory symptoms on the opposite side of the body; but in those cases in which the growth is situated high up in the cervical region, especially if the structures found in the foramen magnum are encroached upon, bilateral motor and sensory symptoms might result from the direct pressure of the tumor upon the cord and by displacement of the cord to the opposite side against the foramen magnum. A tumor located anteriorly or posteriorly to the spinal nerve-roots as they emerge from the cord might

give rise to bilateral sensory and motor symptoms without completely destroying the function of the upper cervical spinal nerve-roots. If, on the other hand, the growth should be situated on one lateral aspect of the cord, so as to directly involve the spinal nerve-roots on that side, bilateral symptoms would result in the cord below the site of the tumor on account of the direct pressure of the tumor against the cord and the displacement of the cord to the opposite side against the foramen magnum, but nerve-root symptoms on a level with the tumor would be more extensive on the side corresponding to that on which the tumor is located. As this difference of spinal nerve-root symptoms between the two sides was absent in this case, the tumor was thought to be situated anteriorly or posteriorly to the spinal nerve-roots.

Could all the symptoms present in this case be accounted for by the presence of a growth in the upper cervical region in the vicinity of the foramen magnum? Neither severe spinal tenderness nor deformity would result from a tumor in this situation, but muscular rigidity, paralysis, and loss of sensation would be likely to occur. These phenomena correspond with the symptoms found in the case here reported.

Location of the Tumor.—This patient had nearly normal sensation throughout the distribution of the cutaneous branches of the great and small occipital nerves and the great auricular branches of the cervical plexus. Tactile sense over the upper posterior portion of the neck, over the posterior portion of the scalp as far forward as the vertex, over the posterior surfaces of the pinnae of the ears, and over the face just in front of and below the ears, is supplied by the first, second, and third cervical nerves. The lateral and anterior surfaces of the neck derive their cutaneous nerve-supply from the superficial branches of the cervical plexus, which is composed of nerve-filaments from the second and third cervical nerves. It will be observed that the function of the first cervical nerve was nearly intact, but that of the second and third cervical nerves was destroyed, so far as the superficial cervical filaments were concerned. Over the upper posterior portion of the neck and over the scalp both sensory and motor function were preserved to a fair degree. The muscles of the ears supplied by the upper cervical nerves moved freely. It was evident that the tumor was connected with the membranes, probably the dura, and was situated sufficiently high in the spinal canal to cause bilateral symptoms by displacement of the cord against the sharp edges of the foramen magnum. That it extended through the foramen magnum could not be determined.

Dr. McNaught accepted my diagnosis, and said that he would operate if I urged it, but he thought the man was too weak to undergo a severe operation. To this I entirely agreed, as the chances were that the patient would die on the table during the operation. He was extremely weak, greatly emaciated, took but little food, and had to be kept under the influence of morphin most of the time. He gradually sank, and died on April 1st—about four weeks after the examination.

Sectio Cadaveris, four hours after death. We were limited by the friends in our *post-mortem* examination to

the spinal column and the cord and its membranes. No tumor, caries, or displacement of the bones was found. On exposing the dura from the sacral region to the foramen magnum, its external surface appeared normal, but at its extreme upper portion, at the foramen magnum, and extending an inch or more below, it was greatly distended. On opening the dura throughout its entire exposed posterior surface, a growth as seen in Fig. 2 was exposed.

The tumor was lobulated in character, seemed quite firm, lay on the right posterolateral surface of the cord, and was attached to the inner surface of the dura over an area about one-fourth of an inch in diameter. It extended from the fourth cervical nerve-root through the foramen magnum just into the cavity of the cranium. In size it was $1\frac{3}{4}$ inches in length by three-quarters of an inch in its greatest diameter, which was found to be just below the

FIG. 2.

Showing the tumor and cord *in situ* after removal of the laminae, spinous processes, and posterior surface of the dura.

foramen magnum. The end of the tumor that extended into the cranial cavity was rather small and conical in shape. The membranes of the cord seemed to be normal except at the point of attachment of the growth, where the inner surface of the dura was a little thickened. The medulla was cut across just above the tumor, which was a little below the calamus scriptorius, and the cord was carefully removed from the canal. It was found that the cord had two indentations, one on the side of the growth extending from the fourth cervical nerve-root to the second, with the greatest depression opposite the third cervical nerve-root, the other on the left side, and a little more anteriorly than that of the right side.¹ The depression on the left side of the cord was caused by the displacement of the cord against the foramen magnum. The displacement of the cord was upward and to the left, so that the great indentation was on a level with that of the right

¹ The nerve-roots had not been directly pressed upon by the tumor or edge of the foramen magnum.

side, or at a point corresponding to the third cervical nerve. On marking the cord into sections about three-quarters of an inch in length, by incompletely cutting across its substance, the upper cervical portion seemed narrow and softened.

The cord and tumor were placed in Müller's fluid, and the fluid changed twice each day for four days. At the end of this time the specimens were put in a five-per-cent. solution of formalin and kept thus for three weeks. The microscopic examination of the specimens was made by Dr. E. R. Axtell, pathologist to the Hospital, and is as follows:

Sections were made of the tumor and of the spinal cord at the level of the first, second, third, and fourth cervical segments; at the mid-dorsal region, and across the lumbar and sacral regions. The tumor sections were stained in alum-carmin and in hematoxylin; the cord sections by Weigert's method.

Examination of the tumor sections shows the mass to be a spindle-celled sarcoma. The cells are arranged largely in rotating groups, and in several parts hyalin masses are seen similar in all respects to those found in psammomata. The tumor has almost no capsule and contains but very little delicate embryonic stroma. The blood-vessels, while not numerous, are fairly well developed, being more than simple embryonic vessels.

The microscopic examination of the first cervical segment shows the right half to be preserved, with the exception of some disintegration posterior to the gray commissure, while the left half is so softened and disintegrated that sections cannot be made, except through the left posterior and left anterior columns. The left posterior gray cornu is seen passing through the disintegrated area. The brunt of the inflammatory process seems to have been posteriorly and to the left. All of the tissues remaining here present evidences of inflammation with degeneration, increased interstitial tissue, destroyed nerve-fibers, thickened blood-vessel walls, and granular debris. The right half of this segment also presents evidences of inflammation, but to a less degree than the left side.

The entire left side of the second cervical segment is disintegrated except the left anterior column and a thin border along the posterior median fissure, a thread of white matter occupying the place of the lateral columns. All of these portions present the signs of inflammation as detailed above. The right side of this section is preserved, with the exception of the lateral columns and the sensory tract of Gowers, all of which are, however, infiltrated with blood elements.

The right side of the third cervical segment can be sectioned if thick sections are made. Under the microscope is seen a mass of nerve filaments and inflammatory edematous tissue in which no distinction can be made between the gray and white matter. The margin of this right half is very soft and quickly becomes detached from the rest of the section. Under the microscope it is seen to be badly degenerated. The left half of this portion of the cord could not be sectioned by any manipulation, being absolutely and completely disintegrated. Some of the

softened material was teased, and under the microscope abundant masses of granule corpuscle, debris, myelin masses and many corpora amylacea were found. In the tissues of this section that did remain, there is evidence of an increase in the interstitial tissue with an increase in the thickness of the blood-vessel walls.

In the fourth cervical segment, there is no absolute disintegration, but the inflammatory process of the third segment extends to this segment, and especially affects the posterior medium and external columns and to a slighter degree the posterior lateral columns.

The mid-dorsal segment shows a normal cord with the exception of degeneration of some fibers in the anterior and lateral columns.

The lumbar segment shows a normal cord, with the exception of slight sclerosis in the left lateral column.

The sacral segment is normal or nearly so.

There are several points of interest connected with the clinical history and pathologic findings in the case reported in this paper. I shall only briefly refer to a few of them at this time. The macroscopic and microscopic appearance of the upper portion of the cord showed that greater damage had been done to that side of the cord opposite to the seat of the growth. Dr. F. W. Langdon of Cincinnati in *Brain*, 1895, vol. XV., p. 551 reported a case of "Multiple Tumors of the Brain; Fibrocystoma of the Pons and Cerebellum, and Multiple Fibropssammomata of the Dura, Pia, Arachnoid and Cortex Cerebri," in which the symptoms indicated that the lesion of the pons was on the side opposite to that of the tumor. It appears, then, that tumors in the neighborhood of the foramen magnum, so situated as to cause displacement of the parts against the bone, may give rise to a greater lesion by indirect than by direct pressure. This is important to bear in mind in tumors above the foramen magnum, but is of less value in growths below the foramen magnum, even should an operation for the removal of the tumor be undertaken.

The position of the tumor and its slender attachment to the inner surface of the dura would have made it a comparatively easy matter to remove the growth in the case of my patient had he been seen early, or before he became so extremely weak.

The microscopic examination shows that the third cervical segment was almost completely destroyed, but that the first and second cervical segments were greatly damaged, especially on the left side. It is probable that considerable destruction of the cervical cord took place after I made a careful examination of the patient's condition, some weeks prior to his death.

From the macroscopic appearances of the cord, it seems evident that the third cervical segment must have been destroyed by compression and by subsequent inflammation. It appears, then, that the first and second cervical segments supply with tactile sense the posterior portion of the scalp, a narrow strip on the posterior portion of the neck as low down as the fourth spinal process, and the face in front of and below each ear.

Dr. M. Allen Starr¹ gives the second and third cervical

¹ "Familiar Forms of Nervous Diseases," p. 128.

segments as supplying sensation to the posterior portion of the scalp and the neck. It is probable that the third cervical segment has nothing to do with supplying sensation to the scalp and posterior portion of the neck, but that it mainly affords sensation to the lateral and anterior surfaces of the neck.

NEW INSTRUMENT.

IMPROVED HYPODERMIC SYRINGE.

By A. C. BARNES, M.D.,
OF PHILADELPHIA.

EVERY physician who has experienced the bother attendant upon the use of the ordinary hypodermic syringe will appreciate the points of excellence possessed by the syringe illustrated in the accompanying cut. The syringe

Mulford's Improved Hypodermic Syringe.

itself, by means of the improved piston and vulcanized rubber packing, permits of instantaneous adjustment so that by a few turns of the end of the piston the packing is brought in immediate contact with the barrel proper of the syringe, and is thereby always ready for immediate use. The syringe needle-holder and the eight vials for tablets fit by means of metal catches upon two aluminum trays which may be removed from the case and sterilized. The case is curved so as to conform to the shape of the body when carried in the vest pocket. The syringe and case is made by the H. K. Mulford Co., Philadelphia.

MEDICAL PROGRESS.

The Disinfection of Large Rooms with Formalin.—ARONSON (*Zeitschr. f. Hygiene und Infektionskrank.*, June, 1897) describes the different attempts which have been made to utilize formaldehyde gas in the disinfection of rooms. Owing to its powerful germicidal action and to the fact that it injures neither metals nor fabrics, it seemed to be the ideal disinfectant. Attempts were first made to diffuse it by heating commercial solutions of formalin.

This method proved to be an impossible one, because as soon as the concentration of the solution exceeds forty per cent. a polymerization of the formalin occurs, with a precipitation of paraformaldehyde, and if the heating is continued this finally begins to burn. It was next attempted to obtain the gas from a solution of formalin in methyl spirit called holzin. This solution spatters badly, and not only is much costly alcohol wasted, but it is not possible to develop large quantities of formaldehyde vapor in a short space of time—a factor which is absolutely necessary for efficient disinfection. Attempts have also been made to develop the vapor by the oxidation of methyl alcohol in lamps, but as aldehyde forms only a small percentage of methyl alcohol, this method is both costly and wasteful, and a large number of lamps are required to disinfect even a small room. Good results in disinfection were first obtained by means of an apparatus in which formaldehyde solutions were superheated under a pressure of three atmospheres. This is necessarily expensive, and its use is attended with a certain amount of risk. Recently Schering has constructed an apparatus in which the solid polymerized formalin or paraform, called also tryoxymethylin, is used for the development of the formalin vapor. It consists of a cylindrical mantel, beneath which is a spirit-lamp with a suitable wick. In the upper part of the mantel hangs a vessel, into which the formalin pastiles are placed. The upper end of the vessel is provided with a number of slits, through which the gases formed by the combustion of the alcohol—carbonic acid and watery vapor—must escape. In their passage through the vessel there is a mixture of these vapors of combustion with the formalin vapors generated by the heating of the formalin pastiles. In such an apparatus from 100 to 150 pastiles, each weighing 15 grains, may be vaporized at once. This is sufficient, as careful experiments have shown that a room containing 3500 cubic feet of air space may be absolutely sterilized.

Suppurative Typhlitis and a Normal Appendix.—In the *Revue de Medecin*, August, 1897, LOP gives the details of a case of suppurative inflammation of the cecum with perforation at its external border, although the appendix was perfectly normal. An artificial anus was established, and after a convalescence, prolonged by hemorrhages from the wound and by pneumonia of the left lung, the patient's condition was greatly improved. Six weeks later the patient died from the effects of an operation which became necessary to relieve a stricture of the intestine near the site of the old wound.

Substitutes for Phenacetin and Antifebrin.—VAMOSSY and FENYVESSY (*Therapeut. Monats.*, August, 1897), who have experimented with two new drugs, called phesin and cosaprin, draw the following conclusions: Both possess certain advantages over phenacetin and antifebrin, from which they are derived. They are easily soluble in water, and may therefore be given subcutaneously; they act quickly; they are less dangerous than the preparations from which they are derived; their action continues only a short time, but this may be overcome by the repeated administration of small doses.

The Best Liquid for Use as an Injection in Young Infants.—

MERCIER (*Medical Week*, August 20, 1897) recommends for use as an injection in young infants, in place of the boric-acid solution, plain water, or normal salt solution commonly employed for this purpose, a saturated solution of naphthol. This substance is sparingly soluble in water, about 3 grains to the quart. The addition of borax increases its solubility, so that 15 grains may be dissolved in a quart of water.

To Detect Minute Quantities of Liquid in the Knee-joint.—

An English army surgeon, DUER, recommends (*Med. Week*, August 20, 1897) the following method of exploration, which he has always found successful: The knee is slightly flexed and laid on its outer side so that the inner side is well in view; the operator then applies firm pressure with his hand directly over the patella. Should the joint contain any liquid, the skin on the inner border of the patella will undergo a manifest degree of expansion. In this way it is possible to ascertain the existence of an articular effusion when fluctuation is not apparent.

Exophthalmic Goiter Treated by Resection of the Two Cervical Sympathetics.—GERARD-MARCHANT (*La Presse Médicale*, July 3, 1897) treated a patient with exophthalmic goiter by resection of the inferior portion of the right and left superior cervical ganglia with about two inches of the nerves, an improvement in the eye condition was noticeable almost immediately, and this increased until the exophthalmos was very slight indeed. The pulse decreased from 80 to 100 to a constant rate of 80.

In the same number of this Journal, CHAUFFARD mentions a similar case occurring in a man. Quenu performed a bilateral operation as above described. The immediate results were scarcely noticeable. Two and a half months later an attack of tachycardia came on, and the patient was given a bottle of digitalis with instructions regarding its use. He took nearly the whole contents of the bottle, and died some hours later of acute digitalism. However, he lived long enough to demonstrate the failure of the operation.

In the same number of this Journal, CHAUFFARD mentions a similar case occurring in a man. Quenu performed a bilateral operation as above described. The immediate results were scarcely noticeable. Two and a half months later an attack of tachycardia came on, and the patient was given a bottle of digitalis with instructions regarding its use. He took nearly the whole contents of the bottle, and died some hours later of acute digitalism. However, he lived long enough to demonstrate the failure of the operation.

A Genital Symptom of Renal Calculus.—ABRAHAMS (*New York Med. Jour.*, Sept. 11, 1897) calls attention to a premonitory symptom of renal calculus which he has observed in four adults, two men and two women. The men consulted him for tenderness, pain and swelling of one testicle. In the women one ovary was similarly affected. At the end of from four to fourteen days after the beginning of the attack these individuals all suffered from renal colic on the affected side, passed a calculus and recovered. The tenderness and swelling of the affected ovary or testicle quickly disappeared.

Round Shoulders.—In the *Boston Medical and Surgical Journal* for September 9, 1897, BRADFORD published an illustrated article upon the round shoulders frequently observed in growing boys and girls, and occasionally in weak adults. The scapulæ drop forward, the posterior edges projecting behind. The neck is thrown forward, and there is an unusual hollow in the small of the back. This is notably increased if the patient while standing

erect is directed to extend both arms in a vertical direction. Bradford considers that the cause of this condition is a faulty arrangement of the clothing. For the sake of convenience, and owing to an exaggerated fear of injury to the pelvis, the skirts and often the stockings of children are fastened to a dress waist. These waists usually have a narrow shoulder strap, which presses upon the trapezius muscle. To avoid this pressure the head and shoulders of a child are dropped forward.

The treatment of this condition is long and somewhat tedious. Its prevention is more important than its cure. As far as possible, the weight of the underwear should be borne by the hips, while the waist should be so constructed as to make no pressure upon the sternum, and where any weight is thrown upon the shoulders, it should be a force which pulls them backward and not forward.

Cysts of the Vermiform Appendix.—MONTGOMERY (*Jour. Amer. Med. Assn.*, July 24, 1897) reports a cyst of the vermiform appendix which was $5\frac{1}{2}$ inches long and about four inches in circumference, and contained a watery fluid. The patient was a woman, aged fifty-two years, upon whom panhysterectomy was performed for multiple uterine growths. The cyst of the appendix was accidentally discovered and was removed. The patient recovered. A number of cases of cysts of the appendix have been placed on record, but most of them have been of small size.

THERAPEUTIC NOTES.

The Medical Treatment of Toothache.—COLEY gives in September number of the *Practitioner* some prescriptions for the treatment of toothache which he has found reliable. He rejects the use of narcotics as not being directly applicable to the seat of pain. More efficacious is the insertion into the cavity of the tooth of a bit of absorbent cotton soaked in a mixture consisting of equal parts of pure carbolic acid and water. A bit of dry cotton should be placed over the moist. The pain ceases usually in a few minutes; if it recurs a few hours later, the treatment should be repeated. Attention is apt to be called to the existence of any decayed teeth by an attack of dental neuralgia. The following prescription may be given with benefit:

R	Quin. sulph.	.	.	.	.	.	gr. ii
	Acid hydrobrom.	.	.	.	.	.	m xv
	Tr. gelsem.	.	.	.	.	.	m xv
	Syrup	.	.	.	.	.	3 iss
	Aquæ,	.	.	.	.	.	3 j.

M. Sig. Twice daily.

A toothache which comes on after eating, and due to excess of acidity, may be relieved with astonishing rapidity by the administration of an alkali. A Seidlitz powder minus one-quarter of the acid fulfils the requirements. Salicylate of soda is at times a most valuable internal remedy for this distressing malady. Fifteen grains repeated, if necessary, every four hours will relieve the pain caused by the inflammatory products surrounding a tooth.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor: J. RIDDLE GOFFE, M.D.,
NO. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

SATURDAY, SEPTEMBER 25, 1897.

OUR COUSINS IN SESSION.

WE have recently had presented the unique spectacle of a meeting of the great national association of our brethren of the Mother Country upon this continent and within a few score miles of our own border; and a brief and informal comparison between it and one of our own gatherings is not without interest.

The first and most permanent impression made upon the observer was the striking similarity between the two, for there was absolutely nothing in the character or appearance of the members of the British Association, the conduct of or attendance at the meetings, the value of the papers read, or the tone of the discussions to make one realize that one was not attending a session of our own Congress of Physicians and Surgeons, for instance, except, of course, the thumb-prints of the British tailor and the broad and beautiful British accent, which were always in evidence. And yet neither association is modeled upon the form of the other; it is simply the common blood and requirements causing the development of practically identical institutions.

There were, however, a few differences in details,

and one apparently in mental attitude which are worth noting. In the first place, there was a refreshing absence from the program of such papers as "The Tomato-Heart," "Results with Ergot in Two Thousand Successive Cases of Labor," "My Last Hundred Ovariectomies," etc., etc., and likewise an absence from the meetings of individuals who looked capable of writing them. This may have been due in some measure to the greater scarcity of the breed, but chiefly, we think, to the fact that the officers of each section formed an actual, instead of merely nominal, board of censors, and exercised their power in the judging of papers submitted without fear or favor. It would be greatly to the benefit in every way of our own long-suffering Sections, with their overcrowded and oftentimes disfigured programs, if the identical executive mechanism could be galvanized into vigorous action.

Another commendable feature, which was of great convenience to those desirous of listening to the reading of the papers in which they were especially interested in the several Sections was the hanging outside the door of each room of a tablet, upon which was written by the doorkeeper the title of the paper under discussion and the name of the member discussing it. The title of each paper and names of speakers, as each rose, were also written upon a black-board in each Section-room itself, so that one had not to depend upon the chairman's muttered recognition of "Dr. So-and-So," or the latter's more diffident self-introduction, in order to determine his identity. Both of these practices are in use in a few of the Sections of our own medical bodies, but they add so greatly to the convenience and enjoyment of a discussion that they deserve a much wider vogue.

The most decided difference between the sister organizations, however, was not one of form, but of spirit, subtle but distinct, and perhaps may best be described as that of mental attitude toward the powers that be. The member of the British Medical Association as an individual, as well as the Association as a whole, is, first of all, British, and, secondly, medical, which, in spite of all that has been said, and with some truth, about the patriotism and pride in existing institutions, is not true *mutatis mutandis* of his American brother or his professional organizations. The whole atmosphere of the meetings, outside of the Sections, was fairly surcharged with pa-

triotism, and the allusions which evoked the surest and most frequent applause were those referring to the Queen and her Jubilee, the Mother Country, and the future glories of Canada. There was nothing forced or perfunctory about it; the feeling was simply there and was irrepressible, and so spontaneous was it that it became infectious, and the guests from the United States found themselves joining in its manifestations with a heartiness which surprised them, partly, no doubt, out of courtesy and cordial sympathy with the success of their kinsfolk, but more deeply and strongly from a feeling, which rose unbidden and often unexpectedly, that they had the blood-right to glory in the large share of this which represented the achievements of a common ancestry; and this feeling was cordially reciprocated by our British and Canadian brethren. These demonstrations of patriotism were not simply to impress us with their loyalty—least of all to make us feel that this was the meeting of a British organization and we aliens, for there was the ever-present feeling that “we be of one blood, you and I,” and that we should unite in being proud of the glories of our common family.

One matter of significant interest, as demonstrating the permanent existing basis of this patriotic enthusiasm and the practical evidence of its application, is the fact that at least six or seven of the twelve hundred or so medical men present are members of one of the Houses of Parliament, either British or Canadian. Our cousins across the water and on the other side of the boundary line are alive to the value of such representation, and show it. Roll all of our medical associations and congresses together and not one member of either national House can be pointed out, to our shame be it spoken. Such a condition of affairs is a discredit to the public spirit of our profession and a very serious disadvantage to the community. The sole honor of representing in Congress the many who practice medicine, with perhaps one partial exception, belongs to a homeopathic physician from New Hampshire, of whose competence and intelligence an idea may be gained when it is remembered that he is the official father of the fanatical and ignorant bill against vivisection which was introduced during the last session. More patriotism of the British sort would redound to our advantage and credit.

The sixty-fifth annual meeting of the British Medical Association is a thing of the past, and will long be remembered. The next time it comes to these shores the American brotherhood will again join its Canadian neighbors in extending the same hearty welcome. *Vale!*

ECHOES AND NEWS.

British Medical Association.—The next annual meeting of this Association will be held in Edinburgh, July 26, 27, 28, and 29, 1898, Sir Thomas Grainger Stewart presiding.

New York State Association of Railway Surgeons.—The seventh annual meeting of this association will be held at the Academy of Medicine, New York city, on Tuesday, November 16, 1897. C. B. Herrick, M.D., Troy, N. Y., secretary.

Dr. Stephen Smith Appointed Commissioner of Charities.—Dr. Stephen Smith of New York has been appointed Commissioner of Charities by Mayor Strong to fill the vacancy occasioned by the resignation of Silas C. Croft, who has been appointed Surveyor of the Port by President McKinley.

American Academy of Railway Surgeons.—The fourth annual meeting of this Association will be held in the Auditorium Hotel, Chicago, October 6, 7, and 8, 1897. The preliminary program promises a most instructive and entertaining meeting. D. C. Bryant, M.D., Omaha, Neb., secretary.

American Public Health Association.—The coming meeting of this Association in Philadelphia on October 26 to 29, 1897, will be the silver anniversary of this Society. An interesting feature of the meeting will be an exhibit of hygienic and sanitary appliances, preparations, etc., including all articles capable of furthering or preserving public or personal health. Dr. Irving A. Watson, Concord, N. H., secretary.

Cancer in the Imperial Family of Germany.—The sad case of the late Emperor Frederick, whose patient endurance of a laryngeal carcinoma gained for him the distinguishing title of “The Noble,” is fresh in the minds of all. It now appears that his brother-in-law, the Grand Duke of Baden, is suffering from a similar malignant disease. His condition is so critical that he is at present confined to his home in the Black Forest.

Antisepsis of the Barber-shop.—Paris barbers and hairdressers are now obliged in accordance with police regulations to employ sanitary measures in carrying on their business. They are required to use only nickel-plated combs, to substitute pulverizers for powder-puffs, to cover the hair cut off with sawdust, and have it promptly removed, and to place all metal instruments, razors, shears, combs, clippers, etc., in a sterilizer for ten minutes before they are used.

Ether as an Intoxicant.—The habit of drinking ether for its exhilarating and intoxicating effects is said to be very prevalent in London and among the peasants of Ireland. That it is cheaper than alcohol, more rapid in its effect, and more delightfully exciting before the stage of unconsciousness is reached recommends it to these degraded devotees. The dangers of its use are very great, and with a fuller knowledge of this growing evil, many deaths from obscure causes may in future be correctly assigned to ether as a beverage.

The Effect of Counter-Irritation of the Skin.—Kronecker and Marti, writing in the *Atti dei Lincei*, give the result of a series of investigations on the effect of cutaneous excitation on the formation of red blood-corpuscles. They conclude: (1) Slight irritations of the skin promote the formation of red blood-corpuscles but modify the formation of hemoglobin in different ways. (2) Strong irritations of the skin determine a diminution of the number of red corpuscles and also of the hemoglobin contained in the blood. (3) Darkness diminishes the number of blood-cells for about two weeks, after which a slight increase is noticed. (4) Continued exposure to intense light—even at night to electric light—induces the formation of red blood-corpuscles and also of hemoglobin.

American Medical Students in France.—It is announced that hereafter the medical schools of France will be open to foreign students, as are those of Germany. On July 9th the *Conseil Supérieur de l'Instruction Publique*, at a meeting held in Paris, decided upon this reform, and determined upon the character of the degree which shall be issued to this class of students. The new degree will be called the Doctorate-Universitaire, and will be issued by the universities directly, instead of by the State, as are the regular degrees of the French schools. The announcement does not declare positively whether this entitles the recipient to practise in France or not. M. Henri Breal, 70 Rue d'Arras, Paris, can furnish to students specific information regarding the requirements and the degree.

To Keep the Feet Warm.—Cork soles have long been employed to keep the feet dry, and more recently an American invention has been adjusted to the sole of shoes to maintain proper ventilation and keep the feet cool. Now a German near Dresden has devised a kind of heatable shoe to keep the feet warm. Within the heel of the shoe, which is adequately hollowed out for the purpose, is a receptacle for a glowing substance similar to that which is used in the well-known Japanese hand-warmers. Between the soles of the shoe, embedded in asbestos, is placed a rubber bag which is filled with water. A system of circulation of the water around the glowing substance in the heel is provided for by which the water is maintained at a proper temperature, the current being produced by the varying positions and pressure of the foot while walking. The warmth given by this arrangement is said to never rise above 70° F. and will last about eight hours. The soles are slightly heavier than the common sort but not much thicker than that of the ordinary wet-weather shoe.

Smokeless Powder and Expanding Bullets.—The deadly effect of firearms is being steadily increased by the constant improvements which are being made. The *Scientific American* says that the deadly effect upon game of small, metal-covered, expanding bullets with high velocity smokeless powder, has been recently satisfactorily demonstrated. Modern weapons possess several advantages over the old large calibers in flatness of trajectory, absence of smoke, long range, increased penetration, high velocity, less recoil, and light-weight ammunition. The expanding bullet produces invariably an area of laceration greater than ever effected by any projectile before used. Without calculating the effect of the nervous shock, extensive splintering of bone and laceration of tissue are produced. The secret of the deadly effect of these small projectiles lies in their expanding qualities and extraordinarily high velocity resulting from the use of smokeless powder, which is only possible when confined by small calibers. These facts are of interest not only to the members of the profession who are notorious Nimrods, when in search of large game, but are of immense practical value to the army and navy surgeon.

The Officiousness of Ambulance-Surgeons.—Probably no subordinate official feels his importance more or asserts his authority as much as the average ambulance-surgeon. Accidents are, of course, every-day occurrences to him, and wounds and injuries are his delight. A New York physician narrates an amusing experience of his, as follows: Happening in a pharmacy, he discovered a man lying upon the floor, a crowd around him, and an ambulance surgeon bustling in and out. The man had sustained a double fracture below the knee. Upon inquiring of the bustling surgeon what the case was, that young man flippantly replied, "Oh, simple fracture of the 'fib' and 'tib.'" Would you like the case?" The case of a somewhat glaring breach of etiquette and decency on the part of an ambulance-surgeon comes from a hospital in Williamsburg, L. I. Upon being called to a mechanic who had fallen from a lofty building, the ambulance-surgeon was requested not to molest the patient, as he was unconscious, until a priest who had been summoned could arrive. Whereupon the ambulance-surgeon is alleged to have said, "To h— with the priest. Let me get to work on the man," and hustled him off to the hospital. The ambulance-surgeon has been suspended awaiting investigation by the president of the hospital.

Health Reports.—The following statistics concerning cholera, plague, smallpox, and yellow fever have been received in the office of the United States Marine Hospital Service during the week ended September 18, 1897:

CHOLERA.

CORRESPONDENCE.

TWELFTH INTERNATIONAL MEDICAL CONGRESS.

[From our Special Correspondent.]

MOSCOW, August 25, 1897.

THE Congress is drawing to a close. The ball at the Nobles' club was delightful notwithstanding the crowd present. The Russians danced their national dances with a gusto which was remarkable, considering that most of them were at least middle-aged, and supposed to be staid physicians. To the Westerner who finds at home a succession of waltzes on the ball program with an occasional two-step, it was a relief to find there is a place where they dance something else. The reception by the ladies' committee this evening was another pleasant reunion which showed Russian hospitality at its best. Everyone votes the social side of the Congress a success.

As to the interesting features which were striking enough to keep a place in the memory, some were new, and some only put in a novel way. After all not every communication at an international congress of medicine represents a distinct advance along some line, and some of them are drearily familiar. The report on the surgery of the lungs and its discussion brought out very clearly the fact that the thoracic cavity is no longer a sealed chamber to the surgeon whose sacred precincts he dare not invade or only at the sacrifice of a human victim to the tutelary deity of surgery. The French surgeons have arranged an en-

tirely new branch of surgery for the lungs, but while it sounds all very fine and some of it supported by reports of successful cases, it is apt to strike one, as yet, as too theoretically complete to be thoroughly practical. Professor MacEwen's simple report, in a few words which took scarcely ten minutes, of what he has done for tuberculous cavities and the results of surgical interference, was extremely encouraging in its assurance of absence of serious danger and results which justified the operative risks incurred. It was all so quietly done that few would imagine that it is MacEwen's work in this line which practically broke ground for others; but that in this, as in brain surgery, in which he was also a pioneer, nothing was formally given to the profession until methods and results were sufficiently perfected to at once place the subject in a clear light. During the discussion of appendicitis one could not help but feel that some American surgeons could have suggested valuable points to their European brethren. Gradually the world is coming around to the necessity for operation in a large proportion of what some are still pleased to call perityphlitic cases. Professor Sonenberg of Berlin, and Professor Roux of Lausanne, both represent very advanced ideas as to most of the pathologic processes of the right iliac fossa, being surgical in their leanings rather than medical, and the general trend of thought as it came out in the discussion of their papers, shows that gradually the opinions of American surgeons on the subject are being recognized as truly conservative, though for so long they were regarded as almost wildly fantastic.

Professor Czerny's paper on gastro-intestinal surgery for pyloric stricture was a masterly review of the subject, and was listened to with a great deal of attention. One of its most noteworthy points was the announcement that the author had abandoned his own invention, the Czerny-Lembert suture, and in fifty-six cases had used the Murphy-button. He gave as his reasons that it was just as safe and much easier, and that it required much less time, which in the debilitated patients usually presenting for the operation of gastro-intestinal anastomosis is an extremely important point. Finally, feeding may begin much sooner than when suture alone is used. In Czerny's opinion one of the greatest advantages of the Murphy-button is that after its use there is no tendency to cicatricial contraction of the intestinal opening.

A new intestinal coupler, also from Chicago, made very like the Murphy-button but of absorbable material—the invention of Dr. Frank, received considerable attention.

Two papers, one from Cairo, the other from Paris, seemed to show that the contra-indications for lithotripsy are growing more and more limited. Professor Albarran representing the school of Guyon, and Doctor Rolfe, what may be called the Anglo-Indian school of surgeons, reported successful operations on very young children and for extremely large stones. The *débris* of calculi weighing from 200 to 450 grams were exhibited, which had been removed after crushing at a single sitting, and so a great advance in conservative surgery is to have even wider application in the future.

Professor Credé, whose demonstration that silver-wire sutures have an antiseptic action because the metal is acted upon by the tissues and forms in wounds compounds which are powerfully antiseptic, claims to have discovered even a wider application for silver. He uses certain of the more insoluble silver salts internally, and after absorption there is sufficient of the metal in the circulation to produce an antiseptic action. For abscesses and especially for erysipelas the results of this general antiseptis have been most favorable, and it is expected to be of the greatest service in septic wounds where the absorption of toxic agents is going on and pyemia is threatened.

In Pott's disease the discussion of the papers presented brought out very clearly the fact that most orthopedists, in recent cases at least, believe in forcible, immediate reduction, and then mechanical retention in the corrected position until healing occurs. Healing does not take longer than if the disease were allowed to run its course in a plaster jacket or with absolute immobilization in bed, and the resulting deformity is much lessened. These are not the opinions of a few men but of all the orthopedic surgeons present.

The discussion of the surgery of brain tumors must have been encouraging and consoling to those who have sometimes trephined and not found the expected tumor, and possibly found one that despite the absolutely limited localizing symptoms it gave was entirely inoperable. One set of statistics showed that about once in ten operations for brain tumor no tumor is found and once in six times the tumor is inoperable. The discussion made clear the fact that only the most absolutely classic localizing symptoms can be depended upon for a diagnosis of brain tumor and even these only in special regions. Certain nervous fibers are, by personal idiosyncrasy, so much more resistant than others that they communicate pressure to parts beyond them and do not suffer from it themselves, thus producing simulation of localizing symptoms at a distance from the lesion.

Another thing which this discussion brought out was that surgeons, owing to the more or less uncertainty of diagnosis in so many cases, are making larger openings in the skull. Doyen of Paris, for instance, believes in a temporary craniectomy in every case, and suggests that the operation carries with it, in these days of aseptic surgery, so little risk that in serious cases it may be done for diagnostic purposes, and that an exploratory craniectomy is as justifiable as an exploratory laparotomy.

Professor Kacher of Berne, after a series of operations for exophthalmic goiter, says that in its early stage it is properly a surgical disease, and may be relieved by surgical means. His theory is that the symptoms are due to oversecretion of the thyroid. To decrease this he removes one-half the gland and ties one of the main arteries—the inferior or superior on the remaining side. At an early stage of the disease the operation is not difficult, and he considers that the employment of useless medication for months and then transferring the case to the surgeon is unjustifiable as the disease is more properly a surgical one from the beginning.

The old principle that fractures must be immediately immobilized and then kept absolutely quiet until the healing process is completed received some serious blows. Dr. Lucas Champonniere of Paris has been treating all fractures for years practically without apparatus and with immediate massage and passive movements. He has obtained particularly satisfactory results in fractures of the upper and lower end of the humerus, those around the elbow and in fractures of the clavicle—the fractures for which the most varied apparatus have been invented, the greatest care in absolute immobilization taken and in which notwithstanding it all the results have, as a rule, been anything but satisfactory. Dr. Champonniere and his ideas were confirmed by others who use only the simplest forms of temporary bandage. By this treatment Dr. Champonniere has obtained in the short period of three weeks solid union without noticeable deformity.

Some of the best Roentgen-ray pictures of the hand exhibited in the surgical section of the Congress were taken without the use of a Ruhmkorff coil. An ordinary two-plate Wimshurst static electric machine, with a Leyden jar in the circuit, had been used to produce the X-rays. The result was so good that some of the histologic details of the bones were clearly developed. With slight changes the same means may be used for a radioscopic work, and it would seem as though some simpler and less expensive, also less technical means of producing these now so much valued pictures may result from further experimentation.

TRANSACTIONS OF FOREIGN SOCIETIES.

The Seventh Congress of German Gynecologists was held at Leipsic June 9 to 11, 1897.

SCHULTZE gave as the *causes of retroversion and retroflexion of the uterus*:

1. The relaxation of the supporting apparatus of the uterus, principally the retractor uteri of Luschka, the muscles in front of the broad ligament, the round ligaments, and the fasciæ. This relaxation may be due to (a) pregnancy and the puerperal state; (b) posterior parametritis in the course of absorption; (c) habitual state of repletion of the rectum; (d) prolonged dorsal decubitus, and especially the action of the abdominal pressure in this position.

2. Fixation of the cervix in a more anterior position than normal: (a) by cicatricial bands resulting from anterior parametritis; (b) by bands arising from extensive lacerations of the neck of the uterus, or supervening after bilateral notching or other operations, performed on the uterus without necessary aseptic precautions; (c) by cicatricial bands due to loss of substance by gangrene in front of the cervix or to the existence of vesicovaginal or vesico-uterine fistulæ.

3. Abnormal shortness of the vagina, more especially its anterior wall: (a) as a result of arrest of development in childhood; (b) as a result of senile atrophy.

4. Habitual state of fulness or extreme distention of the bladder.

5. Distention of the vulva, and laceration of the perineum.

These five etiologic conditions are the most frequent. If several of them coexist, their action is naturally increased. Other less important causes are abnormal length of the cervix, the presence of a tumor of the uterus or of the cervix, abnormal situation of an ovary or a tumor of the same.

The following prophylactic measures are indicated: Excessive distention of the bladder should be avoided in children and young girls. To avoid parametritis, a light aseptic bandage should be worn during the menstrual period by those predisposed to uterine catarrh. Lacerations of the perineum, however small, should be repaired as soon after delivery as possible, in order to avoid distention of the anterior vaginal wall. Careful attention must be paid to regular evacuations of the bowels during the puerperal state and afterward. If subinvolution of the uterus progresses too slowly, ergot or ergotin should be administered.

The diagnosis of retroflexion is in most cases easily made by manual palpation, but in order to recognize exactly all the complications and especially the obstacles to reduction, anesthesia is desirable.

The non-operative treatment of retroflexion consists in reduction of the displaced organs. If no adhesions are present nor any other complication, a pessary should be at once introduced. Celluloid pessaries are most to be recommended, and their shape ought to be adapted to each particular case. A pessary should never be introduced unless reduction is perfect, a rule which unfortunately is often broken. During the first days the pessary should be carefully watched and changed if it does not accomplish its object. To favor the action of the pessary, and to obtain if possible a permanent cure, cold enemata are to be taken daily after each movement of the bowels and ergot during the menstrual flow. In certain cases massage and electricity may be added to the treatment by the pessaries. Although the most favorable results are obtained in recent cases, those of long standing do equally well if the patient has borne a child or has had a miscarriage a short time before commencing treatment.

The most frequent complications are subinvolution of the uterus, metritis, endometritis, and oöphoritis. These complications, if they have not existed too long, often disappear rapidly after reduction of the displacement.

The obstacles to reduction must be carefully made out during narcosis by rectovaginal and abdominal palpation. The obstacles often depend upon a prolapsed ovary, adhesions of the posterior surface of the uterus to intestinal coils or to the rectum, or cicatricial bands occupying the parametrium, the peritoneum or both. If these obstructions cannot be overcome, during narcosis, the abdominal cavity should be opened and the adhesions divided.

OLSHAUSEN spoke of the symptomatology and operative treatment of retroflexion. Many cases give no symptoms for months, but usually there is pain in the lumbar region, headache, a feeling of weight in the stomach and pelvis, difficulty in walking, more or less marked melancholia, constipation and dysmenorrhea,

although a marked degree of the last symptom indicates the presence of complications. In long-standing cases of retroflexion, hemorrhage appears in the form of too abundant or too frequent menstruation. Sterility may result from retroflexion, but is usually caused by the presence of lesions of the adnexa.

Retroflexion is a frequent cause of miscarriage in the second or third month of pregnancy. In most cases, however, pregnancy causes a gradual reduction and thus goes on without interruption to full term. In certain cases there is only a partial reduction of the uterus, and an unreduced diverticulum remains. In such a case miscarriage may be brought about in the sixth, seventh, or eighth month.

Surgical treatment of simple movable or fixed retroversion and retroflexion has of late years been resorted to too readily and injudiciously.

WINTER, from observation made at the Berlin Polyclinic, said that retroflexion exists in about twelve per cent. of all gynecologic cases. In eighty-four per cent. of these the retroflexion exists with complications. The most frequent cause of perimetritis he found to be gonorrhea.

In six years DUHRSEN has performed 281 intraperitoneal vaginofixations, and has seen but six recurrences. Most of these patients had received previous treatment.

WERTHEIM has performed fourteen times for movable and nine times for adherent retroflexion, an operation devised by himself which consists in shortening the round ligaments through the vagina. In only one case was there a recurrence.

MARTIN never operates in cases of simple movable retroflexion. He attaches no importance to anything but complications. In all adherent retroflexions the patient is anesthetized, and the operation selected which best fits the case. Catgut alone is used for sutures.

HOFMEIER, after describing the *varieties of placenta previa*, and their supposed origin, went on to speak of the diagnosis of this condition. The persistence of hemorrhage after the rupture of the membranes raises a suspicion of premature separation, either of a placenta previa or of one which is situated very low in the uterus.

The first indication for treatment is to arrest hemorrhage. For this purpose if the cervix is still closed, the vagina should be thoroughly tamponed with sterile or iodoform gauze. If necessary this can be repeated or kept up for several days. As soon as labor has begun the membranes should be ruptured in order that the descending fetus may press upon the lower uterine segment and so compress the bleeding vessels. From this point many labors progress without further difficulty to a normal termination. In other cases the pains are insufficient and irregular and hemorrhage continues in spite of the escape of the waters. Consequently it is safer to follow the advice of Hicks and to perform internal version at once, and to bring down one foot. This procedure will usually suffice to stop the hemorrhage.

SCHATZ, while admitting that the rupture of the membrane facilitates the pressure of the placenta against the uterine wall, said that this procedure delays the labor

and thus may render dangerous, on account of its long duration, a comparatively small hemorrhage. It should, therefore, never be performed except when the head is ready to engage, or when the cervix is sufficiently dilated to permit of internal podalic version. In other cases a tampon is to be employed without rupture of the membranes.

SKUTSCH mentioned the case of a young woman who had never borne children nor had a miscarriage. After severe pain and the loss of a small quantity of blood, she passed a membrane which was a perfect cast of the cavity of the uterus with a small opening corresponding to the internal os. The conclusion was drawn that the embryo had been passed unobserved in the blood-clots. However, two days later, pain recurred and the woman expelled a perfect embryo about four centimeters (1 3-5 inches) in length. The question arose whether the membrane first passed was a decidua vera or reflexa. The size of the opening in it absolutely precluded the idea that the fetus had been contained in its cavity. Bimanual palpation showed that the right tube was considerably increased in size. The uterus itself was neither bifid nor bicornate. The explanation seemed to be that this was a miscarriage following tubal pregnancy, the decidua vera being first expelled.

BODERLEIN spoke of the danger of intra-uterine injections, mentioning a case which occurred recently in which death followed forty-eight hours after the injection of two cubic centimeters (thirty minims) of a fifty-per-cent. solution of chlorid of zinc. At the autopsy the zinc was found in the peritoneal cavity, although there was no trace of cauterization of the tube. Boderlein experimented upon six uteri which were about to be removed by the vaginal route. Immediately before operation the cervical canal was dilated, and under circumstances which permitted the escape of the excess of the fluid through the vagina, a small syringeful of a solution of methyl violet was injected into the cavity of the uterus in four cases. In one case the fluid easily penetrated into the cul-de-sac of Douglas. In two cases the tubes were found to be obliterated. In the fourth case the tubes were open, but the fluid did not pass through them. In a fifth case, in which tincture of iodine was injected, the tubes were found to be closed. In the sixth case a fifty-per-cent. solution of chlorid of zinc was used. In this instance the peritoneal cavity was afterward found to contain three or four tablespoonfuls of a milky fluid containing coagulated fibrin, a liquid due, in the opinion of the speaker, to peritoneal exudation. The right tube was red and swollen, but did not present the appearances of true cauterization.

SOCIETY PROCEEDINGS.

THE BRITISH MEDICAL ASSOCIATION.

Sixty-fifth Annual Meeting, Held at Montreal, August 31 to September 3, 1897.

[Special Report to THE MEDICAL NEWS.]

SECTION IN DERMATOLOGY.

FIRST DAY—SEPTEMBER 1ST.

MR. MALCOLM MORRIS of London, England, delivered the annual address, entitled

THE RISE AND PROGRESS OF DERMATOLOGY.

The speaker referred to the present being a time of jubilees and centenaries, and to the chastening effect of such retrospects—"showing that, if we have any reason to look upon ourselves as just in a scientific sense, it is largely the result not of our own merits, but of those of the men who prepared the way for us." He further pointed out that they have the great advantage of enabling us to see exactly what we have attained in our knowledge of dermatology, and in showing us what has been done and what remains to be done.

He stated that in the recountings of the triumphs of medicine during the glorious reign of Queen Victoria dermatology has had no part. Dermatology, although its victories have perhaps been less showy than those won in some other special departments, has not lagged behind in the onward march of medicine. He said that his object would be to supply the missing chord in the great *Jubilate*, the echoes of which are still ringing in our ears. He called attention to the fact that the centenary of the birth of scientific dermatology is not long past. In 1790 the Medical Society of London awarded the Fothergillian gold medal to Robert Willan, who had some time before submitted his plan for the arrangement and description of cutaneous diseases. Willan may justly be called the creator of dermatology. Our terminology bears witness that Willan was not the first who wrote on skin disease. The Greeks gave a good deal of attention to the subject, and roughly classified cutaneous disorders, though they confounded much they observed with leprosy, and at a later period syphilis overshadowed everything.

After speaking of various medieval writers and writings upon the subject in hand, he turned to the English school, headed by Willan, before mentioned, and his pupil, Bateman, who completed Willan's unfinished work on skin diseases. A landmark in the history of English dermatology is the work "Diseases of the Skin," by Erasmus Wilson, which appeared in 1851. The characteristics of the British school of dermatology are those of the British intellect in whatever sphere it is set to work, above everything else practical, and a capacity for seeing things as they really are. The living leader of the British school, Mr. Jonathan Hutchinson, was spoken of in terms as laudatory, under the circumstances, as it would be permissible to use. Of him it was said that he brought to the study of the pathology of the skin a knowledge of disease in general such as probably no other dermatologist ever possessed. The facts gathered by the members of the English school have endured while theories and systems have followed

each other into nothingness. Dermatology as it exists to-day is largely the work of their hands.

In France a school of dermatology arose independently during the early years of the century. Skin diseases were regarded, for the most part, as the expressions of some constitutional dyscrasia, which at best was an unnecessary hypothesis, and was sometimes, as in the case of the so-called "dartrous," "psoric," and "herpetic" diatheses, a myth. Indeed, it may be said that early French dermatology was the "last ditch" in which these medieval notions still fought for life. In recent years the labors of Hardy, Vidal, Besnier, and Brocq have placed the French school in the forefront of scientific dermatology—a position which, with such men as Derier, Thibierge, and Wickham to take the place of their seniors, it is in no danger of losing.

In 1844 the first appearance of Ferdinand Hebra before the scientific world marked an era in German dermatology. Hebra applied to the investigation of skin diseases the pathologic teaching of Rokitansky. He classified them according to the nature of the pathologic processes of which they were examples. He used the experimental method, and produced various lesions on healthy skin by artificial means, observing the changes which they underwent when allowed to run their course, and when modified by treatment of various kinds. Hebra rationalized dermatology, and his classification, though it has necessarily been modified with the growth of knowledge, will never be superseded till an arrangement based upon etiology becomes possible.

In regard to American dermatology, the speaker quoted from its history as written by Professor J. C. White of Harvard and by Professor L. A. Duhring of Philadelphia. During the first thirty years of the century little or no interest was taken in cutaneous affections in America. In fact, as Duhring tells us, a disposition existed to consign the whole of this branch of medicine to those outside the professional pale. Signs of a growing interest in the subject soon became manifest. In 1836 an Infirmary for Diseases of the Skin was opened in New York, being the first institution of the kind in the United States, and lectures on skin diseases were delivered there, and afterward in some of the medical schools of New York between the years 1837 and 1854, by Dr. H. D. Bulkley, father of Dr. L. D. Bulkley, whose name is well known to all dermatologists. The establishment of the American Dermatological Association in 1877 gave a powerful impulse to dermatology in this country, yet in 1871 Professor J. C. White complained that as yet America had contributed little to dermatology. Now this reproach has been wiped away, and American dermatology, represented by Duhring, White, Bulkley, and others, is recognized as being in the van of progress.

By the translation of the representative works of each of the three great schools into the language of the others, dermatology has become truly international, the different schools' which were formerly separate being fused into one.

The most striking mark of the progress of this specialty as compared with its status in the beginning of the century, is the knowledge of the nature and causes of skin

diseases which has been gained. Classification has been simplified, until dermatology is no longer a terror to students and practitioners. Further simplification has resulted from learning to distinguish between primary and secondary lesions. Pathologic research has accomplished much in the elucidation of the nature of growth, benign and malignant, of the skin. Real progress, however, has been measured by the increase of our knowledge of the causes of disease. In this respect the speaker thought as much had been done in dermatology as in any other branch of medicine, and stated that the etiology of a considerable proportion of skin diseases is now accurately known. The differentiation of the skin affections due to syphilis and tuberculosis has greatly reduced the region of the unknown in the map of dermatology. The progress of dermatologic etiology has been materially augmented by an increased knowledge of the parasitic skin diseases, particularly by the discovery of the vegetable fungi which cause ring-worm, favus, tinea versicolor, and erythrasma. The speaker also treated briefly the advance in pathology due to the bacteriologic researches of Pasteur, Koch, and their disciples. Many skin affections have already been proved to be of microbic origin. It is practically certain that syphilis has a like cause. Eczema and psoriasis are considered by Unna, who has done much for recent advance in dermatology, to be of microbic causation. The same is said to be true in regard to alopecia areata, acne, and certain forms of erythema. Quite recently Sabouraud has produced evidence which he thinks sufficient to prove that seborrhea and common baldness belong in the same category. Though these views have not all been accepted, there can be little doubt that, as methods of research are perfected, the "sphere of influence" of bacteriology in relation to skin diseases will be greatly enlarged.

The speaker also referred to disorders of the nervous system and to auto-intoxication as causative factors in the production of cutaneous affections, a field as yet but little explored. In reference to therapeutics, he said that now internal medication is used only in response to definite indications.

He spoke of hypodermic injection as one of the most promising improvements in constitutional therapeutics. The serum treatment, though not yet definitely established, has given good results in a few cases of syphilis, lupus, leprosy, etc. Koch's first tuberculin was mentioned as having a distinct use as a preliminary to the surgical treatment of lupus. The newer tuberculin gives promise of much greater usefulness.

The speaker's experience, and that of several other dermatologists, does not lead him to attach much importance to the use of thyroid extract in dermatologic practice. In regard to the improvements in means of local treatment, he spoke in terms of praise, mentioning particularly the long and constantly increasing list of parasitocides, the more cleanly and effective modes of preparation and application, the pastes, plasters, varnishes, soaps, sticks, and other devices which have revolutionized the local treatment of skin diseases.

In conclusion, he spoke of the future of dermatology.

He thought that the newer medication with serums and organic extracts will be the direction most likely to lead to the best results.

At the conclusion of this address, DR. GEORGE THOMAS JACKSON of New York read a paper, entitled

A CASE OF MULTIPLE IDIOPATHIC ANGIOSARCOMA
LASTING TWENTY-ONE YEARS.

The patient was a man, a native of Nova Scotia, aged forty-seven, and the lesions were widely distributed. Involvement had taken place under the administration of arsenic. The pathologic report, by Dr. G. P. Elliott of New York, showed that the lesions were of the type of pigmented spindle-celled angiosarcoma.

DR. NEVINS HYDE of Chicago said that a like improvement under arsenic had taken place in a similar case under his treatment. The clinical characters remove these cases from the category of sarcoma.

DR. JAMES GALLOWAY referred to a case under the care of Dr. Stephen Mackenzie which he had observed during nine or ten years. Histologically, the cells were degenerate in character and resembled those produced by chronic irritation of connective tissue. He agreed that the cases belonged to a category distinct from sarcoma.

A paper on

THE NON-SURGICAL TREATMENT OF BOILS, CAR-
BUNCLES, AND FELONS

was read by DR. L. DUNCAN BULKLEY of New York. He treats all the minor forms of these lesions by internal medication, consisting mainly of sulphate of magnesia and iron, with large doses of freshly prepared sulphid of calcium. Externally he applies carbolic acid and ergot in the form of an ointment. The PRESIDENT expressed the opinion that Dr. Bulkley's views were retrograde in tendency. He was convinced that he would be supported in the view that the best treatment in such cases is to remove the suppurating and necrosed tissue and to use antiseptic methods. An animated discussion took place on this subject.

DR. W. T. CORLETT of Cleveland, Ohio, read a paper on

THE GENERAL MANAGEMENT OF SKIN DISEASES, in which he urged the importance of general treatment, dietetic and hygienic. The PRESIDENT entered a protest against indiscriminate medication and exaggerated precautions in diet. Dr. G. H. Fox of New York expressed similar opinions, and said that in many cases the advice and care given by trainers to those preparing for athletic exercises is of more real value than the prescriptions of the physician. Dr. Nevins Hyde also protested against over-medication, but desired to defend American dermatologists from any imputation of the kind.

SECTION IN PHARMACOLOGY AND THERAPEUTICS.

FIRST DAY—SEPTEMBER 1ST.

DR. D. J. LEECH, President of the Section, delivered an address upon the subject of

PAST AND PRESENT VIEWS AS TO THE ACTIONS OF
MEDICINES.

He said in part: "The Section in Pharmacology and

Therapeutics, over which I have the honor to preside, is one of those which is not always constituted at the Annual Meetings of the British Medical Association. The fact that one side of its work—the therapeutic—can be dealt with in other sections is doubtless the chief cause of this; a second may be a certain lack of interest in Pharmacology. Comparatively little attention has been given in England in recent years to the cultivation of knowledge concerning the method in which remedial agents act. In most countries, however, a constantly increasing interest is being shown in determining, not only the action of remedies, but the mode of their action. The establishment on this side of the Atlantic of that admirable periodical, *The Journal of Experimental Medicine*, in which Pharmacology takes its place with Physiology, Pathology, and Medicine, is a valuable sign of this interest, and my great pleasure at being honored with the office of President of this Section is heightened by the feeling that by its constitution on this occasion evidence is given of the appreciation of the scientific as well as the practical side of therapeutics in this country.

"The discoveries made concerning the curative influence of certain animal substances, such as thyroid gland, and concerning toxins and antitoxins, mark a new departure in therapeutics. Dr. Saundby considers that though the recent discoveries with regard to pathogenic organisms and their products open up to us an altogether new prospect in therapeutics, the system of pharmacology is about to pass into the limbo of the forgotten, and Professor Behring of Marburg thinks that in the light of serum treatment all our older views must vanish. Cellular pathology, he says, has become unfruitful for therapeutics; it is vain to treat the organs which are affected. Serum treatment, if we may judge from the *résumé* of his paper, which was read at the recent *Congress für innere Medizin* at Berlin, is alone efficient. If Behring's view as to its nature is correct, its study is almost outside the boundaries of pharmacology, for he holds that antitoxin is not a definite chemical compound, but a *quality*, inherent in certain albuminous substances as magnetism is in the magnetic oxid of iron. If antitoxins are powers, not substances, we are almost carried into a new world in which pharmacology, as at present understood, has no place. There seems little probability that the view of the enthusiastic supporter of serum treatment has any real foundation, and as I do not know the reasoning which has led to its adoption I shall not attempt to controvert it. The general bearing, however, of treatment by animal substances on our ideas as to the methods in which medicines act is worthy of consideration. My contention is that the new discoveries, while extending the domain of pharmacology, are in no way opposed to its long-established teachings; that the various animal substances act on the same lines as the older remedies, though they possess certain properties which are wanting, or less apparent, in the older drugs, and that even if the most sanguine expectations of their powers are fully borne out, the utility of the pharmacologic knowledge already acquired will not be lessened.

"Concerning the action of thyroid and allied substances I need say but little. Physiologic and pathologic

investigations indicate that the ductless glands, and even those which furnish excretions, supply some material which passes into the blood; and it is just possible that other tissues do the same. These internal secretions are probably necessary for the chemic transformation of other substances in various parts of the system, and if the supply be defective certain ailments result. By giving thyroid gland we can certainly remove the effects due to an insufficient supply of its secretions, and reason has been given for believing that several other animal substances and their extracts yield, when given internally, material wanting in the blood, and thus prove of advantage in some diseases. But we have here no new pharmacologic principle. The administration of a remedy for the purpose of adding something to the blood, which is not present in sufficient quantity, is not a departure from ordinary pharmacologic ideas.

"The effect of toxins and antitoxins requires to be more fully dealt with, but before comparing their action with that of other medicinal substances, let me point out opinions formed during late years with regard to the action of the latter. In the first place, it has become clear that for the changes in functions or tissues we must chiefly look to the effects produced by drugs on the ultimate tissue elements, or cell protoplasts, and Schmiedeberg long ago pointed out that this influence is probably to some extent molecular. The presence of molecules of elements or chemic compounds seems to produce some effect on those of the protoplasm which leads to change in the function of the tissues into which the protoplasm enters. It is quite possible that pharmacologic agents may likewise influence chemic processes in the protoplasm without themselves being changed, but however this may be, it seems clear that the primary effect of remedial agents is exerted through their influence on cell-protoplasm, the nutritional processes of which are altered, with the result that the tissues into which the protoplasm enters are altered in function.

"In some instances their continued contact seems to give rise to further changes; something occurs which causes the drug molecules to lose their usual influence, and tolerance of, or immunity to the drug is produced. How far this immunizing effect of drugs extends we do not know. It seems to occur in certain people only in the case of arsenic. The alkaloid morphin is the best example of it, but it has been shown by Ehrlich to be produced by the two vegetable albuminoid substances, ricin and abrin. On the cause of immunization we can only speculate. The cell protoplasm may, owing to some alteration in its functions, expel the drug with unwonted quickness, or it may destroy it; but it seems more likely that some change takes place in the nutrition of the cell which renders it insusceptible to the influence which under normal conditions alters its functions.

"Turning now to the toxins, it may be noted that they disturb the functions of the various organs like other pharmacologic agents. They have a definite physiologic action, and there is no reason for believing that they act on tissues in a manner fundamentally different from other medicinal agents. They have, indeed, a more marked

power than most drugs in producing immunity. It is impossible to say whether in this respect they act like ordinary drugs, but it can hardly be doubted that they produce their effects in a similar, if not in the same way.

"A third property which toxins have has not been shown to be common to the medicinal agents hitherto employed. They lead to the production of antitoxins, but how, we know not. Protoplasm has the power of altering substances which come in contact with it, and it is possible to imagine that by some subtle chemic influence the toxin is converted into a substance directly antagonistic to it in physiologic properties. But it seems far more probable that antitoxins are produced by the protoplasm itself, under the influence which the toxin exerts upon it. It is shown that the serum of blood does contain a bactericidal substance, and many years ago Hankin pointed out that the blood of certain animals normally contains what he called a 'defensive proteid,' to which Buchner subsequently gave the name of 'alexin,' and which practically is an antitoxin. If cell protoplasm has the property of thus normally producing such defensive material, it is not difficult to imagine that under the influence of certain toxins it may produce special antitoxins.

"The methods in which antitoxins act is as yet shrouded in obscurity. There is no reason for believing that their effects are produced in a manner different in kind from those of other drugs. The action, then, of the new animal substances seems not dissimilar from that of our older remedies."

The discussion on

THE TREATMENT OF INSOMNIA,

was then opened by DR. C. K. CLARKE of Kingston, Ont., who spoke on general treatment. After dealing with the physiology of sleep, and Howell's recent researches in particular, he proceeded to discuss the treatment of insomnia in various conditions. Drug treatment in general was deprecated. In acute mania the warm bath (104° F.), with cold applications to the head, and in neurasthenia massage, frictions, etc., were advocated. Stress was laid on McFarlane's view of sleeplessness as a bad habit, and regularity in the time of going to bed was recommended. Hot milk and beer were advised as adjuncts. In conclusion, the insomnia of toxemias, and that accompanying surgical disorders, was considered.

DR. R. W. WILCOX of New York then dealt with

THE MODE OF ACTION OF HYPNOTICS.

Howell's, Ramon y Cajal's, and Ruckhard's views of the physiology of sleep were treated of in detail and the action of alcoholic radicals, chlorin in organic combination, etc., was alluded to. The treatment of insomnia by drugs was then considered. Of vegetable narcotics, pellotin was regarded with favor; his experience with amylen hydrate, methylal, paraldehyde, chloral, chloralamid, sulphonal, trional, tetronal, and urethan was given, his paper closing with a comparison of paraldehyde, chloralamid, pellotin, and trional as regards potency, rapidity, and duration of action, habituation, and safety.

THE ILL EFFECTS OF, AND CONTRA-INDICATIONS TO
THE USE OF HYPNOTICS

were then considered by DR. A. MCPHEDRAN. The physiology and etiology of sleeplessness were first summarized and the ill effects of individual drugs subsequently dealt with. Hypnotism, it was recommended, should be resorted to but rarely, and only when other means have failed.

DR. EDIS of Jamaica Plains contributed a paper on this subject and dwelt on the value of gentle fatigue.

PROFESSOR RICHEL of Paris gave an excellent description of the pharmacology of chloralose, and the discussion was continued by Drs. D. Macalister, Saundby, Cushing, Barnes, MacCallum, Learned, Campbell, Muir, Brookhouse, Whitla, Rayner, Smith, Atkinson, and the President. There was a consensus of opinion that hypnotics should only be used as a last resource. Chloral was deprecated by the majority, and sulphonal also received some strictures. Dr. Donald Macalister confined his remarks to the insomnia occurring in otherwise healthy subjects, and strongly recommended what he termed the air-bath, the wet sack, and as drugs, strychnin in coffee, and magnesium sulphate. Dr. Saundby believed the older hypnotics were the best, and DR. Learned dealt in detail with a physical mode of treatment he had found beneficial. Dr. Whitla regarded the use of digitalis, with chloral, etc., as useless, and strongly recommended chloral as an hypnotic. Dr. Leech closed the debate by a few pregnant remarks on the treatment of sleeplessness in the old and the middle-aged.

SECOND DAY—SEPTEMBER 2D.

This section met jointly with the Section in Dermatology to discuss the subject of

THE TREATMENT OF SYPHILIS.

The Chair was taken by DR. D. J. LEECH. The subject was introduced by DR. WHITLA of Belfast, Ireland, who said that two drugs alone need be considered—mercury and the iodids. He regarded it as proved that mercury has a specific or curative effect on syphilis, and thought it best to limit his attention to the following points: (1) How mercury and the iodids are supposed to act; (2) when should mercurial treatment be begun; especially, should it be given in the primary stage? (3) the various methods for its routine administration, its dosage, and the length of time necessary for mercurial treatment; (4) the treatment of tertiary symptoms and congenital syphilis. The pharmacology of mercury—the mode of absorption especially when administered by inunction, its elimination, etc., was considered. Mercury he regarded as a vital antidote to the syphilitic poison, and so long as the virus of syphilis remains in the organism, mercury, he believed, would expend its force upon it without injury to the patient. This, he thought, gave a working hypothesis as regards dosage. The question of the bactericidal power of iodids in connection with Binz's view was dealt with, and their inutility in the first and early second stages emphasized. The continuous and interrupted methods of administering mercury were treated at length, although it

was stated that these could not be rigidly separated. The continuous method was favored by the speaker. He prescribes small doses as early as possible. Routine treatment was deprecated. As a guide determining the effect of the mercury, the weight-chart was strongly recommended. Of the various modes of administration, the method of inunction is most generally useful, although this possesses many disadvantages. Under ordinary circumstances small doses of mercurous iodids are sufficient. In the tertiary stage he advised pushing the iodids until the symptoms abate.

DR. NEVINS HYDE of Chicago laid particular stress on the constitution of the individual. He believes that there are mild cases needing little or no treatment, and severe cases (mainly inherited) which seem insusceptible to all treatment. Between these is the mass of cases giving the most satisfactory results. The best effects are obtained where iodids are not used; they are the remedies for the complications.

MR. MALCOLM MORRIS divided syphilitics into those who take alcohol and those who do not. He had not seen good results from intramuscular injections. The mercurial air-bath in certain conditions (extensive ulcerations) is strongly to be recommended, and to this treatment inunction, warm baths, especially those of a stimulating character, are useful adjuncts. The combination of ammonia and sarsaparilla with iodids is beneficial.

DR. L. DUNCAN BULKLEY of New York thought large doses of iodids unnecessary in the third stage if these drugs are combined with a small amount of mercury. The President then closed the discussion by referring to the inutility of other drugs than mercury and iodine, and agreed with Dr. Whitla in believing it often necessary to push iodids in the third stage of this disease. Combination of the iodids with ammonia is useful.

DR. WHITLA, in reply, said that the whole secret of success in the treatment of syphilis is to get as much mercury into the system as possible without producing ill effects.

DR. A. R. CUSHNEY of Ann Arbor, Mich., then read a paper on

PHARMACOLOGY OF THE MAMMALIAN HEART.

He demonstrated his method of experimenting, and showed tracings of the effect of aconite, digitalis, chloroform, alcohol, nitroglycerin, etc.

THIRD DAY—SEPTEMBER 3D.

The discussion on

DIURETICS

was opened by DR. BARR of Liverpool, who dwelt at length on the physics of the circulation, especially in pathologic conditions. He then proceeded to deal with the treatment of diseases in which diuretics are indicated. The flushing process is based on the principle of washing out waste products, ptomains, etc., and natural springs are no better than similar artificial products for this purpose. In granular kidney the best treatment, he thought, is to cut off nitrogenous foods, to take a purely vegetable diet, to drink whey and mild alkaline waters, and to regu-

late the intestinal secretions by calomel. Benzoate of ammonium in uremia was recommended. In heart disease, cardiac tonics, combined in some cases with vasodilators, were regarded as most efficacious. In obstructive lung disease, ammonia, senega, and the saline diuretics; in cirrhosis of the liver, vasomotor and cardiac tonics with mild saline purgatives; in hysteria with anuria, water and whey freely, and general venesection and antimony were regarded as the most effectual agents in the dropsy of acute Bright's disease. In conclusion, the speaker said that diuretics are simply adjuncts to treatment; that no disease or process of disease should be solely treated by them.

MR. C. R. MARSHALL of Cambridge, England, then dealt with the action of diuretics. As this subject could not be separated from the physiology of renal secretion, this was first considered. Various recent views were mentioned and criticized, and the possibility of explaining urinary excretion on a purely physical basis dealt with. Special stress was laid upon the metabolism of the renal cells as factors in accounting for the composition of the urine. The definition, classification, etc., of diuretics was next considered, and an illustration of so-called tachyuretics was given. Munk's, Sobieranski's, and Raphael's work was specially considered, and the action of certain types of diuretics described.

DR. J. E. ATKINSON of Newcastle, England, spoke on the absence of increased diuresis after the administration of nitrites and nitroglycerin, and Dr. Shingleton Smith of Bristol, England, referred to the effect of digitalis and diuretics in certain conditions, and commented on the fact that apocynum cannabinum had not been mentioned. This is little known in England, but in some cases it is a useful diuretic.

DR. H. A. MCCALLUM of London, Ont., then read a paper on

THE ACTION OF BEHRING'S SERUM IN DISEASES NOT CAUSED BY THE KLEBS-LOEFFLER BACILLUS.

The effect on consumption, cancer, pelvic inflammation, lupus, etc., was discussed. In one case of tuberculosis 25,000 units of the serum were given during three months, apparently with benefit. A favorable action was reported in a case of lupus. The theory suggested was that the serum increases the internal secretions.

In connection with this paper, DR. BAZIN's, on

DIPHThERIA ANTITOXIN.

was read. He regarded it as important that the strength, date of production, etc., should be stated on the label. He believed that a "clinical suspicion" affords sufficient grounds for the use of the serum. Bacterial examination should follow this. Immunization should be more generally followed.

THE PRESIDENT asked if cardiac failure does not sometimes follow the injections, but Dr. Bazin believed this is a coincidence, and not a result of the antitoxin. He corroborated Dr. McCallum's observations on the hypnotic effect of the serum, and stated that slight turbidity, or rather fluorescence, is not prohibitive to its use.

THERAPEUTIC HINTS.

Fever Mixture for a Child.—The combination here given will act most efficaciously in reducing the temperature of a child in those cases in which no etiologic factor is discoverable:

℞	Tr. aconiti	gtt. v
	Potassij bromidi	3 ss
	Spt. etheris nitrosi	3 ii
	Mist. potassii citratis	3 ii.

M. Sig. Teaspoonful every three hours.

For Chronic Constipation accompanied by torpidity of the liver the following will prove very efficacious:

℞	Sodii sulphatis	℥ i
	Sodii phosphatis	3 ss
	Potassii iodi	gr. xl.

M. et. ft. Chart. No. viii. Sig. One powder in a glassful of either hot or cold water on rising in the morning.

For Urticaria.—The following remedy is of service in urticaria:

℞	Menthol	1 part
	Chloroform	} aa 3 parts.
	Ether	
	Spirits of camphor	

M. Sig. After an application of the above dust the skin with oxid of zinc. If the urticaria is of a stomachal origin, give laxatives, preferably the saline waters.—*Jour. de Méd. de Paris.*

For Catarrhal Sore Throat.

℞	Pulv. aluminis	gr. xv
	Acidi hydrochlor. dil.	m x
	Mellis	3 i
	Aquæ, q. s. ad.	3 i.

M. Sig. 3 i added to 3 viii of water, used as a gargle when necessary.

An Old and Excellent Tonic Mixture Is the Following:

℞	Liq. arsenici chloridi	3 ss
	Tinct. ferri chloridi	3 iss
	Cinchonæ sulphatis	3 ii
	Strychniæ sulphatis	gr. ii
	Syrupi } aa q. s. ad.	3 vi.
	Aquæ }	

M. Sig. Teaspoonful in water three times a day before meals.

A Good Antineuralgic Combination Is the Following:

℞	Acidi arseniosi	gr. iv
	Strychniæ sulph.	gr. iii
	Ext. belladonnæ	gr. xxiv
	Cinchonæ sulph.	3 i
	Pilulæ ferri carbonatis	3 v.

M. Sig. One pill three times daily after meals.

Chloral May Be Pleasantly Combined as Follows;

℞	Chloral hydrat.	3 i, 3 i
	Tinct. cardamomi	3 ss
	Syrupi	3 i
	Aquæ cinnamomi, q. s. ad.	3 i.

M. A. teaspoonful contains 10 grs. of chloral.

RACIAL DETERIORATION: THE INCREASE OF SUICIDE.¹

By LAWRENCE IRWELL, M.A., B.C.L.,
OF BUFFALO, N. Y.

THE suicide record of the United States since 1890, according to recent statistics, stands as follows: 1890, 2040; 1891, 3531; 1892, 3860; 1893, 4436; 1894, 4912; 1895, 5750; 1896, 6520. The census of 1880 furnishes us with the number of suicides in that year—2511, but as far as I can ascertain, the census of 1890 contains no information upon the subject, the word "suicide" having been omitted from the index of Part 4 of volume 50. However difficult it may be to obtain accurate statistics, it appears certain that in each 100,000 deaths from specified causes, 253 in 1860 were due to suicide, 273 in 1870, and 331 in 1880. These figures, however, give no idea of the actual number of persons who voluntarily ended their existence during the years named; they merely tell us of the number of cases of suicide which were discovered. How many suicides are lost annually to the statistician, no man can say, and I refrain from speculating upon the subject. Statistics of unsuccessful attempts at suicide are obviously unobtainable.

Is suicide increasing in the English-speaking world? I do not find any difficulty in answering this question in the affirmative, although my statistics are very incomplete. Some of my figures are taken from Great Britain. In 1864, in England and Wales, the suicide-rate was 61 to the million persons living; in 1888 it was 81 per million—an increase of one-third (33 per cent.) in less than 25 years. This steady increase is also present in this country. In Massachusetts in the 30 years, 1860 to 1890, self-destruction rose from 69.9 to 90.9 per million living; and in Connecticut from 60.6 to 103.3 per million living. Reliable statistics of suicide in the States of New York and Pennsylvania—if they exist—are not at my disposal.

Admitting then, that self-destruction is on the increase, what, I ask, is the cause of it? The degeneration of the human race, of which the suicidal impulse is a sign, is the result of the many deteriorating

influences inseparable from what we call "civilization," together with those which are the outcome of vice. Among the former may be mentioned want of fresh air, improper food and clothing, premature child-bearing, and unhealthy occupations. These, in themselves, are most injurious to the well-being of the race, but when the degenerating influences of alcohol, tuberculosis, and syphilis are added a combination results which the human organism cannot long resist. In an interesting work, entitled "Degeneration among Londoners," an assertion appears, the truth of which nobody will doubt, that the London poor do not survive beyond three, or at most, four generations. If, however, any expert opinion is necessary to corroborate my statement that self-destruction increases with civilization, I append the words of Morselli, *viz.*: "The certainty of the figures and the regularity of the progressive increase of suicide, from the time when statistics were first collected to now, is such, and so great, even in respect to countries different in race, religion, and number of inhabitants, that it is not possible to explain it otherwise than as an effect of that universal and complex influence to which we give the name of civilization."

The reasons I have given for the degenerating influences of civilization are not altogether applicable to the better-educated classes, but as suicide, insanity, and epilepsy are found among the rich as well as among the poor, the causes of this condition must be sought for. In the first place, if a person is financially and socially eligible for marriage, whether his mother was a lunatic or his brother an idiot, is not regarded as a matter of any importance whatever. While the "educated" classes are quite familiar with some of the laws of heredity, and apply them to the breeding of their dogs, they wilfully ignore the best interests of the human race by the incessant propagation of the unfit. Having money at their command, they endeavor, with the aid of the medical profession, to preserve their degenerated offspring from the natural results of the cosmic process. Never in the history of the world was there a time when such strenuous efforts were made to prolong the lives of the absolutely unfit that they might have an opportunity of reproducing their kind; never was there a race which suffered as the English-speaking race is now suffering from the fertility of the worst specimens of humanity.

¹ Read before the Economic Section of the American Association for the Advancement of Science, Detroit, Mich., August, 1897.

With each generation the vitality of the community is being reduced by its manner of life, and in order to enable it to continue the fight against the inevitable laws of nature, all sorts of artificial aids have been invented. False teeth, spectacles, ear-trumpets, wigs, to say nothing of predigested foods, are a few of the contrivances with which we are trying to carry out the pernicious doctrine of the survival of the unfittest. Further, luxurious excess and the numerous vices of the rich all tend toward racial decay. One word more before I leave this point. The Indian is less civilized than the negro. Suicides among the latter are about eighteen times as numerous as among the former. The white man is far more civilized than the negro. Self-destruction is ten times more frequent in the white race than among the colored population.

By "civilization" we mean, for example, that we are able to dine in New York and to breakfast at Buffalo. We profess to "rest" upon a train which moves at the rate of fifty-five miles an hour; and many of us are foolish enough to expect to be fit for work upon rising from our moving bed. Moreover, the modern vacation is so arranged that it will be almost as exhausting as the average business day. "It is the pace that kills," is an old saying, and it is a very true one. The average nervous system is unable to bear the strain of this pace. Some give up the struggle and retire to the lunatic asylum. Others fight to the premature end, bringing forth a new generation, bearing in every organ the signs of the unnatural life which the parents have lived. From this new generation spring many of our lunatics, criminals, and suicides. In two generations more idiots and deaf-mutes make their appearance. But this condition does not extend indefinitely, for we have not succeeded in counteracting the process of natural selection, and three generations later, the degenerated family is probably sterile.

It is now well-recognized that suicide, insanity, and epilepsy are all signs of family decay. Many alienists have, by following the family history of suicides, been able to demonstrate not only that suicide frequently occurs in some families, but also that, while remaining dormant in one generation, it reappears in the next. How long it will be before we admit that the congenital tuberculous diathesis is a sure sign of a degenerative change in the human organism, I cannot tell, but there is to my mind, abundant statistical evidence that such is the case.

The result of the various abnormal conditions of the constitution to which I have referred is the increase of lunacy, idiocy, instinctive criminality, and habitual inebriety. Are these evils increasing out of all proportion to the increasing strain of modern

life? I think so. Within recent years there has been a tendency, especially in this country, to push women into competition with men in practically every walk of life. The system has not, however, been long enough in operation to have affected the suicidal rate, although it has increased the amount of dementia paralytica and instinctive crime among the female sex. That, in course of time, the female death-rate from suicide will likewise increase is unquestionable. Perhaps it would be well to look at all the facts. Among all nations, ancient and modern, suicide has been much more frequently practised by men than by women. The usual ratio is and always has been about three or four males to one female, and out of the 6520 persons who voluntarily ended their lives in the United States in 1896, 5078 were men and 1442 were women. As might be expected, the rate of self-destruction varies in different countries. In Switzerland, for example, out of every hundred suicides only 12.2 are females, while in England, the rate appears to be for males 104 annually to every million men living, and for females, only 41 per million women living. Spain has, when the sexes are taken together, the lowest suicide-rate of all European countries, but when women alone are taken the rate is about 28.10 per one hundred. The explanation of this phenomenon is, I think, to be found in the two facts that love, hate, and jealousy are less curtailed by Spaniards than by any other nation, and that these passions play a far more important part in the lives of the so-called "weaker" sex than they do in the lives of men.

In the Australian colonies, the female suicide-rate is low as compared with the male. This is what we should expect in a country where women are scarce, and being much sought after, are kindly treated. In Scotland, upon the other hand, the female suicidal rate is higher than in most other countries, the probable reason being that the illegitimate birth-rate is high, a condition which is productive of an unlimited amount of misery and despair among the mothers of the bastard children.

The comparative immunity of the female sex to self-destruction is partly dependent upon the less harassing position which woman has, up to now, taken in the struggle for existence; partly upon the less vicious life which she usually leads, and partly upon her natural repugnance to personal violence and mutilation of the body. In England, at one period of life, the suicidal rate among females not only equals but actually exceeds that of the males. This is during the 15-to-20-years-of-age period, and it is to be accounted for by the severe constitutional change experienced by women at this time. The English statistics show also an increase of female sui-

cides during the 44-to-55-years-of-age period, due, of course, to the climacteric.

The death-rate from the results of drinking alcoholic liquors is probably on the increase. Nevertheless, drinking is becoming less general, for it is now more narrowly confined to the habitual drunkard, who is, in the majority of cases, the victim of hereditary predisposition, than it was fifteen years ago. Thus, though the evil is as virulent as it ever was, its field of action is smaller, the acquired form of inebriety being somewhat less common than it was in the days of yore. As far as the race is concerned, the change is for the better. The conclusion that must be drawn from the evidence is that intemperance is only responsible for a small part of the increase of suicide.

The evil effects arising from the advance of civilization are great, yet improved sanitation must, to some extent, have neutralized them. That being so, the increased severity of the struggle for life cannot be regarded as the *causa vera* of the addition to the suicide death-rate. To what then must the increase be attributed? The answer is to heredity, and to the fertility of the degenerated portion of the community. Suicide is frequently interchangeable in transmission with other diseases, especially diseases of the nervous system. Every alienist is aware of this, and it would be mere waste of time to quote the words of any one of them, or to give the history of families in which suicide has occurred several times. I have before me the statistics of the death-rate in England from 1866 to 1890, from which the following facts are taken:

Cause of Death.	Increase per cent. in 25 years.
Cancer.....	75.5
Nervous diseases.....	10.2
Premature birth.....	26.5
Diabetes.....	103.1
Other kidney diseases.....	63.4
Heart diseases.....	65.9
Intemperance.....	59.0
Congenital malformation.....	21.5
Other constitutional diseases.....	118.7

The death-rate (in England) from pulmonary tuberculosis shows a decrease of 35.3 per cent., but the process of natural selection has been producing a decrease in the deaths from this disorder for (in English cities and towns) some 75 years. That there has been any appreciable increased rate of decrease since the discovery of the Koch bacillus in 1882 is not shown by any statistics that I have been able to discover. As tuberculous diseases still furnish 12 per cent. of all the deaths in England, it is evident that those predisposed to consumption are not abstaining from the reproduction of children, many of whom die insane, and some of whom die of cancer. The extreme contagionists make a great deal of noise, but they appear to forget that a congenital consump-

tive is a true degenerate, both mental and physical, and that the bacillus tuberculosis is the benefactor of the race if it removes him before he has succeeded in adding to the degenerate population. If, however, the contagionists would find some large city where the death-rate from phthisis shows a marked additional rate of decrease since 1882, their "anti-septiphobic" clamor might receive some serious attention. The bacillus tuberculosis does not attack persons in normal health, and it has a special predilection for the insane.

The question of nativity in reference to suicides in America is, perhaps, of some importance, since the uninitiated attribute always every mark of degeneration to "the foreign-born element." To obtain accurate figures upon any subject, outside of industrial questions, is, in this country, practically impossible. The numerous officials who are appointed or elected by the various States, having received positions as a reward for political services, are not interested in statistics, even if they are competent to compile them. The collection of figures once in a decade for the Federal Census is quite insufficient, and the volumes containing the information take years to reach the public libraries. A portion of the Census of 1890 is not yet (July, 1897) ready! A permanent United States Registrar of Statistics, with a competent staff, which ought to be absolutely outside the interference of the politicians—if such a condition is possible—is urgently needed.

The following figures relate to New York City. As far as I can judge, however, they furnish a fairly accurate index to the nativity of the suicides all over the country.

	1892.	1893.	1894.	1895.	1896.
Total number of suicides:	241	314	331	376	384
Nativity.					
1. Germany.....	105	127	122	130	126
2. United States.....	57	81	100	108	109
3. Ireland.....	17	26	20	19	21
4. All others.....	62	80	89	119	128

While I should like to believe that an American nation is being produced which is superior to that inhabiting any other land, I do not find any signs of it in the statistics of self-destruction among the native-born in New York City. It is possible, of course, that suicide may be most common among the children of foreign-born parents, but such evidence as I have been able to obtain seems to show that the American system of living at "high pressure"—the haste to become rich—is not conducive to racial progress.

To sum up: Suicide does not appear to any ap-

¹ It is the fashion to speak of "Americans" as if there existed an American race, the prevalent idea being that, when three generations have been born in the United States, the "race" has been established.

preciable extent among savages, but is a product of civilization; it depends chiefly upon some constitutional depravity, as is shown by its emanation from bad stock, by the hereditary character of the predisposition toward it, and by the fact that in transmission it is very often handed down exactly as are other pathologic variations depending upon constitutional degeneration.

The time at my disposal compels me to devote the remainder of my paper to an attempt to answer the question, How can the brake be applied to racial deterioration, as evidenced by the increase of suicide? I do not wish it to be supposed that all members of every family in which epilepsy, idiocy, insanity, or suicide has occurred are so degenerate as to be unfitted to reproduce their species. Such families, however, must be regarded with suspicion. Other symptoms of decay should be looked for, and if they are, they will frequently be found. The first question to ask is, Does phthisis "run in the family?" or, to use scientific language, Does each generation inherit the tuberculous diathesis, and transmit it to its successor? The ebb of the tide of vitality of the family, and the danger to the race, must be estimated by the sum of the imperfections which are to be met with in the family history.

The appearance of nervous disorders usually proves that a tendency to decay has presented itself in a family; when suicide has also appeared the decay has actually begun. If such a family is to exist for more than three or four generations, an attempt must be made to increase its vitality by the infusion of untainted blood and by attention to the laws of health. I am not sanguine as to the results of these methods, because I do not believe that acquired characteristics are inherited, nor am I convinced of our ability to "breed out" pathologic variations. There is, nevertheless, a process by which the regeneration of the race may be accomplished, *viz.*: by artificial selection in reference to marriage. If those who are abnormal would refrain from the reproduction of the species, the problem would be solved. In my opinion it is our duty to teach that the markedly unfit should not propagate their kind. Of course, we ought to care for the weak and the suffering, but that any individual having a constitutional disorder should contaminate the race and increase suffering and misery by propagating his unfitness is, from a scientific standpoint, unpardonable. Careful and deliberate cultivation of all that is worst in humanity, as exemplified by the lunatics, the epileptics, the scrofulous idiots, the instinctive criminals, the deaf-mutes, the habitual drunkards and the suicides, is largely responsible for the condition in which we find the English-speaking world to-day; and unless

we make a serious attempt to teach the principles of general evolution to our boys and girls, no improvement can be expected. The time has arrived when physicians should speak out; the cure of disease may be a very good thing in its way, but the reduction of it by means of celibacy upon the part of the unfit would be of much greater benefit to the community at large.

THE PRESENT STATUS OF PRACTICAL ORTHOPEDICS.¹

By HENRY LING TAYLOR, M.D.,
OF NEW YORK.

FOR convenience the commoner affections which tend to cripple the framework of the body may be divided into the following classes: (1) Those due to anomalies of development. (2) Those due directly to violence. (3) Those due to pressure or overloading, commonly of weakened structures. This class may be subdivided into the rachitic and non-rachitic. (4) Those depending upon functional or organic nervous disease. (5) Those depending upon some pathologic process in or about a joint, or about the spinal column.

In the treatment of developmental deformities the indications are to correct malpositions, to restore the parts to their normal relations, and, while preventing relapse, to strengthen them by use within normal limits. Of the many congenital deformities only two need here be considered—pes equino-varus, on account of its frequent occurrence, and congenital hip luxation, on account of recent progress in its treatment.

In the case of ordinary clubfoot, treatment by manipulation should begin at once, and in the mildest cases this may suffice; in most, however, the bulk of the work will have to be done through mechanical correction. Whatever the means employed, the varus element should be first corrected, afterward the equinus. Many of the younger cases will do well under frequent applications of plaster of Paris, increasing the correction a little at each sitting. A very satisfactory method is to force the foot outward by a straight Judson brace, afterward correct the equinus, and retain by a Taylor brace; or the latter may be used from the start. The main point is to persist until the deformity is thoroughly overcorrected, after which the foot must be retained and used in this position until there is no tendency to relapse. The patient must be kept under observation for from one to several years. Relapses and unsatisfactory results are nearly always due to imperfect correction, or to too short a period of retention. If the case lags and

¹ Read before the Northwestern Medical and Surgical Society of New York.

ceases to progress under the plan of gradual molding or unfolding of the foot, resort should be had to forcible manipulation under an anesthetic, the massage to continue for from five to ten minutes or until the foot, taken between two fingers, falls readily into the overcorrected position. Tenotomies of the heel-cord and plantar fascia should be performed if necessary to complete reduction. This is a very successful procedure and often saves a great deal of time; it is ineffectual unless followed by thorough after-treatment. Severe operations on the bones or soft parts are rarely necessary when the above plan is faithfully carried out in children under six or seven years of age. In the obstinate deformities of adolescents and adults, very fair correction may be obtained at one or two sittings by means of special apparatus, such as the Bradford adjuster, combined with tenotomy, and followed by proper after-treatment. There is no more satisfactory class of cases; when seen early, all should be cured, and the old and neglected cases are capable of great improvement.

Congenital luxation of the hip may be due to defective development of the acetabulum or to a traumatism at or before birth. A few cases of cure from prolonged traction have been reported, but until operative reposition was begun by Hoffa and improved by Lorenz not much advance was made. Considerable success has followed the improved operation, which has been done over two hundred times by Lorenz. In the meantime, Paci of Milan brought forward a method of reduction by manipulation, which has recently been improved by Lorenz, and he claims very good results in appropriate cases. His procedure is as follows: The leg is brought down into a position of complete extension with abduction by very strong traction until the trochanter is at or below Nélaton's line. The thigh is then flexed to 90° , rotated slightly inward, and abducted to 90° , which jumps the head of the femur over the rim and into the acetabulum with a sound and a shock. The thigh is retained in strong abduction by means of a plaster spica extending to the knee, in order to prevent recurrence, and the patient is soon encouraged to walk with a high patten on the well side in order to mold the acetabulum. At subsequent dressings the abduction is lessened, and after six months or so the patient may walk with an inch extra sole on the well side. Reduction by this method has been performed one hundred times; it is applicable to the younger and unilateral cases. It is too recent for us to judge of the ultimate results, but it offers very great encouragement in this difficult class of cases.

Omitting, on account of lack of time, those deformities due to trauma, we take up the large and

important group of pressure deformities, where, owing to excess of load or, more often, to deficiency of resisting power, some part of the body framework yields and becomes deformed. This group includes flatfoot, weak ankles, bow-legs, anterior curve of the tibia, coxa vara, pigeon-breast, round shoulders, and lateral curvature of the spine. Nearly all of these deformities may be due to rickets, but they are very frequently due to other causes. Any condition which interferes with nutrition and vigor tends to laxity of fiber, and may result in a deformity of that part which bears the blunt of the load, especially during the period of rapid growth. The principles of treatment are to improve nutrition and muscular strength, and to mechanically shift the incidence of the load, so that it shall act as a correcting force, or when that is not possible, to rapidly correct the deformity by a surgical operation.

In bow-legs the tibiae are curved outward, or outward and forward, and the femora and knee-joints may contribute to augment the deformity. Relaxation of the external lateral ligaments of the knee-joints and pigeon-toes often accompany bow-legs. A certain amount of bandy-leggedness is natural to some infants, and this is often aggravated by allowing the child to walk when too young. In mild cases occurring in very young children the legs should be manipulated, and standing and walking limited. In mild cases of longer duration the outer side of the shoe in addition should be built up one-quarter of an inch. When this is not sufficient, and the patient is under four or five years of age, brace correction must be employed, the Knight brace being a good one for this purpose. Most of the mild and moderate cases may be cured by these means. In older patients, or in more obstinate cases, the tibia may be broken or chiseled and the deformity forcibly corrected. The operation usually performed in New York is a subcutaneous osteotomy at the point of greatest curvature of the tibia, which is usually at the junction of the lower and middle thirds. This operation is simple, is not severe, and with proper after-treatment usually cures the deformity.

Anterior curvature of the tibia is much more difficult to treat, and in very bad cases a cuneiform osteotomy is indicated. In both of these affections there is, in the milder cases, considerable tendency to spontaneous improvement, and in cases in which the deformity is arrested, natural growth will improve the shape of the parts.

Knock-knees show much less tendency to self-correction; relaxation of the internal lateral ligament of the knees, weak ankles, and valgus, or flatfoot, are frequent accompaniments. In mild cases, walking and standing should be limited, the legs manipu-

lated, and the inner side of the shoes built up one-quarter of an inch. In cases of moderate severity the Thomas knock-knee brace is often effective, while in older patients and in severe cases an operation is indicated, the preferable one being a subcutaneous osteotomy of the femur a finger's breadth above the condyles, either on the inner side (McEwen's operation) or the outer (McCormac's). The deformity is corrected by manual force after partially severing the bone, and a spica bandage is applied and allowed to remain for six weeks; the legs often require further support by braces or plaster. In general, the results are good or fair; partial correction, however, is not uncommon. An angle remains at the point of fracture, where it does no harm and is partially effaced by growth. Unless great care is taken in the after-treatment, recurrence may follow.

Owing to imperfect development and lack of vigor, weak ankles, with more or less abduction and eversion of the feet, are very common in city people, especially women and children. The conventional treatment with stiff-ankled shoes is perfectly futile.

The shoes, natural shape ("Waukenphast"), should be built up on the inner side, and the legs manipulated and exercised, with special reference to strengthening abduction, inversion, and flexion of the foot, and the general health should be improved.

The modern treatment of flatfoot is a notable improvement over that of a few years ago. Through the labors of Whitman and others, it is now recognized that this affection is a partial dislocation, often complicated by subacute inflammation about the pinched or stretched parts. In mild cases with little or no spasm, building up the inner side of the shoe in order to force the patient to bear more weight upon the outer border of the foot, and manipulations and exercises to favor inversion, abduction, and flexion, will often answer. In other cases, strapping the foot in the inverted position with adhesive plaster is of service. In obstinate cases, with considerable pain, spasm, and rigidity, the malposition must be overcome by forcible reduction under the influence of an anesthetic, and the foot put up over-corrected in plaster for three or four weeks. Occasionally, tenotomy of the heel-cord will be required in order to effect a perfect reduction. After the period of retention, a foot-plate should be made over a corrected cast, and the muscles strengthened by massage and special exercises. The results, even in these bad cases, which were formerly practically hopeless, are very good indeed. Comfortable, useful feet are the rule.

Round shoulders, like the other affections of this group, when not rachitic, are usually due to a se-

condary life, imperfect development, and lack of vigor. This defect is not confined to the trunk, but is general; weak ankles and flat feet are frequently associated with it. It should be remembered that this distortion primarily is not of the shoulders; it is first of all a sagging of the thorax, with posterior projection from lack of muscular tone, deficient chest expansion, and faulty attitude. The remedy is to correct these conditions by outdoor sports, general and special exercises, and tonic and hygienic treatment. Shoulder-straps and exhortations to throw the shoulders back are equally useless. These cases, especially if of long standing, or combined with considerable rigidity of the spine and thorax, are neither unimportant nor easy to treat. The vitality and endurance of an individual so affected is seriously compromised by his deficient chest capacity and breathing power, and it is well worth while to treat the condition seriously. A country life, or if that is not possible, an approach to the conditions of country life, with systematic special training to expand the chest and develop grace and flexibility of attitude and muscular tone, correction of the malposition, is usually followed by excellent results.

The subject of lateral curvature is easily the most difficult one in orthopedic practice. In spite of the extraordinary amount of ingenuity and study devoted to its elucidation, the best authorities have a very modest feeling in regard to their knowledge of its causation and treatment. This is not to say that many facts are not known regarding it, or that treatment is useless, for that is far from the truth; but the subject remains to be mastered. Lateral curvature is, of course, due to a variety of causes, some of them well understood, but the ordinary or idiopathic cases are here particularly referred to, in which no very obvious cause is apparent. In such cases we are in the habit of attributing the condition to muscular debility and habitual faulty attitudes, and no doubt they are partially to blame for it. Our inability to entirely correct the rigid bony deformity makes it exceedingly important that the mild and beginning cases should be recognized early and seriously treated, and one should not be deluded with the vain hope that it will be outgrown. Many cases are spontaneously arrested, with only a moderate degree of deformity, but we are as yet unable surely to distinguish such cases in their early stages from those that will go on to crippling deformity, unless checked by treatment. The mild and early cases do exceedingly well on tonic and hygienic treatment similar to that proper for round shoulders, with much attention to special corrective exercises and manipulations, and to the regulation of the daily life. It is frequently advisable to interrupt school-going for a

time, and to prescribe short daily periods of recumbency. Piano practice I have found to be specially harmful, and it should always be stopped; singing, on the other hand, is beneficial. Cases of moderate severity, with considerable spinal rigidity require more energetic treatment, and for longer periods; some form of suspension may be used in order to increase spinal flexibility, and for some the pressure frame is useful. Apparatus and jackets are not to be employed unless the curvature is increasing, and this should be determined by accurate measurements from time to time. In these cases of medium severity the health may usually be improved, chest expansion, spinal flexibility, and muscular strength increased, and the attitude and appearance of the patient improved, but a considerable amount of curvature still remains at the end of our labors; in favorable cases, however, this is so slight as to be unnoticed under the clothing. In the bad cases, which get worse in spite of treatment, some kind of supporting apparatus must be worn; this should always be combined with daily developing and corrective exercises. Many of these patients, after a long period of treatment, may be able to dispense with their apparatus, and lead active and useful lives free from suffering and with fairly presentable figures. A few cases, usually those seen late or complicated with paralytic or other serious affections, go on to extreme deformity.

The group of crippling disorders, the seat of which is principally in the nervous system, is a large and important one, but only two need be considered here, namely, poliomyelitis anterior acuta, and the infantile cerebral palsies; these are chosen mainly for the reason that while both affections are essentially incurable, orthopedic treatment is of great benefit. The indications for treatment are to prevent or correct deformity, to improve local circulation and nutrition, and to bring crippled parts into action, while preventing undue strain on weakened muscles and flaccid joints. The problem confronting one in both affections is that of educating, disposing, and correlating intact, or measurably intact, parts in such a way as to fit them for the best service of the individual. On the same principle that the hand in wrist-drop, or the cheek in facial palsy should be supported to prevent the deleterious effects of traction upon palsied muscles, so a drop-foot, or other deformity of the limb, should be forestalled and the muscles allowed to recover their tonicity, so far as they are capable of doing, by the use of proper mechanical appliances. These should always be so arranged as to bring weakened muscles into action; it is the unbalanced pull of the stronger muscles that is to be limited. Much permanent damage may be

done by permitting the vitality to be stretched out of muscles which are weakened but still active, by the unopposed drag of gravitation or the unbalanced pull of their antagonists. When seen early, available muscular integrity may be preserved, and serious deformity prevented. Such management gives the greatest effect to efforts to promote local nutrition by electricity, hot air, and massage. Children affected in this way often do great harm to their feet and knees in their efforts to walk unaided, when the adjustment of proper apparatus would be of the greatest benefit. Deformities which have already occurred should be corrected by mechanical or surgical means and relapse prevented.

The operation of tendon-grafting, which has recently come into prominence, is capable of doing considerable good in properly selected cases. It consists in attaching the tendon of an active muscle to that of one which has lost its power. The active tendon may be split, so as to pull upon both its old and its new insertion. The operation of arthodesis, or joint stiffening, has proved only moderately successful in infantile paralysis.

In cerebral palsies contracted tendons should be divided, as tenotomy not only permits the correction of the deformity but to a marked degree allays spasm and tends to restore the muscular balance. This will improve locomotion, and in some cases enable perfectly helpless patients to walk, and at the same time will exercise a happy effect upon the mental condition. When these measures go hand in hand with exercises and training to promote muscular control, marked improvement usually follows in all but the worst cases.

Functional nervous disorders may mimic almost any crippling affection, and often require more skill in their treatment than the disorders they suggest. Many cases of weak, tender, or aching back belong in this category. The condition of the bedfast or semibedridden neurasthenic appeals strongly to our sympathy; these are border-line cases—the treatment of which few care to undertake. I mention them here only to say that I have usually found them very amenable to energetic and systematic treatment.

There is still left the very important group of affections tending to cripple through inflammation or disease of the spinal column, or of one or more of the articulations. These joint troubles may be traumatic, tuberculous, suppurative, rheumatic, gonorrheal, syphilitic, tabetic, or may follow the acute infectious diseases. The indications for their treatment are to eliminate systemic poison when present, to allay pain, build up the system and improve the quality of the blood by the oxygen of the open air, diet, and medicaments, and to arrest

the local morbid process by means of enforced local rest, and the application of fixation and traction splints, with longer or shorter periods of recumbency. While the local process is subsiding, deformity must be prevented or overcome, and the articulation restored, so far as may be, to its proper function. The large majority of tuberculous spines and joints get well under faithful and persistent treatment. Something like ten per cent. of the patients afflicted in this way succumb to the morbid process or to complications. Diseases of the larger joints, when seen early, often recover without serious deformity or interference with function; sometimes without any. In the spine the result is less frequently so favorable. Patients suffering from a more advanced type of the disease in which loss of substance has already occurred, may, and usually do, recover with more or less stiffness, deformity, and disability, but still with very useful members. Those suffering from the worst form, and those in whom the condition is neglected, die, or recover with crippling deformity.

Excision has rather a restricted field in these cases. The results are better at the knee than at the hip. For patients who remain deformed after the cure of their disease, much may still be done to alleviate their condition. In fibrous ankylosis the flexed hip may often be mechanically stretched out, or forced down by careful manipulations. In severe adductions the long median abduction splint has given much satisfaction. If the union is a bony one, the femur may be chiseled below the lesser trochanter (Gant's operation), a procedure giving excellent results. At the knee, Bradford and Goldthwaite's method of forcible mechanical correction gives excellent results in apparently hopeless cases of angular deformity. Where there is bony ankylosis, resort must be had to excision. True pus must be evacuated whether in a joint or in the soft parts, but the collection of tuberculous detritus known as cold abscess does not call for summary treatment. Provided the original lesion is properly treated, the patient will do well, whether the abscess is evacuated or not; he is quite likely to do badly in either case if the diseased joint is neglected. Iodoform-ether and other injections are useful in old sinuses, even when they communicate with bone, but deep injections into the undrained joint or its neighborhood are quite as apt to do harm as good.

Leprosy in North Dakota.—The Surgeon-General of the Marine Hospital Service in Washington has been informed of the existence of two cases of leprosy in Walsh county, North Dakota. The disease is said to be well developed. Both of the patients are Scandinavians.

TYPES OF EDEMA IN INFANCY AND CHILDHOOD.¹

By J. P. CROZER GRIFFITH, M.D.,

OF PHILADELPHIA;

CLINICAL PROFESSOR OF DISEASES OF CHILDREN IN THE UNIVERSITY OF PENNSYLVANIA;

AND

WILLIAM S. NEWCOMET, M.D.,

OF PHILADELPHIA;

PHYSICIAN TO THE CHILDREN'S CLINIC OF ST. AGNES' HOSPITAL.

EDEMA, developing in early childhood, and especially in infancy, is sufficiently uncommon, as compared with its greater frequency in adults, to render its occurrence a matter of interest, particularly as its etiology is often so very obscure at this time of life. Our attention has been turned in this direction through a series of cases recently under observation, in some of which it was most difficult to determine the true nature of the affection.

In studying edema as presented in early life one's thoughts naturally turn first to the possibility of the presence of nephritis. That this disease may occur in the very young has been amply shown by many writers, notably by Jacobi², and by Felsenthal and Bernard.³ We ourselves have witnessed it repeatedly. Scarlatina is certainly one of its commonest causes, but it is well to remember that other infectious diseases, as measles, erysipelas, malaria, pertussis, diphtheria, and varicella may be accountable for the renal inflammation, and that eczema and other cutaneous eruptions appear to be the cause in occasional instances. Intestinal disease is not infrequently the exciting factor in infants. Often we can discover no cause for the renal disorder, and sometimes we may be able to surmise only; as, for instance, when slight traces of redness or of desquamation indicate that possibly an erysipelas or a scarlatina had previously been present.

That congenital syphilis is capable of producing nephritis and consequent edema is not yet universally admitted, although there are cases on record which appear to prove this with reasonable certainty. Yet these cases are rare. Audeoud,⁴ in a recent careful paper, was able to collect but six instances, besides one reported by himself, of what seemed to be undoubted nephritis from congenital syphilis, as judged by the symptoms during life. The cases reported are those of Bradley,⁵ Potain,⁶ Coupland,⁷ Massalongo,⁸ and Hock.¹⁰ In four cases autopsy confirmed the clinical diagnosis, and in three the evi-

dences of nephritis and of syphilis disappeared under antisyphilitic treatment.

The two following cases observed by us are of interest in this connection:

CASE I.—J. J., two months old, mulatto; seen for the first time January 21, 1897. The father acknowledged no symptoms suggestive of syphilis. The mother was apparently healthy and had had no miscarriages. Three other children were alive and well. When a month old the patient had some sort of erythema, which appears to have been slight and limited in extent. One week before his first visit he developed a bad attack of coryza. On examination, the child was seen to be of fairly healthy appearance. The nostrils were filled with a thick discharge which interfered with respiration. On January 27th, a desquamation was noticed over the hands, feet, face, and forearms. This was of a distinctly peeling character, suggesting scarlet fever; but interrogation of the mother failed to elicit the history of any eruption which would satisfactorily account for the symptom. A flat, macular, pale-red eruption, having all the appearances of syphilis, was present over the nates and especially about the anus and to a less extent over the thighs and about the knees. There was some excoriation about the anus. The nasal discharge was unabated. On January 29th the condition described was practically unchanged, and there was in addition evident edema of the lower extremities, and to a slight degree of the face also. Inunctions of mercurial ointment were ordered. This treatment was changed on February 1st to gray powder, internally, owing to the dermatitis which had been produced. Improvement began and continued slowly. By February 13th, the edema was scarcely noticeable in the face, though still present to some extent elsewhere. The anal excoriations were healing and the rhinitis was much better. By February 16th, the syphilitic eruption had nearly disappeared, and there was no more scaling, but still a little general edema. Examination of the urine made about this time showed quite a thick ring of albumin with Heller's test. Decomposition had advanced too far to permit of finding casts if present, but some leucocytes and small epithelial cells were observed. The child was seen for the last time on February 24th. It was then better in every way, although some rhinitis and edema were still present.

In this instance it seems impossible to determine absolutely whether the cause of the nephritis was syphilis or scarlatina. The whole complex of symptoms, however, and the recovery under antisyphilitic treatment, leave us in little doubt that the nephritis was syphilitic.

The second case appears to be an undoubted instance of syphilitic nephritis, in spite of the failure to procure urine for examination.

CASE II.—Baby R., male, born July 25, 1896. The mother appeared healthy; the father acknowledged having syphilis, and presented symptoms of the disease. The child was small, thin, and weighed but

4¾ pounds. The skin of the feet and hands looked as though blistered, was cracked, and came off like a glove, leaving a raw, bleeding surface. Over the body, but especially on the limbs and around the mouth, nose, and anus was an annular eruption, varying from pin-head to small-pea size. Coryza was present. Mercurial ointment was applied on the binder. On July 27th, the eruption had become pustular, with thick crusts and fissures about the nose, mouth, and anus. Some small aphthous patches were present in the mouth. The child improved slightly, but on August 3d dropsy appeared in the legs, and by the next day involved the lower extremities, face, and abdominal cavity. Under the continued use of mercurial ointment, combined with diuretics, the edema rapidly disappeared, as did the cutaneous symptoms later, and the child steadily improved in health, gaining two pounds by September 4th. It has continued well since that date.

In addition to the causes of nephritis mentioned, there seems no reason why a general septic infection should not produce severe parenchymatous changes in the kidneys. The following case appears to be an instance of septic nephritis: The origin of the infection could not be discovered. All the tissues of the body were examined except the bones, and it is possible that a septic inflammation of these may have existed. The case occurred in the service of Dr. J. C. DaCosta in St. Agnes' Hospital, Philadelphia, where we had the opportunity of seeing it. For the notes of the autopsy we are indebted to Dr. A. O. J. Kelly, pathologist to the hospital.

CASE III.—Eleanor M., born October 10, 1896. Weight 7¾ pounds. Except for slight ophthalmia and coryza, from both of which she recovered promptly, the child was entirely well until December 31st, when feverishness and malaise developed. On January 1, 1897, the evident illness had increased; there was decided pallor, and the right leg from the knee down was swollen, as was also the vulva. The latter was red and angry-looking, yet without the appearance of erysipelas. By January 2d, the edema had extended to the thigh, and on this day or the next a swelling appeared over the left parietal bone. On January 3d, swelling of the left elbow-joint set in.

We saw the child on the morning of January 4th, and found it very ill, seeming to suffer pain and crying weakly if disturbed. It was of a waxy pallor, with a slight icteric hue, and the conjunctivæ were decidedly yellow. On the left parietal prominence was a large projecting swelling, very hard, and the size of a walnut. The eyelids, both upper and lower, were edematous, making the eyes appear deep-set and small. The rest of the face was slightly swollen. The left elbow presented a spindle-shaped swelling, somewhat tender but not red. The right leg and thigh were very edematous throughout, the swelling being tense but without redness. Both external labia were swollen but not discolored. Nothing abnormal could be discovered about the bones of the lower extremities. The ribs were slightly beaded.

Examination of the liver and spleen gave negative results. A stool passed during the examination was formed and almost white. No temperature record was kept. The child died a few hours later. Urine taken from the bladder after death contained about one-sixteenth albumin by bulk, with leucocytes and numerous bacteria, but no casts could be found, the decomposition having doubtless destroyed any which might have been present.

The autopsy showed that the parietal swelling had flattened very much after death. Pus was discharged on incision. The left elbow-joint was very much swollen, the bones being loosely attached and giving a rough sensation when rubbed together. The joint contained pus. The external genitals were much swollen. The right lower extremity was greatly swollen, pitted on pressure, and on incision discharged a clear serous fluid. The crural vessels were normal. The thoracic viscera showed nothing worthy of note except that the heart-muscle was flabby, friable, and yellowish-red in color. Incision of the abdominal cavity revealed an acute general peritonitis with recent adhesions and a seropurulent fluid with flakes of lymph. The spleen was much enlarged, very soft, and dark reddish-brown; the liver enlarged and slightly fatty; the kidneys enlarged, soft, pale-yellowish in color, with reddish areas, and with the cortex thickened. The other abdominal viscera and the internal genitalia were normal. Microscopic examination of the organs showed slight fatty degeneration of the heart-muscle and of the liver. There was general hyperplasia of the elements of the spleen. Many of the epithelial cells of the convoluted tubules of the kidneys had desquamated, and many had lost their outline, and the nuclei stained little if at all.

Children may develop an edema, more or less general, in which no distinct evidence of nephritis exists. For instance, it sometimes happens that erysipelas neonatorum will leave a comparatively extensive dropsy, yet without signs of renal disease. Sometimes scarlet fever is followed by dropsy yet without albuminuria. Quincke¹ refers to an epidemic of scarlet fever occurring in Berlin, described by Phillip, in which anasarca developed in about one hundred cases, and in at least sixty of these no albumin could be discovered in the urine. Goodhart,² also, has reported similar cases, and warns against the hasty conclusion that nephritis is not present because there is no albuminuria. Dickinson³ reports some interesting cases in which no cause whatever could be discovered for the widespread edema, and in which there had certainly been no scarlatina, and no albumin could be found in the urine, yet in which autopsy showed the existence of nephritis.

As in adults, localized edema may occur as the result of pressure upon venous trunks. This is per-

haps oftenest due in children to the existence of enlarged bronchial glands. The existence of valvular cardiac disease may produce a general edema in early life. So, too, any state of extreme exhaustion, debility, and anemia may be attended by a marantic edema, during which no albumin may be found in the urine. In our experience, this is proportionately much less common in infants than in adults, if we take into consideration the vast number of instances of marantic states which occur in early life. The causes of this edema at any time of life are the same; *viz.*, a hydremic state of the blood and a tendency for the serum to leak through the vessel walls. Some of the cases have been proved by *post-mortem* examination to be entirely free from renal disease, but in other instances the reverse is true.

In this connection we may refer to the strange disease known as edema neonatorum. As Ballantyne¹ has well pointed out, this is rather a symptom of several conditions than a pathologic entity. But until we understand the matter better it is convenient to classify these conditions together under the one name. As ordinarily described, edema neonatorum usually occurs in very weakly or premature infants. It generally, but not necessarily, begins before the third day of life. It is characterized by low temperature, coldness of the surface, and a widespread edema, which pits on pressure, although with difficulty. The child is apathetic and unable to nurse; the pulse and respiration slow and weak. Death nearly always takes place, but recovery is occasionally observed.

Whether or not edema neonatorum is to be considered identical with sclerema neonatorum, has been, and still is, a much disputed question. Parrot believed them different, and Ballantyne and others share this opinion, while, on the other hand, many describe them as identical or at least as forms of the same affection. There seems, we think, good reason to believe them entirely different, and it is even a question whether sclerema is justly to be classified as an edema of any sort.

Edema neonatorum and sclerema neonatorum are alike in their development in feeble and often in premature infants, in the low temperature present, and in the excessive weakness seen, but in sclerema the skin is hard and will not pit, cannot be pinched up into folds, is often discolored, seems adherent to the subjacent parts and will not exude serum when cut at the autopsy. There is also rigidity of the whole body. It is certain, however, that the two diseases may be associated in the same case, as Parrot states.

Sclerema begins oftenest during the first two

weeks of life, but may not develop until later. The induration is limited at first, but spreads rapidly over much of the body. A discoloration of the skin is often present, as already stated. Although often confounded with it, the disease is to be distinguished from scleroderma, which is a chronic, usually localized, and generally not especially dangerous affection of the skin.

Various theories have been advanced to explain the hardening of the skin in sclerema, one being that it depends upon a thickening of the subcutaneous bands of connective tissue. Possibly, also, it is due in part to a solidification of the fat, dependent upon its different constitution in very young children, as claimed by Langer.¹

The following case of sclerema recently came under our observation:

CASE IV.—John C., Italian, fifteen days old. The father and mother and two of their children were living and well. Two other children had died from causes unknown. The patient was said to have been ill for a week with rapid respiration and a cough, and had vomited milk at times. He was taken to one of the Philadelphia hospitals where the diagnosis of pneumonia was made. No careful examination was made of the surface of the body, but slight subconjunctival hemorrhage was noticed. On the same day, or possibly the following day, the child was taken to the Children's Hospital, Philadelphia, where he was admitted February 6, 1897, at about 1 P.M. He was apparently in a dying condition, being cold, stuporous, and pulseless, with corneal reflex scarcely obtainable. The temperature in the rectum was 93.8° F., and the respiration 48. The mother called attention to the hardness of the child's cheeks, which she said she had noticed on that day for the first time. Ecchymotic spots were present on the eyelids, and these, the father maintained, had been there since birth. Discoloration of the nates, resembling bruises, was observed. This, the father insisted, had not been present before the child's visit to the hospital referred to.

The child was at once put to bed and stimulants and external heat employed. After some reaction had occurred, the chest was examined and the physical signs of pneumonia found. At 6 P.M., his temperature was 94° F., and respiration 42. During the night following, the child had a convulsion. We saw it for the first time on the morning of the next day, February 10th, when it presented the following condition: It was evidently extremely ill and lay for the most part perfectly still, with the eyes half closed. Respiration was rapid and shallow, the pulse feeble, the color pale and slightly cyanotic. Slight subconjunctival hemorrhage was present, and some small ecchymotic spots on the eyelids. Both cheeks appeared rather full, and on examination were found to be much thickened and of stony hardness, without the slightest pitting on pressure. There

was no discoloration of the parts. Examination of the inside of the cheeks with the finger revealed nothing abnormal. Over the buttocks, lower part of the back, and upper part of the thighs, the tissues exhibited the same indurated condition, with a bluish, and in some places yellowish discoloration, exactly resembling the colors of a bruise a few days old. This bruised appearance was best developed in the neighborhood of the anus. The thighs were hard and rigid, but not discolored except in the upper parts. During the morning of February 10th, his temperature rose to 101° F. (possibly aided by the continued application of heat), he had a few convulsive movements, and died at noon.

No autopsy was allowed. Examination of the surface of the body after death showed that the blue color had faded to a slight extent. A faint bluish discoloration had appeared over a small area near the navel. The induration of all the affected parts was unchanged, except being a little less marked over the nates. The bladder was aspirated to obtain urine for examination, but without success.

Sclerema neonatorum is rare in all parts of the world. We have looked through the medical literature at our command in order to discover the cases reported in America and have found but few. Some of these are of rather doubtful nature, while others are merely referred to in the discussions which took place of some of the papers contributed upon the subject. We have found but five fully detailed cases which exhibit the complex of symptoms usually considered characteristic of the disease. We have epitomized them as follows:

A. H. Robinson (*Arch. of Dermatol.*, viii, 337, 1882): Well-nourished boy, seven months old, had many convulsions during the first day of life and intense jaundice on the third and fourth days. On the second day of life induration appeared over buttocks and extended half way down outer aspect of thighs. Affected skin not unusually pale, and not cooler to touch; moderately edematous. Temperature taken once registered 101° F. Child steadily improving at time of report.

In the discussion of this case, Weisse referred to two instances of the disease seen by him, in one of which the induration began at the back of the neck and extended all over the body and the back of the legs. Both patients recovered. Piffard said he had seen one case. Taylor had seen two cases, both in children two to three weeks old, and both terminating in recovery. The disease extended over the entire body.

In the absence of further details the suspicion is strongly aroused that the cases referred to in the discussion were instances of some form of edema, and not of sclerema.

Ellen A. Ingersoll (*Peoria Med. Monthly*, viii, 240, 1887-8): Mother alcoholic. Boy, well developed at birth. On third or fourth day of life scrotum and anterior surface of thighs became swollen and hard, the skin and subcutaneous tissues being involved. The affection spread over lower extremities, then attacked face and neck, then chest and upper extremities. Death within forty-eight hours, apparently from involvement of muscles of respiration and deglutition.

¹ Wiener Sitzungsbericht., 1881.

W. P. Northrup (*Transac. Amer. Ped. Soc.*, i, 140, 1889): Girl, five days old, one of twins, weight seven pounds. Feet puffy, rectal temperature 96.5° F., and remained low. Examination two days later showed induration throughout lower and upper extremities, hips, shoulders, scalp, and face; most marked on thighs, arms, and cheeks, least so on abdomen; color brownish-yellow. Body stiff and very cold, as though frozen. Rectal temperature would not reach lowest figures of the thermometer, i.e., 96° F. Died on ninth day of life. Autopsy revealed no edema; tissues cut hard; microscopic examination of skin showed nothing abnormal.

In the discussion of this case Huber said he had seen a fatal case in a child several months old. The symptoms were identical with those described by Northrup. Koplik said he had seen cases. Holt reported a doubtful case in a child thirteen days old, in which scattered sclerematous patches appeared over the shoulders, back, arms, neck and in the cheeks. The temperature was not subnormal. At the end of five months the patches had nearly disappeared. [Later, Holt ("Diseases of Infancy and Childhood," p. 117, 1897) says he has seen five cases.]

L. F. Barker (*Trans. Amer. Ped. Soc.*, v, 142, 1895): Boy, well developed at birth, taken with pneumonia when nearly nine weeks old. On the eighth day of this illness skin of buttocks was found to be hard. By the next day whole body was of woody hardness; skin could not be picked up and was cold; limbs rigid; power of swallowing lost. The scrotum was the only portion not affected. The child died on the succeeding day. Temperature during the attack of sclerema was not depressed, and on one occasion reached 102.5° F. Autopsy showed skin of marble whiteness without pitting on firmest pressure. It creaked when cut. Microscopic examination showed principally swelling and thickening of the fibrous bands of skin and subcutaneous tissue.

In the discussion of this paper Jacobi stated that he had seen a few cases.

J. L. Porteous (*New York Med. Jour.*, lviii, 442, 1893): Infant (sex not stated), developed the disease when two days old. When seen on the fourth day of life skin of legs, feet, arms, hands, back of shoulders and upper part of chest "had the feeling of india-rubber stretched over a frame." Color varied from deep purple to pink. Cry feeble, respiration seemed difficult; child stretched itself frequently "as if it felt stiff all over." Temperature 97° F. Constipation obstinate; punctures of skin let out only a little blood and yellowish fluid. On sixth day of life temperature fell to 87° F., and child died.

In addition to these cases there are two which have sometimes been considered instances of sclerema, but which cannot properly be placed in this category. They are as follows:

C. D. Smith (*New York Jour. of Med.*, xii, 190, 1854): Male child, presumably more than a year old; well when born. At age of six weeks developed swelling of the right hand, which progressively increased for six months, and then remained unaltered without extending. Child still living and in excellent health. Induration was hard as marble, with the local temperature lower and the color whiter, but sometimes purplish. It was painless and would pit on pressure.

C. C. McDowell (*Maryland Med. Jour.*, i, 203, 1877): Child three weeks of age had "the dermal lesion," involving the cutaneous surface largely (but a nearer description is not given). Subject to attacks of partial pulmonary collapse, and with these the dermal lesion was

"always exacerbated." It recovered after four or five weeks.

We have still to refer to that curious condition, angioneurotic edema, as it was first called by Quincke. This affection, not particularly common at any period of life, is certainly uncommon during early childhood and especially during infancy. The following case seems properly to belong in this category:

CASE V. — Andre P., aged two and one-half months, of apparently healthy Italian parentage. The history could be obtained only with the greatest difficulty. It appeared that two other children were living and well. The patient apparently was well and properly developed when born, and remained in good condition until about one and one-half months old, when red blotches began to develop on different parts of the body. These would last only a few hours in any one spot and be followed by edema. The redness and edema shifted from spot to spot, lasting a few hours to several days altogether. The bowel movements had been loose and green for about a week before the child was seen by us.

The first examination, made June 18, 1896, showed the child to be much emaciated and decidedly anemic. The heart and lungs appeared to be normal. The right hand and forearm were edematous, pitting on pressure, and of normal color except for a glassy appearance. This condition was said to have been present for four days. The right leg and foot were swollen, and the mother stated that they had been more so, and that the genitals had been swollen also. The right side of the face was flushed and slightly harder than the left, but there was no distinct edema of the face, although it was stated that there had been some earlier that morning. The child's temperature was 100° F. The urine did not contain albumin. On June 19th, the left little finger was edematous and glassy in appearance. The redness of the face had disappeared. The right hand and leg were much swollen. The temperature was 99.2° F. On June 20th the edema of the left little finger and of the right hand and forearm had disappeared and that of the right leg was much better. There was a swelling over the right biceps, which had developed during the night. It was the size of a walnut, red, painful, and very hard. His temperature was 100.2° F. A second examination of the urine was negative. By June 22d all edema had disappeared except over the biceps, where it was somewhat more extensive and still slightly red. By June 25th this was less red, more glassy and very painful. The disturbance of the bowels had continued more or less from the first visit.

The child was lost sight of until July 17th. Then it was learned that the swelling on the upper arm had seemed obstinate in disappearing, and that the child had been taken to some hospital. There it was supposed that an abscess was present and an incision had been made, but as far as could be learned no pus was discharged. The child was still thin, but appeared well in other respects.

Angioneurotic edema is certainly closely allied to

urticaria, and, in fact, is probably identical with the so-called giant urticaria. It is certainly related to some of the manifestations of peliosis rheumatica and to Henoch's purpura. The following case, occurring in a child, illustrates a condition which might be described either as angioneurotic edema or as purpura urticans. The element pointing toward the former is the fact that the edematous part of the body was but little affected by the urticarial eruption.

CASE VI.—Barty C., five and one-half years old. On the evening of March 2, 1897, he developed a rash on the back and abdomen which strongly suggested measles, yet without the characteristic grouping, and with the presence of a few urticarial wheals. On March 3d the rash of the day before had become purpuric, and there was an additional development of a widespread erythema, with wheals. The face was very edematous, not flushed, and looked like typical nephritis. By March 4th the eruption was rapidly fading and the edema better, and by March 5th all symptoms had disappeared. Repeated examination of the urine had shown nothing abnormal.

The chief characteristic of angioneurotic edema is expressed by the definition "acute, local transitory edema." It is possible, however, as some cases have shown, for the edema to be more persistent in character. As a rule, the swelling appears suddenly upon some part of the surface, perhaps always the same in each attack, or varying in locality in different attacks, or leaving rapidly one part to develop suddenly in another. It lasts for hours or days. Gastro-intestinal disturbances not infrequently accompany the swelling. Heredity has a very decided influence in many cases. Exposure to cold is often an active exciting cause. The disease is probably a vasomotor neurosis, as Quincke maintained. It is associated in some way with forms of urticaria and of purpura, as the case just detailed exemplifies.

Angioneurotic edema developing early in life is rare, as we have said; yet it is noteworthy that one of the first reported cases (Dinkelacker) occurred in an infant. We have made some search, although not exhaustive, through medical literature for cases beginning during early life, but have found few. Very briefly abstracted they are as follows:

Dinkelacker (*Inaug. Dissertation*, Kiel, 1882): Boy of one year; had attacks of local edema from the age of three months. The father was also subject to the disease.

Falcone (*Gaz. degli Ospedali*, vii, 125, 1886): Boy of seven years; had well-marked attacks. His grandfather also had the disease.

Widowitz (*Jarhb. für Kinderheilk.*, xxv, 252, 1886; xxix, 388, 1889): Three cases. (1) Girl of seven years, in whom attacks of edema of nose, cheeks, and fingers had occurred since age of four years. (2) Boy of eight years, in whom attacks of edema of fingers and cheeks occurred from exposure to cold since age of six years. (3) Boy of six years, with swelling of face, and often of fingers, resulting from cold.

Johnston (*Amer. Jour. Obstet.*, April, 1885): Five-year-old girl; affected since three months old. Feet and hands grew red, swollen, and painful. Attacks brought on by exposure to cold.

Josephs (*Berlin. klin. Wochenschr.*, No. 4, 77, 1890): Five-year-old boy; affected since age of 2½ years. Swellings of unclothed parts when in cold wind. He had had an attack of hemoglobinuria. An eight-year-old cousin had similar swellings.

Loimann (*Wien. Med. Presse*, 753, 1888): Six-year-old boy; affected for three years. Attacked eyelids especially. Later, face and genitals.

Graham (*Ann. of Gynec. and Pediat.*, April, 1894): Child of seven years and nine months; affected since one year old. Frequent swelling of eyelids and face.

Mooney (*Detroit Med. Age*, xiv, 10, 1896): Girl of nine years. Backs of hands attacked.

Yarian (*MEDICAL NEWS*, August 29, 1896): Woman had had attacks from childhood. Edema, with vomiting, epigastric pain, and weak pulse. Mother had attacks from childhood. Maternal uncle affected. A girl cousin had attacks of edema. Boy cousin had the disease and died at age of seven. Maternal greatgrandfather and grandfather and some of the great uncles had periodic edema.

Gevaert (*Rev. Mens. des Malad. de l'Enfance*, xii, 369, 1894): Girl of three years; had transitory edematous tumor of left side of neck.

Osler (*Amer. Jour. Med. Sci.*, xcv, 362, 1888): Family history of five generations; twenty-two persons affected. Among them one man suffered from his youth; one girl of ten or twelve years was affected; one girl began to suffer when four or five years old; one girl had swollen legs ever since she was a small child.

Henoch (*Vorles. ü. Kinderkr.*, 8 Aufl., 612): Four cases reported, the first evidently belonging here; the others not so certain and not called angioneurotic. (1) Girl of four years; attacks of edema of feet, hands, and face, with malaise and vomiting. (2) Girl of four years; attack of edema of face and feet from exposure to cold. Pain in feet; anorexia and slight fever. (3) Boy of nine years; an attack of edema of face, scrotum, and prepuce. No cause found. (4) Child of four years; an attack of edema of face and thighs. No cause found.

Rotch (*Pediatrics*, 484, 1896): Two cases. (1) Boy of 2½ years. First attack at nineteen months. Eating of eggs would cause edema of eyes. (2) Boy of three years. Edema of hands. Attack ceased after circumcision of tight prepuce.

Masterman (*Brit. Med. Jour.*, i, 846, 1897): Boy of eight years. Severe edema of left leg and arm, and of eyelids, with purpura and pain, then of right arm with fresh purpura and severe pain. Later, an attack of dysentery.

There are, finally, the cases of edema occurring during infancy, which are of entirely doubtful origin and nature. We have already referred to the element of doubt attending many cases. Milroy¹ reports an interesting family history, in which, out of ninety-seven individuals in six generations, twenty-two had been affected. The edema involved one or both legs, and was permanent. It was congenital in origin except in one case, not beginning in this until the age of twelve years. These cases were believed by Osler to be allied to angioneurotic edema; but Mil-

¹ *Omaha Clinic*, v, 101, 1892.

roy believed them rather to be dependent on some congenital absence of valves in the veins. They certainly do not present the complex of symptoms of angioneurotic edema.

The following instance of edema is allied in some respects to those of Milroy; and, like them, its nature seems entirely obscure. We had the opportunity of seeing the patient through the kindness of Dr. Arthur Van Harlingen.

Benny S., four years old, seen January 27, 1897. The mother was healthy in appearance. There was nothing of note in the family history. Several other children were entirely well. The mother stated that the child was well when born, and remained so until he had measles at three months of age. The testicles and scrotum were said to have been very large at birth, but this enlargement disappeared later. At three months of age, or shortly afterward, swelling of the left leg and of the face began, and this has continued more or less ever since. At times the eyes have been so swollen that the child could hardly see. The swelling of the leg was constant, and, as it would appear, varied less than the swelling of the face. The operation of ritual circumcision had left edema of the remains of the prepuce. The child had always been normally bright. The mother stated that the urine had been examined repeatedly and nothing ever found wrong with it.

Examination showed a child well-developed bodily for his age, but rather pale. The intelligence seemed to be entirely normal. The head was slightly asymmetrical, one parieto-occipital region being slightly flatter than the other. The bridge of the nose was unusually broad and rather flat, this appearance being distinctly added to by a decided edema of the tissues about the bridge. The eyes had rather a peculiar, deep-set appearance, this being due possibly to the edema of this portion of the face. The left ankle and leg were swollen, giving the member a cylindric form. The edema would not pit on pressure, and was so firm that at first it seemed as though the tibia itself was greatly thickened, but further examination made it reasonably certain that the bone was of natural size. The child had coryza at the time of the examination and the voice was rather nasal. The examination of the urine a short time later was entirely negative in its results. Under treatment by pressure with medicated plasters the edema of the leg diminished considerably. The patient then disappeared from observation.

The peculiar persistence of the edema, and especially the localization to so great an extent in the left leg, made the case very obscure; and this obscurity was added to by the firmness of the swelling there. The expression of the face was decidedly suggestive in some respect of cretinism, yet there were no other symptoms which supported this diagnosis. We are entirely unable to account for the condition.

The following instance of edema of doubtful nature

occurred in the Children's Hospital, Philadelphia, in the service of Dr. Alfred Stengel, where we repeatedly studied the case.

Harry B., twenty-three months old; admitted November 7, 1896. Family history negative. Previous personal history good. The present illness began five weeks before with fever, diarrhea, cough and cold extremities. On entrance to the hospital it was found that the child's liver was enlarged, and there was dropsy of the feet, eyelids, and abdominal cavity. The urine did not contain albumin. Examination on the following day showed the child to be evidently very ill, with cyanosis, great dyspnea, edema of the lower extremities, and to a less extent of the hands, and with physical signs of fluid in the abdominal and right pleural cavities. The heart-sounds were practically normal. There was no evidence of pulmonary consolidation. The blood examination gave 65 per cent. hemoglobin, and 3,500,000 red blood-cells to the cubic millimeter. The liver extended almost to the umbilicus. This was apparently due partly to displacement by the pleural effusion and partly to actual enlargement.

Under the administration of digitalis and purgatives the fluid disappeared from the abdominal cavity and the limbs, but that in the right pleural cavity continued to a considerable extent. On November 14th a second examination of the urine was made, with negative results. On November 24th the fluid was still present in the right pleural cavity but in less quantity. By November 30th it was decreasing here, but at about this date it was also found to be accumulating in the left pleural cavity. By December 11th fluid was still present on the left side, and to some extent on the right. The child's temperature up to this date had ranged from 99° to 100° F., but it now rose to 103° F., and varicella developed. This ran a moderately severe course, but disappeared without any sequelæ, the temperature now ranging about 99° F. By December 20th the child was improved very much in every respect, although fluid was still present in the left pleural cavity. By December 31st no fluid was to be discovered. He was discharged cured on January 4, 1897.

The origin of the edema in this case was at first entirely inexplicable. There existed no especial degree of malnutrition or anemia which could account for it, or any albuminuria or evidence of an inflammatory process anywhere. Later, when the fluid appeared in the left pleural cavity, it seemed possible that the child might be the subject of general tuberculosis, and that the behavior of the effusion indicated tuberculous pleurisy; but the subsequent course of the case renders even this improbable, and we are still in the dark regarding the nature of this case of anasarca.

No conclusions are necessary to close what has been said, further than to state that it has been our object merely to impress the importance of careful and more extended study of the forms of edema as

observed in children, and to illustrate those forms by the citation of cases which have recently occurred in our experience.

CLINICAL MEMORANDA.

A SUCCESSFUL OPERATION FOR INTESTINAL OBSTRUCTION IN AN INFANT SIXTY-FOUR HOURS OLD.¹

BY EDMUND J. A. ROGERS, M.D.,
OF DENVER, COL.;

PROFESSOR OF SURGERY IN THE UNIVERSITY OF DENVER; SURGEON TO ST. LUKE'S AND ARAPAHOE COUNTY HOSPITALS.

FOR the details of the family history, and for the personal history of the patient during the sixty hours before entering the hospital, I am indebted to the physician in charge, Dr. MacArthur of Littleton, Col., to whose early diagnosis and close attention the successful issue of the case is in very great measure due.

The mother is twenty-four years of age. She was married in 1893 and has had three children. The first was born on July 4, 1894, and died three weeks later, presumably from septic absorption from a superficial abscess. The second was born in November, 1895, and lived only three days, dying with symptoms similar to those manifested in this case, a *post-mortem* examination proving the cause to be intestinal obstruction. From a description given by the father of the condition at the time of this operation, I infer that the obstruction was probably due to a constriction with a Meckel's diverticulum.

The third child, a male, whose case I am about to report, was born at 8 A.M. on Friday, May 21, 1897. At birth it seemed strong, healthy and well-developed. The parents were of course very anxious and apprehensive, and every symptom was closely watched. It was found that during Friday there was no passage from the bowels, although the parts seemed perfectly normal. At nine o'clock that evening, Dr. MacArthur irrigated the bowel with warm water and obtained about a dram of white mucus. Early on Saturday morning the irrigation was repeated, and the rectum examined by means of the little finger. At about 9 A.M. the administration of castor-oil in small doses was begun, and this was continued at intervals throughout the day until the evening, when a teaspoonful was given at one dose.

About two hours after its birth the child vomited a quantity of greenish water, but with this exception all through Friday and Saturday there was no vomiting. Its temperature remained about 99° F., in the rectum, and it appeared to be doing well in every way. Early Saturday evening, immediately after nursing, it vomited undigested milk. At about 9 P.M. a No. 8 soft rubber catheter was passed high up into the rectum and about two and one-half ounces of warm water and glycerin were injected. The catheter passed quite easily, and when the fluid returned hard white shreds of mucus were brought away. At midnight two ounces of olive oil were given in the same way. The child's abdomen was now a little

distended but it nursed heartily, passed its urine, and did not vomit.

On Sunday, at 9 A.M., the high injections were again tried and two mucus shreds about three inches long came away. About 11 A.M. for the first time the child vomited a quantity of dark-brown fluid which had a slightly fecal odor. The vomiting was repeated at 3 P.M., when a large quantity was ejected, and again a smaller quantity at 8 P.M. During the afternoon the oil injections were repeated about every two hours. The friends think that gas may have been passed on Saturday. The injections on Sunday caused the child to strain with great violence.

About 8 P.M. on Sunday I found Dr. MacArthur waiting to consult me at my office. He was clear and emphatic in his conclusions that the case was one of absolute obstruction, and said that the parents realized the hopelessness of the condition and would consent to anything that promised a possibility of saving the child. He then started for Littleton, and returned before 11 P.M. to St. Luke's Hospital with the father and infant, having driven the eleven miles in an open carriage.

The operating-room at the hospital had been heated and the temperature was maintained at 90° F. The baby was then sleeping quietly. There was some distension, but no great amount of tympanites, the heart was beating 145 times to the minute and the symptoms seemed in no way urgent. Rectal injections, given in different ways, were tried, but with negative results, the water returning without stain. As there seemed to be no possibility of relief, and as delay would destroy the only chance of surgical interference proving successful, it was decided to operate immediately, and this was done between 12 and 1 A.M. on Monday, the child at that time being between sixty-four and sixty-five hours old.

In the operation I was assisted by Dr. MacArthur, while Dr. Elder, the anesthetizer of the hospital, administered the chloroform.

As no routine technic which would apply in the case of an adult could be followed in so young an infant, I was compelled to adopt such measures as seemed in my judgment best suited to the occasion. The abdomen was first carefully washed with soap and water, no stiff brush or hard rubbing being employed. The skin was then sponged off with one-to-sixty carbolic-acid solution, and the cord was trimmed down with scissors as closely as seemed safe and the surface of the stump carefully touched with a one-to-twenty solution of the same acid. These were the only disinfectants used in any way during the operation.

An incision was then made in the median line, carefully circling the umbilicus, and was extended as far as possible in both directions, the entire opening when completed being less than four inches in length. As soon as the peritoneum was penetrated, quite a large amount of fluid gushed out, showing that the cavity was fairly full. Several loops of gut immediately presented, which proved to be the upper small intestine. These were greatly distended, appearing to be more than one and one-half inches in diameter resembling adult intestines. They were immediately removed from the cavity and the small

¹ Read before the Colorado State Medical Society, June 16, 1897.

intestine followed down. The whole abdominal contents were very dark, the circulation seeming to be almost stagnant. The upper third of the small intestine was distended, and on following the gut downward it was found that it looped suddenly backward and all distension ceased, not in a marked line, as is usually the case in a distended intestine in the adult, but by gradual diminution. At about the middle the small intestine was closely bound to the posterior portion of the cavity by a transverse band. This band passed directly across the intestine, but was not adherent to it, although quite tightly drawn. I easily passed my fingers under it, when I found that I could flatten it out into a broad strip, the vessels and marked fibers contained in it running transversely across the bowel. In structure it appeared like the omental bands commonly seen leading into hernial sacs and to old adhesions. I quickly loosened it with my fingers, and, dividing it into two parts, tied it with catgut ligatures on each side and cut away the central portion. I did not stop to examine its attachments at each side, but they appeared to be deep. At this time I expected to have an opportunity to thoroughly dissect them out at a subsequent examination in the course of a few hours, but lessened the chance of being able to do so by losing no time in examining them then. Below this band the small intestine was contracted to about the size of a little finger and seemed to contain semisolid material. I removed all of the intestine from the cavity and found no obstruction below this. The attachment of the mesentery appeared quite normal. Even the cecum with the appendix attached came easily from the abdominal cavity. Considerable oozing took place from the engorged vessels and it was necessary to take up some blood with sponges moistened with hot salt solution. I did not flush or irrigate.

Without further delay the intestines were all returned, the abdomen stitched closely with silkworm-gut sutures, and a plain sterilized dressing applied. A gauze roller bandage was then put on with more than moderate tightness, so as to support the abdominal walls, and the child was wrapped in hot, dry blankets and artificial heat applied in many ways. He was under the influence of the anesthetic for thirty-five minutes.

Soon after stopping the chloroform, a very large amount of substance, which to all appearances and smell was ordinary myconium, such as would be passed by a normal child immediately after birth, was vomited. At 2 A.M. the child was removed to a room artificially heated to as high a degree as possible. Before the operation one-tenth of a grain of spartein was given hypodermically, and was repeated once during the anesthesia, and at this time one-sixteenth of a grain was given, also hypodermically, and this was repeated at intervals of about two hours. At 3 A.M. the child again vomited dark matter, and this occurred half-hourly until 7 A.M. At 4 A.M. urine was passed, and at 8 A.M. the first small bowel movement occurred, consisting of dark mucus-looking material. At 6 A.M. I began giving small frequently repeated quantities of hot water by the mouth, and at 10 A.M. injections of salt solution into the rectum. At 11 A.M. half a dram of malted milk by the mouth was first given,

and occasionally repeated until the mother arrived. The vomiting ceased at 7 A.M. and was not repeated until 2.40 P.M. Artificial heat to the body and in the room was kept up, but the child's temperature in the rectum continued at about 103° F. and the heart-beat at about 160. In the evening, small bowel movements were frequent, having rapidly become pure myconium, and at about 9 P.M. a large quantity was passed at one time. From this time on the discharges were frequent and profuse, the child crying occasionally but resting a great part of the time, and generally doing well.

The hypodermic injections of spartein were reduced to one-twenty-fourth of a grain toward Monday evening and a few drops of aromatic spirits of ammonia were given internally at intervals. The malted-milk feeding was gradually increased in frequency and quantity, and the injections of salt solution used whenever it seemed necessary. On Monday afternoon it was discovered that the dressings were becoming thoroughly saturated, and on removing them at 1.30 P.M. clear blood was found oozing from the wound throughout its entire length. It was impracticable to directly check this, as it was so general, so a narrow strip of iodoform gauze was laid along the wound, the sterilized dressing applied outside of it, and the bandage more tightly applied. The dressings became stained again, but not in sufficient quantity to necessitate changing before the next day, when the oozing was too slight to demand special attention. From this time on the dressings were changed daily. The stitches and margins of skin became red and angry, but soon improved and repaired perfectly.

The child rested well at broken intervals, during Monday night, sleeping altogether about three hours, but when disturbed would cry with considerable vigor. On Tuesday a few drops of Scotch whisky were given with the malted milk, the temperature gradually becoming lower. The patient slept a great part of the time and the bowels acted frequently. On Tuesday evening, the mother having arrived, the child nursed with vigor and appeared to enjoy it. It was now attempted to stop the administration of spartein hypodermically, but after missing two doses it had to be renewed. On this day the black stools gradually gave way to normal, healthy movements, but these becoming greenish on Wednesday morning a dram of castor-oil was administered, and acted satisfactorily. The child now appeared almost normal and was treated as a normal child in every way, except that the mild stimulation and the heating of the room was continued. On Thursday morning its temperature fell to 98½° F. and did not again rise. From this time on, improvement was constant, there being, however, a tendency to looseness of the bowels. The hypodermic injections were finally discontinued on Friday. Spartein was continued by the mouth during a few days longer. The stitches were all removed on Monday, the 31st, when the wound was perfectly healed and all redness and irritation had disappeared. On the fourteenth day the mother and child returned home. The latter has rapidly improved in every way, its weight increasing from six pounds on June 4th to nine and one-half pounds on June 16th.

This case has been one of great instruction and interest to me. It emphasizes markedly the fact that in an apparently hopeless case an operation which holds out any chance whatever should never be refused. It is never an easy or a pleasant duty to operate in the face of desperate odds, but it is a duty which should never be shirked. It tends also to show that perhaps young infants bear surgical operations much better than has been supposed. In this instance there seemed to be no shock, and no exhaustion followed. Indeed, when a week old the infant seemed to be in average health for a child of that age.

There is little to be said about the operation itself. As little as could be done, was done, and in as direct and simple a way as possible, the conservation of all energy and the avoidance of the danger of toxic absorption from the use of so-called antiseptics being especially aimed at. The great danger seemed to lie in the presence of the necrotic tissue at the cord attachment, but no infection occurred.

A matter of great difficulty, and in which there was very little to direct one's judgment, was the after-treatment. Especially, I had never before attempted to systematically stimulate an infant by hypodermic injections, but no unfavorable symptom or result followed.

A CASE OF TUBERCULOSIS INVOLVING THE HIP-JOINT, LUNGS, TESTICLES, INGUINAL GLANDS, AND ONE OR MORE OF THE VERTEBRÆ.¹

By HERBERT MAXON KING, M.D.,
OF GRAND RAPIDS, MICH.;
PHYSICIAN TO BUTTERWORTH HOSPITAL.

THE patient presented himself at my office for examination, June 23, 1896. He was twenty-eight years of age, born in Sweden, had lived in this country ten years, was a furniture-carver by trade, was married, and the father of one healthy child. Both parents were living and in good health. During the summer of 1895 he suffered from what he thought was rheumatism, which in December of the same year caused such marked pain, referable to the left hip, that he entered the Chicago Swedish Home and Hospital. A diagnosis of hip-joint disease was made, and Dr. C. W. Johnson curetted the diseased bone and effected good drainage. Upon microscopic examination of the *débris* the disease was pronounced tuberculosis. While recovering from the operation "hemorrhage of the bowels" occurred, which complicated matters, and he was not discharged from the hospital until two months later.

The patient consulted me because of cough and expectoration, and pain in the left shoulder and in the lumbar region upon coughing. I found consolidation at the apex of the left lung. He expectorated about one ounce during twenty-four hours. The sputum was mucopurulent and contained bacilli tuberculosis. Urinalysis gave negative results. Maximum temperature in the afternoon from 100° F. to 101° F.; pulse from 100 to 120 per minute. The patient did well under treatment (yeast nucleinic acid, hypodermically, inhalations under pressure of medicated vapors, and the usual attention to

nutrition), and I sent him into the country, August 4th, much improved, the temperature and pulse being much lowered and expectoration much less. He returned September 1st, feeling better than when he went away, but a few days afterward the pain in the lumbar region, which had never entirely ceased, became very severe, compelling him to remain most of the day in bed. Several urinalyses at this time failed to demonstrate the presence of any kidney lesion. On September 15th, the patient called my attention to a swelling of the right testicle, which was attended with much pain, especially upon standing or walking. He was then placed in a recumbent position and ice packs applied, with the effect of reducing the pain both in the testicles and the back, but the former remained very sensitive to pressure and the swelling did not diminish. At the same time the right inguinal glands become indurated and enlarged, one of them to the size of a pigeon's egg.

While suspecting the true nature of the orchitis, I was unable to verify the diagnosis until October 18th, when by delicate palpation a point of suppuration became evident. This was explored by means of a sterile needle and a drop of pus withdrawn, examination of which revealed the presence of bacilli tuberculosis. The diagnosis thus placed beyond doubt, removal of all of the involved tissues, as far as possible, was unquestionably indicated.

The patient was admitted to the surgical ward of Butterworth Hospital, and on October 20th Dr. Hugo Lupinski enucleated the right testicle (which was the size of a goose egg) and removed the involved superficial structures well into the healthy tissue. An effort was also made to enucleate the enlarged inguinal glands (which had now softened) without rupture, but, in handling, the sac of one was broken, and the pus escaped into the wound. The spermatic cord was tied off with silkworm gut as high up as possible, and in what appeared to be healthy tissue. The wound was not irrigated and the cavity made by the removal of the lymphatics was packed with gauze. The wound healed by first intention except where packed with gauze, and this soon filled with healthy granulations which closed the wound. Convalescence from the operation was uneventful. Upon cross section the testicle was found to be thickly studded with miliary tubercles, in many instances partially broken down and cheesy, there being two foci of suppuration, from one of which I had obtained the pus by which the diagnosis was verified.

Microtome section through the more solid portions of the gland, where the young miliary tubercles were so thickly studded, very prettily demonstrated the tuberculous process in its early stages (giant cells, etc.), and when treated for demonstration of the bacilli tuberculosis the latter also were found. After the patient was able to walk about he experienced a return of pain in the back, and this increasing, Dr. Lupinski discovered disease in the second and third lumbar vertebræ. Early in December the spine was fixed and supported in a cast, which gave marked relief. Pus finally found exit by two fistulæ on the left side, one in the inguinal line and

¹ Read before the Michigan State Medical Society, May 14, 1897.

the other about three inches below Poupart's ligament. When it became necessary to evacuate the pus this was effected by aspiration, and an emulsion of iodoform injected afterward. One fistula has ceased to discharge and has closed; the other is practically dry.

Seeing this case as late in its history as I did, I can only theorize as to the location of the primary focus of infection; natural inference would, I think, place it in the apex of the left lung, from whence radiated the subsequent deposits. My purpose in reporting it is: (1) that of demonstrating to what degree it is possible for some patients to become, in a sense, immune to the seriously injurious effects of the infection of tuberculosis, especially when it is a simple and not a multiple infection, even though it be carried to the point of saturation, so to speak, and (2) that of making a plea for perseverance in treatment, *medical* as well as surgical, in all cases of tuberculosis, and not to relegate a patient to the list of incurables as soon as a diagnosis is made.

MEDICAL PROGRESS.

An Advocate of Blood-letting.—HOFF (*Jour. Amer. Med. Assn.*, August 28, 1897) reports twenty-six cases in which after other remedies proved unsuccessful, venesection restored the patients to life. The list includes puerperal fever, eclampsia, paralysis from congestion of the brain, brain fever, meningitis, and cerebrospinal meningitis, pneumonitis in its first stages, congestion of the lungs, liver, and abdominal viscera, peritonitis, croup, tonsillitis, hemorrhage of the lungs, and incipient phthisis. "Repeated bleedings," says the writer, "will do more to cure consumption in its early stages than any other single agent, especially when used in conjunction with an open-air life, and in a dry and medium high atmosphere." Hoff would have every medical student instructed in the art of venesection, so as to be ready to apply this much-neglected therapeutic measure in cases of acute congestion of the internal organs.

Mushroom Poisoning.—CAGLIERI (*Medical Record*, August 28, 1897) reports that a family of six persons partook sparingly of poisonous mushrooms supposed to be the *Agaricus muscaria*. Three children, all boys, aged five, eight, and ten years, respectively, ate one-sixth to one-half of a mushroom for supper. The following morning they appeared somewhat sluggish, vomited after the administration of castor-oil, and suffered from mild diarrhea with little or no pain. They died after periods of coma of varying length in 29, 40 and 80 hours after the ingestion of the mushroom. A little girl, aged four years, and her mother, each ate about one-sixth of a mushroom, and had no symptoms, except slight vomiting. The father, who ate nearly two mushrooms, presented gastro-intestinal symptoms in a marked degree, and was stupid for two days, with a moist skin, small, rapid and regular pulse, and quick, shallow breathing.

These patients, with the exception of the first boy, who died, and the little girl, were given one-fiftieth of a grain of

sulphate of atropin every two hours. Strychnin was also administered. The pulse and respiration were improved by this treatment, but the coma was not changed. Caglieri explains the failure of the atropin to restore the patients, by the fact that it was administered thirty-six hours after the mushrooms were eaten. He regards it, nevertheless, as the best antidote for muscarin poisoning, but in another case he would give it in smaller doses, at shorter intervals.

The Yellow Fever Bacillus of Sanarelli and of Havelburg.—In the Public Health Reports, Washington, July 30, 1897, GEDDINGS calls attention to the fact that Sanarelli and Havelburg, working independently, and in places remote from each other, have each claimed to have discovered the specific microbe of yellow fever. Both agree that this is a bacillus, but the two germs described are in no wise similar. There is every reason to suspect that Havelburg has simply "rediscovered" the coli bacillus, a fate which many well-known investigators have met. The bacillus of Sanarelli was not found in one-half of the cases he examined, and although it killed guinea-pigs when injected in sufficient quantities, the organs of these animals did not present appearances at all similar to those of yellow fever; so that the evidence that the bacillus he describes is the real cause of this disease, is far from conclusive.

A New Splint for Nasal Fractures.—In the *Jour. Amer. Med. Assn.*, July 17, 1897, HAWES describes an appliance for the treatment of nasal fractures which is simple, easily made and applied, and which permits inspection of the nose without removal of the apparatus. It consists of a piece of No. 15 spring brass wire of suitable length, bent first into the form of a rectangular letter U, the arms of which are about an inch apart, and long enough to extend from the center of the upper lip to the crown of the head or beyond that point. Opposite the supraorbital ridge a sharp angle is formed, in order to permit the splint to enter the orbital cavity just beneath the orbital ridge. This angle is a means of fixation of the splint against the supra-orbital ridge, and is one of the most essential features of the appliance. The lower end of the splint; *i.e.*, the transverse portion, is carried forward, away from the lip, for a distance of half an inch.

Suitable compresses placed between the splint and the side of the nose will correct deviations. If necessary, a silk suture may be passed through the septum of the nose and tied to the transverse portion of the splint. No other appliance for drawing down and holding firmly the point of the nose or its alæ has ever been devised. In certain cases the inventor adds to the external splint an intranasal wire, which should be less stiff than that used externally, and covered with a soft rubber tubing. The splint is held in position by a strip of rubber adhesive plaster passing over the forehead and around the back of the head like a hat-band.

Plague Attacks Europeans.—It is reported that the plague is increasing in the Bombay presidency, and that several Europeans at Poonah have been attacked by the disease.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor : J. RIDDLE GOFFE, M.D.,
NO. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

SATURDAY, OCTOBER 2, 1897.

THE PRESENT-DAY METHOD OF TEACHING MEDICINE.

As the time is at hand when the medical college throws open its doors in cordial greeting to the incoming class, it may not be amiss to examine somewhat critically what is offered the ambitious student and sometime doctor, and perhaps to suggest certain lines along which the present system of medical instruction may be improved.

Argument is not necessary in order to enforce the statement that medical pedagogy lags far behind in the onward march of methods of instruction in general. The reason for this lack of progress is not difficult to find; it lies in the fact that medical teaching, in this country at least, has ever been a tail to the kite of practice. A community is indeed small that cannot furnish accommodations for the teacher's rostrum and student's bench, the faculty receiving no compensation except that accruing from the personal aggrandizement attaching to the title of "professor." To teach with all the nobleness the phrase implies lies far from the purpose and the comprehension of many who, perhaps unthinkingly, assume the obligation. This reprehensible condition

of affairs will undoubtedly continue until, as our institutions become older, the great centers of learning, with salaried teachers who remain in touch with the profession only through the medium of the clinic, will exemplify in their work the higher and better methods.

It has been said that the science or art of medicine is a difficult one to teach, the truth of which statement one is unable to admit when it is remembered that to its study is attached a novelty almost continuous, and novelty always engenders interest, which, again, is the cornerstone of successful teaching. Correct pedagogic methods are everywhere centering about this word "interest," and it can but be acknowledged that he is the most successful teacher who best succeeds in exciting and sustaining it in the pupil. It is the failure of so many instructors to reach the required standard of excellence which is bringing the lecture method of instruction into disrepute, and it is into this method, also, that the personal equation enters so largely as to make it inapplicable as a universal teaching system.

In seeking something better a long step backward has been taken. The possession of a great mass of uncorrelated and unassimilated facts should not be a part of the armamentarium of the able physician, and yet it seems as though we are educating the student to do tricks and make set speeches during an examination, lengthening the college course a year or two in order that more speeches may be learned, only to be forgotten when they are no longer necessary for examination purposes. It would be absurd to think that such is the object of a longer course, but, nevertheless, it too often remains as a net result. Facts as facts have no place in education, but when they are properly correlated with others the opposite is true, and to be assimilated they must find a natural resting-place in the mind, in other words must fit into something which is already there. Possessing a keen and sustained interest and a goodly store of well-digested facts the next and final step, the deduction of principles, or formulation of correct action, becomes comparatively easy.

In what way may these great principles of teaching be put in practice? In the first place, interest may be sustained by making the entire medical course a perpetual clinic, for with an actual case as a text attention will never flag. About the positive

example may be grouped all the branches of medicine, from pathology to therapeutics. Facts should be taught, metaphorically speaking, by means of blocks, for one never grows so old that one does not best learn in this way. For example, the anatomy lecture-room is the dullest, most sleepy of places, while, on the other hand, that which it correlates, the dissecting-room, is always lively, always fascinating. Why? Because in the latter case, though the subject remains the same, the student is learning with blocks; he constructs the human body by taking it apart, and the lesson remains with him always, for although he may forget its terminology he never does its substance. The old scheme of preceptorship owed much that was good in it to such a system.

The clinic should always be a recitation-room, for it is here that the student should deduce those principles and confirm those facts which, later, are to be the mainspring of correct action. With the popularizing of the newer, but really older, system we may sometime realize the final examination which instead of being a mere test of memory will be a test of qualitative thinking, thus determining the quality of the man who, after all, must earn his living as a practitioner of medicine, surgery, and midwifery.

THE MOSQUITO AS AN ETIOLOGIST.

ALL joking aside, the question whether a mosquito can carry contagion, is an important one; grave enough to have attracted the attention of serious investigation. The latest testimony along this line seems to be against the insect. It is given by Ross in the *Indian Medical Record*, May 1 and 15, 1897. A mosquito bite, like any other wound, may be the starting-point of infection; and the object of Ross' investigation was not to establish this fact, but to learn by experiment whether or not malaria may be transmitted by means of mosquitoes.

It is conceivable that this transmission might be brought about in a variety of ways: by the ingestion of water in which they have laid their eggs, or which contain their *débris*; or by the inhalation of dust from the dried pools in which they have lived, or by their bite, or by the feces, which the insect leaves upon the skin, getting into the mouth from fingers which have scratched the irritated surfaces.

In the series of experiments conducted by Ross, no results followed the bites of insects previously fed

upon malarial subjects, although in one instance no less than thirty-six insects were turned loose upon one man whose history showed him to be likely to contract malaria on slight exposure. The mosquitoes were kept for various lengths of time before they were used, in order to give the malarial parasites time to reach the proper stage of development. It is possible that the species of mosquitoes employed were not the varieties which are capable of carrying malaria, as the species of this insect are many, and it is at least supposable that only one of them, or a limited number of them afford suitable conditions for the growth of the parasite.

The experiments with water in which mosquitoes had lived, and which contained their *débris*, including the spores of the gregarian (*pseudonavicellæ* or *psorosperms*), were more successful. In three out of twenty-two experiments, the ingestion of such water was followed by a distinct though slight attack of malarial fever; while in two other instances, there was a slight reaction which may or may not have been malarial in its nature. Leaving these indefinite cases out of consideration altogether, there still remain three positive results in twenty-two cases, and Ross estimates that although the natives in his district are subject to frequently recurring attacks of malarial fever, a liberal average would allow every native one attack each year, and that gives one case in every seventeen subjects in a period of three-weeks' duration. It may be urged that these cases are so few that they may still have been a coincidence; but this is an interesting line of experimentation, and the result is sufficiently striking to warrant further investigation.

HOW EVERY TOWN MAY POSSESS A GENERAL MEDICAL LIBRARY.

A SUGGESTION under this title is made by one of our correspondents which is worthy the careful consideration of every member of the profession residing in a town not yet possessing a public medical library. There are certain standard works which every practising physician must feel are indispensable to his daily work, and which he must have at hand for constant consultation. At the same time the fact must be recognized that few physicians are able to own all the books which at times they feel the necessity of consulting. To provide for such

contingencies, the suggestion of our correspondent seems practicable and worthy of prompt and general adoption.

In connection with the subject of books, we are apt to recall the familiar statement of Emerson: "I visit occasionally the Cambridge library, and I can seldom go there without renewing the conviction that the best of it all is already within the four walls of my study at home. The crowds and centuries of books are only commentary and elucidation, echoes and weakeners of these few great voices of Time." This is true in the realm of letters, but does not suffice in the department of medicine. Medical science is advancing so rapidly at the present time that the latest and best book of the highest authority becomes antiquated in many of its details and demands a revised edition almost before the first has been exhausted. Moreover, no single authority is able to present all of the facts and experiences of the different observers from which his conclusions are drawn. Every practitioner who is at the same time a student in his special work desires very often to go behind the conclusions even of the best authority and investigate the facts upon which his deductions are based. The doctor, therefore, is called upon to buy many books, and his desires in this direction frequently outrun his ability to satisfy them. By adopting the suggestion of our correspondent, especially when consultation is held as to how the investment in books from year to year shall be made, all of the latest and best authorities may be brought within the reach of the humblest practitioner.

ECHOES AND NEWS.

Dr. Nammack Appointed Visiting Physician to Bellevue Hospital.—Dr. Charles E. Nammack has been appointed visiting physician to the Non-collegiate Division of Bellevue Hospital, New York.

Dr. Joseph Collins Receives a Prize.—The Alvarenga Prize of the College of Physicians of Philadelphia, for 1897, has been awarded to Dr. Joseph Collins of New York, for an essay on Aphasia.

Alumni Association of St. Mark's Hospital.—The graduates of St. Mark's Hospital, New York, have formed an Alumni Association. Meetings will be held monthly at the hospital. President, Leon F. Garrigues, M.D.; secretary, Martin J. Schur, M.D.; treasurer, Casper Stock, M.D.

The University of California Rejects the Petition of the Hahnemann Hospital College.—At the last meeting of the

Regents of the University of California, the petition of the Hahnemann Hospital College requesting admission to the University was rejected. Fourteen members voted against and four in favor of such affiliation.

Indian Plague in Caucasasia.—A despatch to the *Daily News* (London) from Odessa says it is reported that there has been an outbreak of the Indian plague in the northern Caucasus. The officials refuse to give any information concerning the invasion, but it is known that a sanitary commission has left Tiflis to investigate.

Deadly Well Water.—Water from an abandoned well has given rise to several cases of typhoid fever near Rye Beach, N. Y. A party consisting of half a dozen persons went into camp near that place and drank water from an old abandoned well. The whole party immediately became ill, and two of the members have since died.

Diphtheria in Woonsocket, R. I.—Five deaths from diphtheria have occurred lately in Woonsocket, R. I. Since July 1st, there have been fourteen deaths from the disease, and it is estimated that over a hundred cases have existed in the city. The health officers and the board of city physicians are doing all in their power toward stamping out the epidemic.

Strange Equine Malady in Maryland.—Dr. A. W. Clements, State Veterinarian, reports the existence of an alarming epidemic among horses on the Eastern Shore of Maryland. More than one thousand have died of the disease, which is supposed to be caused by eating some poisonous vegetable matter. It is feared that the epidemic will become general throughout the State.

Prize Awarded to Dunant.—Moscow, in honor of the Medical Congress just held here, gave \$1000 for a prize to be awarded to some person who has done eminent service to medical science during this generation. On Professor Virchow's motion, the prize was given by the Congress to Henri Dunant, founder of the Red Cross Society who is living in great poverty in Switzerland.

Occupation of Cats as Mice-Catchers Gone.—Cats are to be dropped from the German military establishment; they have now an allowance of \$4.50 a year each for training, medical care, food, and badges. They are employed to protect the depots of military stores from mice. Professor Löffler, however, having discovered a typhus bacillus fatal to mice, this will be substituted for the cats.

Paris Hospitals.—It is said that several of the Paris hospitals which are built of wood and in a wretched condition are to be demolished and structures of stone and brick erected in their stead. Among these are the Pitié Hospital, built during the reign of Louis XIII., the Broussais Hospital, built in the course of six weeks in 1883, and the Aubervilliers Hospital, which is reserved for contagious diseases.

Success of the Recreation-Piers.—At a recent meeting of the New York Dock Board, a report was read stating that during the eighty-two days in which the recreation-pier at the foot of East Third street has been in use over 325,000

persons have availed themselves of it. The new pier at the foot of East Twenty-fourth street, which cost \$150,000, and was dedicated September 25th, will be enclosed in glass during the winter, and arrangements have been made to give concerts and popular lectures there.

Health Board War Ended.—In a decision handed down by Justice Barnard of the Supreme Court of New York, it is declared that the Board of Health of Northfield, Staten Island, was illegally constituted, and that the removal of Health-Officer Woods was illegal. Last spring the village trustees found fault with the Health Board, which consisted of five members, and increased the number to seven. As no provision was made in the charter for such an increase, Justice Barnard decided that the trustees had no power to make it.

Insurance Against Twins and Triplets.—*Apropos* of a new form of insurance referred to in the last issue of THE MEDICAL NEWS providing against the accident of twins or triplets, the so-called enterprising insurance man would doubtless be enabled to follow his calling in England, as a correspondent writes that he is cognizant of the existence of such a society in London. A lady of prominence in London social life took out a policy for £500 last year, which was paid without question by the company nine months later when she was delivered of twins.

Value of Pure Milk.—The great value of Pasteurized milk in reducing the number of deaths among infants from diarrheal diseases, is shown in a letter sent recently by the Brooklyn Board of Health to Nathan Straus, who supplies it to the poor at a nominal price. The death-rate of children under two years of age decreased from 137 in 1895, when the milk was not used, to 119 in 1896, when Mr. Straus introduced it, and 101 this year. These figures, based on an estimated population of 100,000, cover thirty-eight corresponding weeks in each year at a time when the disease is most prevalent.

A Case of Prolonged Unconsciousness.—Much attention has been given in England to a peculiar case, known as the "Dover Cliff Mystery." On August 5th, a young girl, aged seventeen, was found unconscious and bruised on the beach near St. Margaret's at the foot of a cliff 200 feet high, and was removed to the Dover Hospital. The character of her injuries (a severe bruise on the right side of the forehead and slighter contusions on the occiput and left ankle) makes it seem most improbable that she had fallen over the cliff, as was at first supposed, and it has been suggested that she was sunstruck while walking on the beach and received the bruises in falling to the ground. The possibility of the case being one of typhoid fever arises when it is remembered that long periods of unconsciousness, lasting more than four weeks, have been known to occur in this disease. The temperature curve, also, is not unlike that of typhoid. The principal treatment has been the use of the cold pack whenever the temperature rose above 102° F. Bromid of ammonium and iodid of potassium were given internally, with a diet consisting of milk and beef-tea. The systematic use of the ice-pack

and indefatigable attention to nutrition have thus far preserved the girl's life, but she still lies unconscious.

Health Reports.—The following statistics concerning cholera and yellow fever have been received in the office of the United States Marine Hospital Service during the week ending September 25, 1897:

YELLOW FEVER—UNITED STATES.

Beaumont, Texas.	September 22	1	..

Notes on the Yellow-Fever Epidemic in the South.—Two patients with yellow fever reached New York quarantine on September 22d on the steamer "Finance" from Colon. They were immediately transferred to Swinburne Island, and the other passengers and the crew of the steamer were sent to Hoffman Island, where they will be kept under observation.

The city council of New Orleans, at a special meeting held recently, placed \$25,000 at the disposal of the Board of Health with which to fight yellow fever. An additional \$25,000 is held in reserve to be used if the situation becomes serious enough to make this necessary. The members of the board, however, think there is no danger of the epidemic spreading.

The city authorities of Atlanta, Ga., have threatened with severe punishment anybody who spreads an inaccurate report that there is yellow fever in that city.

A death from yellow fever is reported in Beaumont,

Texas. A rigid quarantine has been established in the hope of checking the progress of the disease.

The Queen Regent has ordered that special surveillance be exercised at Spanish ports on all arrivals from the United States ports, in consequence of the outbreak of yellow fever in some of the Southern States.

At the request of the Pennsylvania Railroad, Health Inspector Benjamin of Jersey City furnishes health certificates to conductors of trains which are to pass through Alabama, as the laws of that State require that all conductors be examined and certified to before they leave the North.

Because the Board of Health of New Orleans made arrangements to use a school-house for a temporary fever hospital, a mob of excited individuals living in the neighborhood ordered the doctor and Sisters of Charity to leave the building and proceeded to set fire to it. Part of the building only was destroyed. As it stands in a park by itself, away from other buildings, it would seem that those living near were unnecessarily alarmed.

Dr. Lovell, son of Colonel Starr Lovell of Mississippi, died at New Orleans on September 22d from yellow fever. He contracted the disease while attending fever patients.

CORRESPONDENCE.

HOW EVERY TOWN MAY SECURE A MEDICAL LIBRARY.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: That a large, well-selected public medical library is an absolute necessity for any one who wishes to write upon or thoroughly study any subject connected with the art and science of medicine, no one will dispute. The experiences of ages and the results of innumerable investigations are crystallized in books. Every book is a great institution by itself. On this shelf is my physiological laboratory, on the other my biological institute; here my anatomical theater, there my lying-in-hospital. Whenever I wish, I can converse with Virchow, Da Costa, and Keen. I can at will make all the dead, from Galen to Charcot, arise and give me in turn some of their wisdom.

I do not presume I have said anything new, for every one of us is somewhat of a book-worm, yet the number of cities that possess a public medical library may be counted upon the fingers. True, some of our fortunate brethren-in-Esculapius can buy all the books they wish to read, but no individual can afford to get together all the books that he *might* at some time wish to consult. It is obvious, that the most practical and most economic way for each community is to own a public medical library, where the best works may be gathered together, and where one book supplies the wants of many, at a small cost to all concerned.

When I came to Denver, after having fattened upon the luxuries of the library of the College of Physicians of Philadelphia, I thought that in the wild and woolly West I should miss entirely this pleasure. I was, however, pleasantly disappointed in finding a wisely selected, thoroughly indexed and well-kept medical library.

Having had an occasion to make some extensive research, I found, to my regret, that the library was not sufficient for my purpose. It was natural that I should turn to my friends and acquaintances for assistance. I went from one physician to the other and inquired for the volumes I wished to consult. And, lo and behold, to my great joy I had to cry *eureka* a good many times a day; in fact, I found upon the shelves of the private libraries of my friends here and there a book which would make the mouth of the Surgeon-General water. Furthermore, I have convinced myself that the physicians themselves on account of lack of proper arrangement and the absence of an index or catalogue did not know what valuable books they owned. The larger the collection of books, the more difficult it was to ascertain what it contained, and the less available it was for reference.

I then conceived the idea of a Union Catalogue of Medical Books and Journals and on December 9, 1896, I read a paper before the Denver and Arapahoe Medical Society, entitled: "How the Library of the Colorado Medical Association Can Double the Number of its Volumes without Making Any New Purchase—A Suggestion." The title of the paper, which seemed to many to be of the "catchy" sort, brought to the meeting all the officers of the library, and also the accomplished librarian Mr. J. C. Dana, all of whom were eager to find out how to make something out of nothing.

My suggestion was a very simple one. A catalogue of the public medical library should be sent out to every physician residing in Denver with a circular letter requesting that he should at his leisure prepare a list of such of his books and journals as are not found in the public library; such list to be returned to the librarian. The librarian should prepare a card catalogue of such books and periodicals as the lists should furnish; such catalogue to be kept for reference. Each card should indicate in whose office each book may be found, and at what hours it would be accessible to readers. By adopting this plan I was sure that a thousand volumes of medical works which are not to be found in the public library could at once become available for use, and this, without expense or inconvenience to any one.

The writer of these lines had the satisfaction of hearing the consensus of opinion that the plan was both useful and feasible.

The work has been accomplished. The librarian has prepared a carefully indexed card catalogue by author, title, and subject of all the books and journals from the lists which I have furnished. The result has exceeded the most sanguine expectations. We have added to our library about two thousand titles, and more than six thousand volumes. The physicians without exception have heartily co-operated in the work, and cheerfully offered their books upon the altar of mutual helpfulness.

Of course, this plan may be carried out more efficiently in any city where there is a medical library. But in cities where there is no library by adopting this plan the foundation of such can be laid, provided the physicians will show a spirit of fraternity and co-operation. Even in small cities there are enough books scattered among

the practitioners to constitute a good reference library, if they were only supplemented with a good index. Experience has taught us that we cannot leave the work of making out the lists to the physicians themselves. The work must be accomplished by one or two individuals. He who has just graduated, or who has a superabundance of time on his hands should undertake this work of love. He will soon find that the work besides being profitable to the whole profession, which will be gratefully acknowledged, will at the same time be of great help to him in the future. He will acquire an acquaintance with the medical literature which he could not otherwise obtain. He will see all the prominent physicians at their best, for no matter how uncommunicable a man may be by nature you will find him talkative and genial when the subject concerns his favorite books.

I hope that this plan will be adopted wherever the profession is fairly organized and living together amicably. This practical and inexpensive plan will not only foster learning and facilitate research, but it will strengthen the moral ties which bind the members of the profession one to the other, and, eventually will serve as a nucleus of a future library.

C. D. SPIVAK, M.D.,

No. 608 CALIFORNIA BUILDING, DENVER COL.

TWELFTH INTERNATIONAL MEDICAL CONGRESS.

[From our Special Correspondents.]

MOSCOW, August 23, 1897.

THE Section of Bacteriology and Hygiene met August 20, 1897, in the Historical Museum, the President, Dr. M. S. Boubouff of Moscow, occupying the Chair. The first day was devoted to reports and communications in regard to water supply.

Professor T. Hueppe of Prague in the discussion of this subject said that in the examination of water it is always necessary to consider the geologic conditions surrounding the source. He emphasized the point that the bacteriologic examination may be negative and yet the water be unfit for use, in consequence of which such an examination is not alone sufficient, but must be supplemented by careful chemic and geologic analysis as well. Hueppe approved in general of the filtration of water to be used for drinking purposes, and of the method of sand-filtration in particular, but stated that such systems should be constantly under the supervision of a competent bacteriologist who should make daily examinations in order that the filter may be cleansed at the proper time. He did not think that a bacteriologic test would always indicate whether or not the water is infected—a point which was disputed by some of the members present.

Professor Victor C. Vaughan of the University of Michigan, U. S. A., read an able paper, entitled the "Bacteriologic Examination of Drinking-Water." Professor Vaughan has been engaged in such examinations for the past nine years, particularly specimens of water supposed to have caused typhoid fever. During the past four years he has examined 359 samples, 83 of which were suspected of having caused typhoid; 157 specimens

were regarded with suspicion, and 119 had been examined in view of selection of a proper water supply. The examinations had consisted of the ordinary plate-tests, counting of germs per cubic centimeter, isolation of the different micro-organisms, and the inoculation of animals with mixed and pure cultures of the germs found in each of the specimens examined. Of the 359 samples, eighty contained germs which proved to be pathogenic for different animals, and fifty-six of these were specimens of water from the class supposed to have caused typhoid fever. He divided the pathogenic germs into two classes, *viz.*: (1) those of the colon group, and (2) those resembling the typhoid bacillus. Vaughan did not find either the typical germ of typhoid, nor did he succeed in isolating a pathogenic spirillum. Waters containing germs belonging to the colon group he did not condemn, but those containing germs resembling the typhoid bacillus were all condemned; and the fact that every epidemic of typhoid fever ceased as soon as the use of such water was discontinued proved that such examinations are of great value.

In the discussion which followed Professor Dense of Hamburg pointed out the important results which had accrued to the city of Hamburg from the use of filtered water, and further, that cholera and typhoid fever ceased upon the introduction of sand-filtration.

The next day, August 21, 1897, an interesting paper was read by Professor Victor C. Vaughan, entitled "The Prevention of Tuberculosis." The following is a summary of the author's conclusions: (1) All milkmen should be provided with a license from the municipality; such a license not being granted until the cattle have been inspected by a competent veterinarian who should apply the tuberculin test in every instance, and any animal found suffering from tuberculosis should be immediately destroyed. (2) Cattle killed for food should also be subject to skilled inspection. (3) The disinfection of sputum from consumptive individuals is absolutely necessary, and such persons should not be allowed to expectorate in the streets or public vehicles. (4) Houses and rooms which have been inhabited by consumptives should be disinfected. (5) The government should construct, equip, and maintain, hospitals for paupers suffering from tuberculosis; such hospitals should be divided into two classes—one for incurables and the other for those who may recover. (6) Tuberculosis in its early stage is a comparatively curable disease, therefore, persons yet in this stage should be examined once or twice a year by a physician, and the government should furnish physicians to make such examinations for the poor.

Dr. Stchepotier of Constantinople discoursed upon the subject of "Sanatoria for Consumptive Poor for the Protection of Public Health." His conclusions were: (1) The true treatment of tuberculosis, hygienic and dietetic, cannot be applied except in a special hospital situated at a sufficient distance from any urban district. (2) Pure air and sunlight are the most potent enemies of this disease, therefore, such sanatoria should be located where the patients may spend the greatest length of time in the open air. (3) Consumption being principally a disease of the poor, it is desirable that governments, municipalities,

philanthropic associations, medical and public-health societies, should assist in the foundation of institutions for the care of consumptives of the poorer classes. (4) Every large urban population should provide such an institution located outside the city where conditions are as favorable as possible for the cure of tuberculosis.

"The Periodicity of the Occurrence of Epidemics of Diphtheria in the Rural Portions of Russia" was the title of a paper by Dr. A. K. Tschepourhovsky of Moscow. He stated that such epidemics occur about every ten years with a certain amount of regularity, the interval between epidemics depending upon various factors, among which the following are the most important: Age, individual susceptibility, rapidity of the spread of the disease, efficiency of the measures taken to arrest the epidemic or the absence of such measures. The fact that it is possible to know in advance the time when an epidemic will appear allows precautionary measures to be taken. The study of these epidemics, their periodicity and origin, is a subject worthy the attention of the health-officer and epidemiologist.

Professor Edward Nocard of Paris spoke upon "Serum Therapeutics in Tetanus." He considered the tetanus antitoxic serum both as a prophylactic and curative agent. His conclusions were as follows: (1) When tetanus has once declared itself, the antitoxic serum has no action; it is powerless to arrest the fatal termination of the disease, and this without reference to dosage or strength of serum; those alone are cured who would have recovered in any case. (2) The serum-treatment is, however, useful even in actual tetanus, for although the number of cures is not increased, yet those who do recover do so more quickly. (3) The antitoxic serum, even in weak dosage, if employed at the moment of the reception of the suspicious injury, or even some time afterward, will prevent the onset of the disease. (4) The dose must be both larger and stronger according to the length of time intervening between the reception of the wound and the employment of the serum; intravenous injections are more potent than hypodermic; the attack of tetanus is not always warded off, but, as a rule, if the disease occurs it is of a mild type, and the animal recovers, even though injected with a dose of toxin invariably fatal to a control animal.

Dr. A. Mennella of Rome read a paper upon "Cycling," in which he endeavored to prove that cycling had lost its true aim, and that the exaggerated manner in which it is now employed has changed the advantages which it possesses into real and sometimes dangerous disadvantages. A medical man should not consent to wheeling as an exercise for anyone of whose health he is not sure, as it is dangerous for persons predisposed to pulmonary, heart, or genito-urinary disease. Cycling is injurious to health from three causes—the contraction of the muscular system, chills following perspiration, and the stooping posture, which renders respiratory movements defective.

The labors of the Section were terminated by a visit to the Institute of Hygiene of Moscow and the city abattoirs, which latter are situated far enough from the city to obviate any sanitary nuisance.

MOSCOW, August 28, 1897.

SIR WM. MACCORMAC, who presided at the last general session of the Congress by invitation of the President, Professor Sklifosovsky, closed the session and at the same time the Congress, not with "*adieu*" but "*au revoir*," at Paris in 1900. Just before the end of the meeting there was a very touching scene. Professor Virchow, as the representative of the medical men assembled from all over the world, thanked the Committee of Arrangements, and especially Professor Sklifosovsky, for the perfection of entertainment the members had enjoyed, for the cordiality of their reception, and for the hospitality they had found everywhere in Russia, and especially here in Moscow. The words of grateful appreciation were evidently heartfelt, and above all they echoed the sentiments of the members of the Congress. Virchow's address was followed by prolonged and enthusiastic applause. Feeling that too many of the thanks were coming to him, Professor Sklifosovsky turned to the audience to explain that the greater part of whatever success the Congress had met with was due to his collaborators on the committee, but words failed him for the expression of his feelings in a foreign tongue, and with tears in his eyes and broken voice he proceeded for a few sentences in Russian, of which the untutored stranger's ear could catch only the word "*bratj*," "*brothers*," and then broke down completely. It was because Russians have worked together shoulder to shoulder as brothers that the successful result has been attained. A wave of sympathetic emotion which could be felt passed over the audience and for a moment the east and west of Europe were united in more cordial feelings of brotherhood than ever before.

The last general assembly was at least as interesting as had been the preceding ones. The paper of Professor Loukianow of St. Petersburg on "The Inanition of the Cellular Nucleus," was the simple relation of a bit of ground-breaking work which may have far-reaching results. The morphology of the cell is much better known than its biology; in fact almost nothing is known of life processes within the cell except in so far as they affect its form. As to the nucleus, the obscurity is still deeper and practically nothing has been known regarding it up to this time. About a year ago the results of some work was published from Loukianow's own laboratory in the Institute of Experimental Medicine, in which some facts as to the effects of inanition on the cell-nucleus were deduced from its analogy with bacteria. It was found that bacteria lose during the first four to six days of inanition fifty-one per cent. of their substance, and then remain in a state of comparative equilibrium as regards weight for forty to eighty days. During this time cultures may be made, showing that life is still present. Nuclei have a good many analogies with bacteria in their life history, and so it was argued that nuclei, too, might lose one-half their substance and yet not undergo degeneration.

Some direct experiments to demonstrate this were undertaken and the results of these observations formed the basis of Loukianow's paper. In animals which had lost thirty-five per cent. of body weight from inanition, care-

ful micrometric measurements of the cells of the pancreas showed that while the cell itself had lost thirteen per cent. of its volume the nuclei had lost but three per cent. This seemed to demonstrate that the nucleus was independent biologically of the cell body. This autonomy of the nucleus would demand a composite structure, but beyond the varied granular appearance which different stains brings out, no structural arrangement was discoverable.

Further experimentation, however, brought out another fact in the biology of the nucleus. White mice were fed on a series of exclusive diets, some on lard alone, others on sugar, some on peptone, white of egg, and hay. When the animals of each series had lost about thirty per cent. of their body-weight, which required very different lengths of time for the various dietaries, the nuclei of their liver and pancreas-cells were examined. They were found to have reacted very differently according to the kind of food which had been given. In one series they had lost forty-four per cent. of their volume, or more than the bodies of the animals, and in another only twelve per cent. The nuclei would seem, then, to have a selective action in their nutrition. In these observations, however, as in the others, no differences of structure and no noteworthy modifications of the general appearance could be discovered.

Professor Leyden spoke of "The Therapy of Tuberculosis." Notwithstanding all that has been done and claimed for various special therapeutic measures in the treatment of tuberculosis, the conclusions, as expressed at the last International Congress of the Nineteenth Century, are that no specific treatment is known, and that only careful constitutional treatment under favorable climatic and hygienic conditions avail to arrest the progress of the disease. For Professor Leyden, sanatoria for tuberculous patients constitute the best means we have to increase the resistive vitality of the organism, to prevent the further progress of the disease, and eventually in many cases to lead to a cure of the condition if it has been taken in time.

The discussion of the subject at the sessions of the Medical Section of the Congress during the week had already showed that this is the impression generally prevalent in Europe as to the therapy of tuberculosis. Tuberculin, even in its latest form, has given no results that can be considered even encouraging, and not much hope seemed to be expressed in the ultimate successful serum-therapy of the disease. It is to be noted, however, that this is the opinion of practical therapists, not of bacteriologists, who in their section were of another mind.

Professor Lombroso of Turin, was welcomed with prolonged applause which showed how popular are the man and some of the ideas in psychopathology which he represents. His discourse was rather a popular exposition of the present position of what may be called "physiologic psychology" rather than a scientific exposition of its principles. He considers that the best guarantee we have at present that the new science is really and essentially a science is the opposition its development has awakened, for every new science has met with just this opposition at its inception. The idea of criminal anthro-

pology, however, is not to take the criminal out of the hands of the law, but to protect the irresponsible and even the seeming criminal in as far as he is irresponsible from the rigors of a code founded to too great an extent on the absolute accountability of all men for their acts and without sufficient consideration for, and appreciation of, the physical elements which modify that accountability. The science acquires additional interest from the fact that its investigations are leading us to a closer knowledge of the relations between genius and insanity and the far-reaching influence of heredity in mental conditions.

One of the great drawbacks to the development of the science of psychopathology has been the inability to find definite anatomic lesions as the basis of its symptomatic affections. The objection, however, holds for most of the nerve-affections and it is only the further progress of minute cerebral anatomy in which so much has been accomplished during the last few years that can give us the keys to the mystery of disturbed as well as normal brain functions. Lombroso thinks, however, that the adoption of precocious explanatory hypotheses will delay rather than further the progress of the science. The explanation of certain of the phenomena of memory, of sleep, of double consciousness, of hysteria, and of hypnotism on the theory of the contractility of the neurons, with making and breaking of nerve-circuits, he considers supported by too few observations to be tenable. It is an alluring bit of theory but nothing more, in the present state of our knowledge. Lombroso, seems, however, to admit more easily, a good many of the disputed observations with regard to hypnotic states and double consciousness which have of late years done so much to bring certain phases of the new physiologico-psychology into prominence. There was even a suggested explanation for certain telepathic influences—*actio mentalis in distans*—which smacked of mere wordiness, *vox et præterea nihil*, "for the polarization of certain cerebral molecular elements," as the condition underlying such influence, would sound as delightfully theoretic as the modern formula solution of psychic problems often is.

The conferring of the first prize of Moscow on M. Henri Dunant was a most graceful tribute to a man who has so well deserved of humanity, and comes at a most opportune moment, for it is generally understood that the founder of the Red Cross Society has been in needy circumstances for some time. The honor is enhanced by the fact that the prize is conferred on him at Professor Virchow's suggestion. The announcement of the selection of M. Dunant as the person on whom the first of the series of Moscow prizes was to be conferred was the signal for acclamations which showed how thoroughly the work he has instituted is appreciated by the medical world.

ST. PETERSBURG, September 3, 1897.

THE fêtes organized for the medical visitors to Moscow ended with the soirée of adieu, given by the doctors of St. Petersburg, at the Nobles' Club, on the evening of August 30th. Those of us who remained in the capital of all the Russias for a day or two longer found that Russian hospitality was not at an end just because the

regular program had been finished. Medical visitors to the hospitals, to the clinics, to the laboratories, even to the public museums, libraries, the palace, etc., were as warmly welcomed as during the three days when such visits formed part of the regular routine, and all this was done, though at the same time in St. Petersburg there was being held the International Congress of Geologists, to the members of which the special privileges of guests of the city were accorded, and who were most enthusiastic in their praise of their Russian hosts.

The medical institutions of St. Petersburg are well worth a visit, for their internal arrangements, as a rule, are regulated by the best principles of modern hospital hygiene and the requirements of modern surgery. They have not the advantage that is so striking to the visitors in Moscow of perfectly new buildings where every requirement was foreseen in the construction, but they have in every case obviated the inconveniences and disadvantages of the older buildings in a way to call forth the admiration of the visitor in every department. The attention to details in the management seems to be admirable. After the perfect way in which the General Medical Committee succeeded in handling the immense crowd that came to the Congress—a much larger number than attended previous congresses and almost unexpected—the visitor has had brought home to him the fact that Russian medical men are not lacking in administrative ability, and he is not surprised to find their hospitals admirably managed.

The medical institution of St. Petersburg, however, which perhaps is best worth a visit, is The Imperial Institute of Experimental Medicine. There is nothing elsewhere in Europe that is quite like it, for it contains departments for the study of both human and animal diseases (at least for rabies), and is also provided with a clinical department where patients are taken care of and given the Pasteur treatment. If the Pasteur Institute at Paris, and the Veterinary Institute at Alfort, were united, then France would have an institution such as the one at St. Petersburg. Situated on the shore of one of the islands in the Neva, on large and magnificent grounds presented by Prince Oldenburg, there is plenty of room for the many already existent departments and those in contemplation. With the largest branch of the Neva, the greater Nevsky, flowing close by, the Institute is admirably situated scenically and as regards its water supply. All the departments necessary for the study of experimental medicine are thoroughly equipped. Chemistry, physiology, physiologic chemistry, pathologic anatomy, bacteriology, and serum-therapy—each has its place. The animals intended for experimentation are well cared for, their kennels being planned with an eye to thorough cleanliness, and are light, airy, and roomy. The facilities for the transportation of animals in cars and on elevators are calculated to eliminate the unpleasant scenes sometimes connected with the moving of animals for experimental purposes. The precautions taken against the spread of such diseases as Indian plague and rinderpest during the course of experiments are most complete and include hot ovens with powerful draught in each, in sepa-

rate compartments of which all parts of affected animals are completely destroyed. The operation-, bathing-, and disinfection-rooms, for animal experimentation are as complete as the nicest details of antiseptic surgery require. The mechanical and scientific apparatus in use in the laboratories are of the latest and most perfect pattern. The whole institution has been planned and equipped for the carrying out of the very best and most advanced scientific work in all branches of experimental medicine.

No wonder that the journal of the Institute, which is published in Russian and French at times during the year when a sufficient amount of matter is at hand, should attract general attention in the scientific world, and should be one of the journals oftenest quoted in experimental medicine. No wonder, too, that the work of the directors of the various departments should be considered as of great scientific value and be carefully looked for by those who are sedulously watching the forefront of medical advance along various lines. All in all, the Western visitor to Russia has, I think, obtained very different ideas as to the medical situation in the East of Europe from those with which he came. To all of us the magnificent university clinics at Moscow came in the light of a surprise. No one unacquainted with the actual condition of affairs could have imagined for a moment that the finest set of hospital buildings in the world, covering acres of ground, almost all absolutely new, models of architectural beauty, was to be found a way off in the center of Russia; but the Western visitor came and was convinced. The idea that the effete East was no longer productive vanished before the persuasion that there were elements of stirring youthfulness, with outspoken promise of further development in all this that must be reckoned with in the evolution of science in the very near future. If the Westerner had heard during his trip through Germany and Austria some echoes of the contest between Germans and Slavs where the two races come in contact, as at Prague, it was only to think that the attempt to raise a Slavic people and Slavic tongue in the midst of Teutonic culture could only end in signal failure. But here everything bespoke the Slav, and there came the realization of the wonderful latent powers just ripe for development that exist in this illy understood people of Eastern Europe. The Slavs themselves claim that the future is theirs. Roman, Celtic, and Teutonic civilization, culture, and literature have had their apogee. The genius of the people has exhausted itself in the effort and now must make room for a new people whose development is yet to come. All of this of course sounds like the vainest boasting of over-enthusiastic patriotism to the stolid Westerner confident in his position at the head of the race, but it must have seemed just as improbable to the old Latins that they should be succeeded by Teuton and Gaul, and Hun and Goth, in the sovereignty of the world. The present generation will not see the rise of the new race, but if we are to judge of the future by what is to be seen in the present the evolution may be confidently committed, should the time ever come for it, to the Slavs of the East of Europe.

Another Eastern race attracted some attention at the

Congress when the delegate from the Japanese Government asked that in 1903 the Fourteenth Congress be held at Tokio, in Japan. The proposal was the source of not a little merriment, for even to the thousands of medical men who had traveled as far as Moscow to an international medical congress, it scarcely seemed serious. A talk with the Japanese representative showed, however, that the request was made in all seriousness, and that even details of the arrangements necessary had been thought out. It is considered highly probable, by those in a position to know, that the Japanese Government would charter a sufficient number of vessels on which at government expense all foreign members of the Congress would be transported free of charge to Tokio. As to arrangements in Japan itself ample guarantee is given that the reception would be a most cordial one, and that the guests of the nation would be given a chance to appreciate thoroughly Japanese hospitality.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

MEETING OF THE AMERICAN ELECTROTHERAPEUTIC ASSOCIATION IN HARRISBURG — PHILADELPHIA COUNTY MEDICAL SOCIETY — PATHOLOGICAL SOCIETY OF PHILADELPHIA—ADDITIONS TO THE FACULTY OF THE MEDICO-CHIRURGICAL COLLEGE—DR. CHARLES W. BURR—DR. WILLIAM G. SPILLER—DR. H. AUGUSTUS WILSON—VITAL STATISTICS FOR THE WEEK ENDING SEPTEMBER 25TH.

PHILADELPHIA, September 25, 1897.

THE seventh annual meeting of the American Electrotherapeutic Association was held in Harrisburg, at the Academy of Medicine, on September 21st, 22d, and 23d. A large attendance was evidenced, and many new and interesting electrotherapeutic instruments and appliances were shown. Papers were read by Drs. G. Betton Massey of Philadelphia, Robert Newman of New York, E. R. Corson and R. J. Nunn of Savannah, F. B. Bishop of Washington, Lucy Brown-Hall and Margaret A. Cleaves of Brooklyn, and by G. E. Bill, W. T. Bishop, and J. Z. Gerhard of Harrisburg. The important question of electric meters was thoroughly discussed on the first day of the meeting, and the application of an efficient instrument for the control of the current was held to be the only reliable agent guiding the scientific application of electricity in therapeutics. A reception by Governor Hastings was tendered the Association on the evening of the second day of the meeting.

At the last meeting of the Philadelphia County Medical Society, held on September 22d, Dr. Edward Martin read a valuable communication on the subject of "The Operative Treatment of Goiter." After having given careful consideration to therapeutic measures other than operative intervention in the treatment of this condition, and having shown the uses and limitations of such procedures as the use of thyroid extract, galvano-puncture, and the injection into the goitrous mass of iodine and iodoform emulsion, the speaker went on to describe the operative treatment which he had employed in the series of cases, seven in number, which formed the basis of his report. The operation was

essentially that recommended by Kocher, preference being given to a transverse incision over the growth, although in a tumor extending down into the chest, a larger angular incision was deemed necessary. The patients operated upon by Dr. Martin were exhibited before the Society at the close of the reading of his paper, and conclusively demonstrated the tenability of the speaker's argument in favor of this operative measure. In none of the cases was the scar unsightly, in but one had the operation been attended with noteworthy complication, and in all either complete cure or marked improvement in the nervous and other phenomena had resulted. Dr. John B. Roberts remarked upon the rarity of operations for goiter in this city, a fact emphasized by Dr. Martin, and deplored that the laity misapprehended the seriousness of the operation and magnified the danger attending it. He reported also a number of cases with results similar to those of Dr. Martin. Dr. Roland G. Curtin expressed the opinion that in Graves' disease the operation indicated in simple cystic goiter was uncalled for, and might even prove detrimental, and related a case in which, after the injection of ergotin, the goiter suppurated and disappeared. Dr. A. A. Eshner maintained that all forms of goiter, whether simple or exophthalmic, presented similar indications for operative interference, and thought that in the latter condition it was justifiable to remove the gland for therapeutic purposes. Dr. G. G. Davis also spoke in favor of the operative treatment of the disease, and discussed the mortality and the risks of such treatment. The President of the Society, Dr. James Tyson, in discussing the treatment of goiter from the standpoint of the physician, remarked that his personal experience in the medical treatment of the condition had not been encouraging.

At a stated meeting of the Pathological Society of Philadelphia, held on September 23d, Dr. David Riesman reported a case of carcinoma of the gall-bladder and liver, in which partial involvement of the stomach and pancreas was also present. During the discussion of this paper an interesting point was brought out concerning the value of albumin percentage of fluids withdrawn from the abdominal cavity for diagnostic purposes, and it was shown that in no single disease accompanied by a collection of fluid in the abdomen, was the richness of such fluid in albumin indicative of the nature of the lesion. Dr. Joseph McFarland read a paper on the coccidium oviforme, and demonstrated the gross pathology and the microscopic characteristics of this condition.

The faculty of the Medico-Chirurgical College has been augmented by the addition of four new professors, who will enter upon their duties with the opening of the winter term of this institution, on October 4th. The newly elected teachers are Dr. Charles E. de M. Sajous, whose election to the chair of laryngology was announced early in the summer, Dr. Louis Rodman, who has left the professorship of operative surgery in the Kentucky School of Medicine to accept the chair of surgery, Dr. John C. Heisler, professor of anatomy, and George S. Meeker, B.S., professor of chemistry.

A chair of neuropathology having been created at the Philadelphia Polyclinic, Dr. Charles W. Burr has been

elected to the professorship in this branch. It is also announced that Dr. W. G. Spiller has been elected professor of diseases of the nervous system in the same institution. Another change at the Polyclinic is the resignation from the faculty of Dr. H. Augustus Wilson, who for many years has occupied the chair of orthopedic surgery, and was one of the founders of the school.

The total number of deaths in Philadelphia for the week ending September 25th was 352, a decrease of 9 from the preceding week, and an increase of 3 over the corresponding week last year. Of the total number of deaths reported 122 were in children under five years of age. Of contagious diseases 178 cases were reported, with 22 deaths, as follows: diphtheria, 77 cases, 13 deaths; scarlet fever, 43 cases, 2 deaths; enteric fever, 58 cases, 7 deaths.

SOCIETY PROCEEDINGS.

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY OF NEW YORK.

THE President, CHARLES L. DANA, M.D., in the Chair.

SYPHILITIC INFECTION OCCURRING TWICE IN THE SAME LOCALITY.

DR. JOSEPH COLLINS narrated the history of a case, which was of interest because of its rarity. The patient, a physician, came to him three or four years ago complaining of pain in the middle finger, which he thought was caused by a hangnail. A diagnosis of Huntarian chancre was at once made, and, in due course of time, the secondary manifestations appeared. He was put upon mercury during a period of about two years, which he tolerated very well. This was stopped for three or four months and the iodid of potassium given, which was not well tolerated, iodid inebriation being manifested throughout the vascular system, and also by eruptions. He was then given four or five ounces of sherry wine each day with the iodid, with the result that the latter was well borne. During the past summer, he worked hard during the hot weather, and began to suffer from attacks which seemed to be due to some disturbance of the vascular system. There was numbness of the right hand, arm, and leg, and also a number of symptoms which seemed to resemble the hemiplegic variety of vascular neurasthenia. This was accompanied by a great deal of mental depression, and he was placed upon vasomotor stimulants.

About two months ago the patient came to him complaining that something was the matter with the finger which had formerly been the seat of the chancre. There was pain and swelling, and the finger had the appearance of being about to fester. A diagnosis of tuberculous syphilid was made and he was placed upon a tonic treatment, together with iodid of potassium, until the lesion disappeared.

DR. A. R. ROBINSON said that several similar cases had been mentioned by Hutchinson, who called it recurring chancre, in which the secondary manifestations

showed themselves years after the first. He saw no reason why such secondary infection should not occur, although he had never seen such a case.

DR. COLLINS replied that in this instance the lesion did not have the appearance of a recurring chancre, it was not greatly indurated, not soft, there was no solution of continuity, and no history of specific infection. It looked more like a bursitis in the beginning.

DR. H. S. DESSAU referred to the use of cocoa wine in combination with iodid of potassium, and said that the result was the same as that which followed the use of sherry wine in Dr. Collins' case. He thought it a valuable aid in the treatment of syphilis, especially where the patient did not respond well to the drug.

THE PRESIDENT said that the administration of ten drops of the tincture of belladonna, three times a day, together with the iodid of potassium, often produced a good effect.

LUPUS OF THE SCROTUM.

DR. CHARLES H. KNIGHT related the case of a child, aged seven months, who was brought to the German Hospital. When the child was one month old, a nodule appeared on the upper segment of the left side of the scrotum, and since then four others had formed in the cutis. There was no involvement of the deeper tissues. Dr. Jacobi removed the nodules, after which a red streak appeared along the penis and glans and a lymphangitis developed, due to secondary infection. None of the glands was involved. The specimen had the gross appearance of lupus and was now being examined by Dr. Prudden. According to Dr. Jacobi, lupus is very rare in young children.

DR. ROBINSON thought there must be some doubt as to the correctness of the diagnosis. In the case under discussion the course of the disease was more acute than that of lupus, and he thought in all probability it was one of lymphangitis.

The paper of the evening, entitled

THE PRESENT STATUS OF ORTHOPEDICS,

was then read by DR. H. L. TAYLOR. (See page 424.)

DISCUSSION.

DR. ROBERT NEWMAN spoke of the difficulty in obtaining a properly constructed and sensible shoe for children, most shoemakers making them so narrow and small that they will not fit any foot. He thought the extensive use of gymnastic exercises, as advocated by Dr. Taylor, a very important point in treatment. It is beneficial in all cases and results in correction of the deformity in some instances. He referred to cases of partial fracture of the coccyx, and expressed the opinion that the treatment of such injuries should belong to orthopedics.

DR. L. DUNCAN BULKLEY referred to two cases of "orthopedic neurasthenia" which had come under his observation. The first was that of a woman, forty-five years of age, who practically had been bed-ridden during six months and was under the care of a gynecologist. She was treated by hydrotherapy and muscle exercise, and

in six months was so well that she began to ride a bicycle. The second patient was a woman who had sustained some injury of the spine by the falling of an elevator and was suffering from traumatic neuritis. She had been wearing some form of jacket or support. This was removed and she was treated in the same manner as the other patient, with the result that she was entirely cured and able to return to her duties as nurse.

DR. S. N. LEO said that he heartily approved of Dr. Taylor's admirable paper. He thought the enormous immigration to this country is responsible for most of the rachitic children who are brought to hospitals and dispensaries to be relieved of deformities. The majority of these cases occur among Italians, who live in over-populated quarters of the city and are always ill-fed. He also thought that the hard benches, and the cramped and faulty position which children are obliged to maintain while in school have much to do with the development of orthopedic diseases.

DR. JOHN F. ERDMANN asked the author of the paper if he had ever seen sloughing follow the use of Bradford's adjuster. He could easily see how this might occur over bony prominences where pressure was brought to bear. He also asked if he had ever employed injections of chlorid of zinc in congenital dislocation of the hip; also, if in using the Bradford genuclast, there was not danger of rupturing the popliteal artery, and referred to a case in which this had been done by manual correction. He also wished to know whether the author had ever employed Dr. Frederick McGuire's method of treating ankylosis by excessive temperature.

DR. JOSEPH COLLINS said that he had seen many cases in which the lack of proper orthopedic treatment at an early stage was very evident. Everyone would agree that after the acute phenomena in anterior poliomyelitis has subsided, a certain amount of benefit could be obtained by the proper employment of electricity, massage and hygienic measures; but there is one point which was not sufficiently recognized by the general practitioner, and that is that these measures must be employed early. He was surprised to hear Dr. Taylor speak favorably of tendon-grafting in anterior poliomyelitis, as the results which he had seen follow this method of treatment had not been good. He thought the subject of lateral curvature a very important one, and was of the opinion that it is due to an original defect in the tissues from which muscle and connective tissue are formed. He did not think that cases of neurasthenia accompanied by irritable spine or any of the traumatic neuroses should be discussed in a paper on orthopedic surgery, as such cases rarely require the attention of the orthopedic surgeon.

DR. DESSAU said that the subject covered by the paper was very broad, and, while the author had handled it from the standpoint of the specialist, he showed very plainly the necessity of the specialist being familiar with the entire field of medicine. He appreciated more than anything else the stress which had been laid upon hygienic measures, which he considered an important point, as unhygienic environment is an important factor in the causation of rachitis.

THE PRESIDENT said that he was surprised that nothing had been said about the use of the bicycle, and was curious to know if any injurious effect is produced by the faulty attitude in which boys usually ride. He did not agree with those who thought that braces or some form of jacket is not necessary in cases of spinal irritation, for he had known of cases in which an apparatus of this kind gave great comfort.

DR. TAYLOR, in closing, thanked the members for the attention they had given his paper, which was a difficult one to discuss in a general society, for the reason that it necessarily had been very much condensed. He had intended to give an outline of the orthopedic science and art at the present time, and he trusted that the paper has not seemed too dogmatic.

Fracture of the coccyx, mentioned by Dr. Newman, is a very painful affection, which requires appropriate treatment, but he did not consider it strictly orthopedic. Dr. Fruitnight had mentioned heavy gymnastics for lateral curvature. At present this is in the experimental stage. The bad sanitary condition of many school-rooms and the prevalence of rachitic diseases among the foreign population had been mentioned. It is a fact that a large proportion of these cases in New York occur among the children of the Russian and Polish Jews and Italians, and there are two reasons for this—their ignorance and their cupidity. They are ignorant as to what constitutes proper nourishment, frequently allowing their children to nurse until two or three years of age, and then feeding them largely on tea, coffee, and cake. Their cupidity is manifested by their saving out of their meager earnings, at the expense of nourishing food. He thought the whole subject of school sanitation and the health of the pupils should be seriously treated.

In regard to sloughing as a result of the use of the Bradford apparatus, he said this is possible, but it is rare when the technic of the operation is well understood. He had had no experience with injections of chlorid of zinc in congenital dislocation of the hip. In regard to heat and electricity in the treatment of ankylosis, good results have been obtained from both, and much is to be hoped from the development of these methods of treatment. The disabilities following multiple neuritis resemble those resulting from infantile paralysis, and similar treatment is required. He had felt justified in speaking hopefully of tendon-grafting from the reports of Goldthwaite and others.

Dr. Collins' remark about lateral curvature had interested him very much. It was the habit to attribute the commoner forms of lateral curvature to muscular weakness and habitual faulty attitude. These explanations have never satisfied him, nor has any explanation which has as yet been brought forward. In regard to bicycle riding, he, of course, did not approve of the doubled-up attitude, but had never known of particular cases of injury from it. Morton's disease sometimes bothers orthopedists as well as neurologists. The treatment indicated is to so adjust the shoe as to remove pressure from the heads of the metacarpal bones. In obstinate cases, the inflamed nerve-filaments should be excised.

REVIEWS.

A SYSTEM OF PRACTICAL THERAPEUTICS. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia; Physician to the Jefferson Medical College Hospital. Vol. IV. With illustrations. Philadelphia and New York: Lea Brothers & Co., 1897.

The enormous strides made by therapeutics during the past five years has induced the editor of this well-known "system" to add a fourth volume to the work. In the selection of his contributors he has displayed mature and careful judgment, and the result is a series of most excellent papers and monographs embodying much that has been accomplished in this field during late years.

The introductory chapter on "Recent Advances in Hydrotherapy" by Dr. Simon Baruch is a clear *résumé* of the various applications of water in disease, and furnishes a very satisfactory supplement to the author's article in Vol. I. Of Dr. S. Edwin Solly's article on "The Present Treatment of Tuberculosis," we need only mention that it is fully in accord with the accepted modern views of the subject, and is based largely upon original work. Dr. Edward Martin's chapter on "The Present Treatment of Syphilis" is a very satisfactory one. The author rightly says that absolute reliance cannot be placed on Keyes' method of gauging the dose of mercury; however, he commends the procedure as an excellent one. Dr. J. M. Anders has written on "Typhoid Fever and Malarial Diseases," and the subject is treated in a clear and scholarly manner. It is not generally known that a one-fifth-percent. solution of mercuric chlorid requires six hours to thoroughly disinfect typhoid stools, and that twenty-four hours is required by a five-per-cent. solution of carbolic acid. The urine should be treated in the same manner, as typhoid bacilli have been repeatedly found in this secretion. Among the hypnotics used in typhoid fever we are somewhat surprised not to find trional mentioned.

In Dr. Hare's article on "Influenza," the affection is described as "arising as the result of infection by some agent as yet not discovered." The omission of Pfeiffer's bacillus is also noted in the chapter by Ingles on "Nasal Affections." We are convinced that this is a simple, careless oversight. Dr. Hare has also written the chapters on "Scarlet Fever and Measles," "Diabetes Mellitus," and "The Intestinal Parasites."

The articles are somewhat short but fully satisfactory. Dr. E. Fletcher Ingals' discussion of "Diseases of the Nasal Chambers and Associated Affections," is fully what we would expect from the author's previous writings on this subject, and the article is well illustrated. The chapter on "Diseases of the Uvula, Pharynx, and Larynx" by Dr. S. Braden Hyle, gives in brief compass the various therapeutic measures used in these diseases. Dr. William H. Park in the chapter on "New Facts and Methods in the Treatment of Diphtheria" contributes many valuable tables of statistics of the antitoxin treatment in New York City, and gives a clear *résumé* of the methods used. "Asthma, Bronchitis, and Whooping-cough" receives

full and systematic consideration by Dr. Norman Bridge.

Dr. A. J. McCosh's discussion on "Pleural Effusion and Empyema; Abscess and Gangrene of the Lung" is exhaustive and scholarly, and a very satisfactory consideration of the etiology of these diseases is given. All directions for the surgical treatment are clearly detailed. Dr. James B. Herrick contributes the chapter on "Pneumonia, Croupous and Catarrhal, and Pleurisy" and presents the subject in a clear and straightforward manner, mentioning the various "specifics" which have been advocated in pneumonia. The chapter on "Diseases of the Heart" by Dr. Frederick P. Henry fairly covers the ground. The Schott treatment is fully described. "Diseases of the Blood" by Dr. Ralph Stockman covers less than twenty pages and is supplementary to Shattuck's article in Vol. II. The etiology and pathology are well discussed, and the author gives references to several of his recent writings on the subject. Dr. Joseph Eichberg has written on "Diseases of the Liver," and although most of the pathologic conditions affecting the liver receive separate headings, the chapter is not entirely satisfactory.

"Diseases of the Thyroid and Thymus Glands, Myxedema, Cretinism, Graves' Disease, and Obesity" is the title of Dr. S. Meltzer's contribution, and it gives evidence of an intimate acquaintance with the literature on the subject and of a large personal experience. The ground is well covered, and most of the recent views as to the etiology of these diseases are given. In the chapter on "Diseases of the Stomach" by Dr. Thomas G. Ashton, we believe that too much weight is given to the influence of electricity in the treatment of chronic gastritis and dilatation of the stomach. The use of methyl-blue in the treatment of cancer of the stomach is mentioned, but methylene blue is undoubtedly the drug referred to. Dr. George R. Fowler has written on "Peritonitis, Non-operative and Post-operative, Appendicitis, Paratyphilitic Abscess, and Obstruction of the Bowels." His classification of the various forms of peritonitis is not at all satisfactory. In discussing perforative peritonitis, the author says: "In this variety the infection has its origin in the intestinal canal." The perforation of any abdominal or pelvic abscess may cause this form of peritonitis, but the etiologic factors together with several others are all classed under the general term "infectious peritonitis." The other forms mentioned are, "symptomatic peritonitis," "tubercular peritonitis," and "undetermined infections."

The chapter on "Diseases of the Rectum and Anus" by Dr. Joseph M. Matthews gives in a practical way the usual means for dealing with the affections. Dr. W. W. Johnston discusses "Diarrheal Diseases and Dysentery" in a most satisfactory manner, and all the most recent methods of treatment are enumerated. "The Modern Treatment of Diseases of the Skin" is by Dr. H. W. Stelwagon, who has briefly described some of the rarer skin diseases not mentioned in Vol. III., in addition to the modern treatment of the more common forms. A most satisfactory chapter is that on "Spasmodic Affections of the Nervous System" by Dr. Joseph Collins. The author advises larger doses of exalgin in chorea, especially in very acute cases, but liberal doses of iron should be

administered at the same time. Arsenic, however, is advocated in all cases, but extremely large doses are not necessary. The author's condemnation of operations on the generative organs for the cure of hysteria meets with our approval. Following this is an excellent chapter on "The Drug Habits" by Dr. F. X. Dercum. A valuable and most interesting article on "The Disorders of Sleep" is contributed by Dr. Hugh T. Patrick, and the value of hydrotherapy as a hypnotic procedure is fully appreciated.

The remaining articles are the "Therapeutics of Renal Diseases" by Dr. Nathan S. Davis, Jr.; "Therapeutics of the Genito-urinary Diseases of Women" by Dr. Edward E. Montgomery; "Therapeutics of the Male Genito-urinary Tract" by Dr. William T. Belfield; "Diseases of the Eye and their Treatment by the General Practitioner" by Dr. Casey A. Wood; and "Diseases of the Ear, and their Treatment by the General Practitioner" by D. S. Maccuen Smith. Space does not admit our reviewing these chapters in detail, but we have read them all with interest and profit.

All in all, the volume before us contains a wealth of valuable information and is one deserving of highest commendation. We congratulate the editor and the makers of the book for an extremely satisfactory modern work on practical therapeutics. The volume forms an excellent complement to those already published and gives the work a completeness, which if it did not demand, is exceedingly satisfactory nevertheless.

TWENTIETH CENTURY PRACTICE. BY LEADING AUTHORITIES OF EUROPE AND AMERICA. Edited by THOMAS L. STEDMAN, M.D. In twenty volumes. —Volume IX., Diseases of the Digestive Organs. New York: Wm. Wood & Co., 1897.

JOHANN MIKULICZ and Werner Kümmel open the ninth volume with a description of the local diseases of the mouth, including those of the lips, gums, and cheeks. Especially to be recommended is the description of the diseases of the tongue.

In the section devoted to the diseases of the intestines, Ewald gives an excellent account of the treatment of habitual constipation. The article on appendicitis and perityphlitis is well worth the reading. We looked in vain, however, for a systematic classification of the varieties of appendicitis, and we find practically no mention of the gangrenous form of that disease.

Virgil P. Gibney and J. B. Walker of New York contribute a well-written and well-illustrated article on hernia and its treatment. The section devoted to diseases of the spleen comes from the pen of Dr. Alfred Stengar of Chicago. Professor Semmola and Dr. Geoffredi write on the diseases of the liver. The authors give an admirable account of the physiology of the liver and the general symptomatology of hepatic diseases.

The article by Murphy of Chicago is a comprehensive, yet concise description of the symptoms and treatment of diseases of the gall-bladder. The section on "Movable Kidney," by Kendal Franks, seems to us to be out of place in a volume devoted to the "Diseases of the Digestive Organs." We cannot understand why it was

inserted in this volume. The paper, however, is well written and well illustrated. The author makes a clear distinction between floating and movable kidney; the former always being congenital. The author gives a very satisfactory explanation of the infrequency with which movable kidney is found at the *post-mortem* table.

THERAPEUTIC HINTS.

The Treatment of Common Colds.—BLONDEL (*Revue de Ther.*, August 1, 1897) recommends the following treatment for acute bronchotracheitis.

1. In the beginning, and only in the beginning, of the illness:

℞ Tincture of aconite root . . .	15 drops
Tincture of ipecac. . . .	2.5 drams
Menthol } aa	1.2 grains
Saccharin }	
Alcohol	10 drams
Syrup of tolu	4 ounces.

Two or three teaspoonfuls of this mixture are to be taken at intervals of one hour after the two principal meals of the day.

2. For the coryza one may use a powder composed of equal parts of biborate of soda, alumnol, and powdered sugar.

3. If the treatment is undertaken later two teaspoonfuls of the following mixture may be taken every two hours:

℞ Tincture of aconite root . . .	15 drops
Antipyrin	30 grains
Syrup of codein	3 drams
Syrup of polygala	5 drams
Syrup of tolu	1 ounce
Syrup of cherry laurel	13 drams.

4. For the final period, that of expectoration, etc., turpentine, creosote, or guaiacol, may be given in capsules after each meal.

Pills for the Treatment of Sciatica.—

℞ Pulv. opii	} aa	gr. xv
Pulv. ipecacuanhæ		
Sodii salicilat.		3 iss
Ext. cascariæ segrad.		q.s.ad.

M. Ft. pil. No. xx. Sig. One to three pills daily.—Richardson.

For Acne Rosacea.—In the local treatment of the first grade of acne rosacea, Van Harlingen reports rapid results from the application, several times daily, of a lotion composed as follows:

℞	Sulphuris precip.	.	.	.	.	3 i
	Pulv. camphoræ	.	.	.	.	gr. v
	Pulv. tragacanth	.	.	.	.	gr. x
	Aq. calcis	} aa	.	.	.	f 3 i.
	Aq. rosæ		.	.	.	

M. Sig. Apply night and morning.

For Pruritus Vulvæ.—One of the best preparations in the treatment of this affection is the following:

℞ Zinci oxidi	3 vi
Acid. salicylici	gr. xv
Glycerini	3 vi.

M. Sig. Apply at frequent intervals.

WOUND-INFECTION WITH THE BACILLUS ÆROGENES CAPSULATUS.¹

BY JOHN F. ERDMANN, M.D.,
OF NEW YORK;

ATTENDING SURGEON TO ST. MARK'S AND GOUVERNEUR HOSPITALS;
WITH DISCUSSION,

BY EDWARD K. DUNHAM, M.D.,
OF NEW YORK;

DIRECTOR OF THE CARNEGIE LABORATORY;
AND BACTERIOLOGIC REPORT,

BY HARLOW BROOKS, M.D.,
OF NEW YORK;

ASSOCIATE IN BACTERIOLOGY, PATHOLOGICAL INSTITUTE OF THE
NEW YORK STATE HOSPITALS; ASSISTANT CURATOR
OF BELLEVUE HOSPITAL.

ALTHOUGH the subject of the bacillus ærogenes capsulatus belongs to the field of the bacteriologist, the infection by the bacillus is so powerful and rapid as to present a clinical picture to the surgeon well worthy of study.

During the year 1891 Dr. Wm. Welch of Baltimore wrote an article describing the organism and its methods of cultivation. In the *Journal of Experimental Medicine*, January, 1896, a paper was published, to be concluded at a later date, by Drs. Welch and Simon Flexner, entitled "Observations Concerning the Bacillus Ærogenes Capsulatus," in which a series of twenty-three personal observations by these gentlemen is reported. In each of these cases but a brief history is given, with a view of demonstrating the presence, *ante-* or *post-mortem* of this bacillus, and from this article I shall make free collations from the group of strictly surgical cases presented.

It is said that this bacillus is, or may be, conveyed through the soil, and, from an analysis of all cases reported in which an examination of the intestinal contents has been made, I am inclined to believe its chief habitat in man is the intestinal tract, from whence it is conveyed by the lymphatics and blood to various regions of the body. It will be noted that in several of the surgical cases the infection was particularly marked in cases involving the anoperineal region, several of these being genito-urinary cases, and in addition to these I have had access to the proof of an article, by Dr. E. K. Dunham of this city, published in the *Johns Hopkins Hospital Bulletin* for April, 1897, containing the histories of five cases, the second of which is the one reported by

myself, and also one case, unpublished, occurring in the service of Dr. Bryant, at St. Vincent's Hospital, of this city.

For a long time, and even at present, cases of infection by the bacillus ærogenes capsulatus were called malignant edema, air-embolism, emphysematous gangrene, etc., but since the study of this bacillus by Drs. Welch, Flexner, and Dunham we know that the cases are entirely different, at least in the causation, although decidedly similar in their clinical appearance. This confusion is due to the development of a type of gangrene and marked emphysema in most cases, with delirium and fever allied to the cases of malignant edema. On autopsy in cases of infection with this bacillus we have the "Schaum-organe" (so-called by the Germans) as a result of the development of areas of gas in various viscera which gives the peculiar foam or "schaum" appearance to these structures.

The infection may be pure or mixed. By analysis of the reported cases of Welch, Flexner, and Dunham, it will be seen that there were two cases of pure infection, with two deaths, and fourteen cases of mixed infection, with ten deaths, although one of these was probably due to tetanus; that the organisms most frequently found were the bacillus coli communis and the streptococcus pyogenes, and that in several patients who recovered the streptococci were found. From these results it is readily seen that all recoveries were instances of mixed infection, and also that patients with mixed infection in whom the disease terminated fatally lived longer than those in whom there was a pure infection. This fact would incline us to consider cases of mixed infection as being by far the more favorable. In a case of pure infection (Frankel) there was no pus, but a turbid, brownish fluid, and a grayish, macerated condition of the underlying muscles were found. This condition was found in the case reported by myself in the article mentioned, while in cases of mixed infection pus is usually found. In a number of the cases reported the bacillus was observed only on *post-mortem* examination, due to the fact that cultures were not taken during life. This naturally causes our statistics to lose a certain degree of interest, but, at the same time, in cases of infection of unbroken surfaces it can only be reasoned that the bacillus must have been present during life, but developed after death, as it is proven that this germ multiplies rapidly in the dead. The infection, as be-

¹ Read before the Surgical Section of the New York Academy of Medicine, May 10, 1897.

fore stated, may be conveyed by means of the blood, or by instruments, as in one case reported by Dr. Dunham, following catheterization by the patient himself. Two cases reported by Frankel, contained in the article by Welch and Flexner, were due to hypodermic injections, one of morphin and the other of camphor oil. One case reported by Halsted was due to an infected bullet.

In but one case out of twelve reported by Welch and Flexner a chill is reported as the first symptom.

As a rule, delirium, rapid pulse, high temperature (101° to 105.5° F.), with emphysema and discoloration of the diseased area, or marked abdominal distension when the peritoneal cavity is involved, are the main symptoms, the emphysema and discoloration being very rapid. Upon incising the emphysematous tissues the escaping gas, when light is applied, will burn with a blue flame. The duration of the disease after evidences of infection varies from four to forty-eight hours in the pure and from forty-eight hours to ten days in the mixed type. The sudden delirium and general condition of stupor or somnolence seem to be due to a toxemia rather than to blood-involvement by the organism.

The importance of an early diagnosis in these cases is of inestimable value, as amputation, when possible, or liberal incisions with free drainage in cases of pure infection, is the only rational treatment; while in cases of mixed infection, the evidences not being so acute, evidently held in abeyance by the mixture of bacilli and cocci, free incisions for drainage, followed later by amputation if the disease is rapidly progressing, is indicated.

The history of my case is as follows:

L. M., seven years old, fell from the fourth floor of a house to the ground, on September 19, 1896, at about 3 P.M., and sustained a compound fracture of the right humerus at about its middle, and also a small scalp wound. He was seen about two hours later, and in addition to the above injuries was found unconscious. The arm was very dirty and grimy. Considerable contusion of the right shoulder was sustained. Every antiseptic and aseptic precaution was taken, and the patient was put to bed in very poor condition. At 8 P.M. his temperature was 100° F., pulse 130 and respirations 44. The extremities were cold. On September 20th the temperature throughout the day was from 101° to 101.6° F., pulse 130 to 140, and respirations 30 to 42. The patient was unconscious. September 21st, 9 A.M., temperature 101.6° F., pulse 150, respirations 42; 2 P.M., forty-seven hours after the injury, temperature 104.4° F., pulse 144, respirations 44.

Apparently the increase in temperature and pulse was the first evidence of the infection. The dressings were removed, and the arm and pectoral region of the right side were found tense, of a greenish-bronze color, and, upon incising, a peculiar brown-

ish fluid with slight odor escaped. The muscles of the arm were thoroughly macerated. As the process had extended to the chest, amputation was deemed inadvisable, but free drainage was made with incisions, and bichlorid of mercury dressings were applied. At 9 P.M. his temperature was 105.4° F., pulse 166, and respirations 32. September 22d, 3 A.M., temperature 104.6° F., pulse 170, respirations 40. The arm was again dressed. Edema had extended to the right half of the chest and shoulder and down the forearm. There was at this time some emphysema present. The patient died at 3 P.M., three days after the injury and one day after the first marked evidences of this infection. Thinking the case to be one of malignant edema, a culture was taken before death, but after the second dressings had been removed.

In addition to this case, I will briefly summarize those published in the articles of Welch, Flexner, and Dunham having a distinct surgical aspect, and comment upon the cases of infection with medical bearing. There were ten observations by the first-named observers upon general surgical cases occurring in the services of Drs. Halsted, Tiffany, Kelly, and Mann, which I have arranged in the accompanying table, to which I add the five cases, including my own, reported by Dr. Dunham, and the case already mentioned, for which I am indebted to Dr. J. D. Bryant of New York.

It will be observed that the best results followed in cases in which amputation was performed, and that in all cases of recovery the infection was of the mixed variety. The organism most frequently found in the cases of mixed infection was the streptococcus, and in six of the tabulated cases—Nos. III., XII., XVII., and XVIII., by Welch and Flexner, and Nos. IV. and V., by Dunham—the colon bacillus was found. In addition to these tabulated cases there are four cases of Frankel's (reported by Welch and Flexner), one of pure infection and three of mixed, three patients recorded as dying, while the result in the fourth case (of mixed infection) was not stated.

In looking over the medical cases reported by Welch and Flexner we find the bacillus present in the peritoneal cavity in the following: No. VIII., cancer of the duodenum, with perforation. No. X., typhoid, with perforations. No. XI., typhoid, with perforations. No. XIII., diabetes mellitus and cirrhosis of the liver. No. XIV., arteriosclerosis, chronic diffuse nephritis, etc. In Cases No. XV. (acute endocarditis and chronic Bright's disease) and XVI. (thoracic aneurism and pulmonary infarctions) the bacillus was found in the infarcted areas and in the pleura, and in these two cases the authors question the possible infection from the lungs or conveyance from the intestine.

From the above observations we deduce the following:

1. That, from the frequency of the presence of this bacillus in the peritoneal cavity, and also its frequent association with the colon bacillus, we are justified in believing its habitat in man to be the intestinal tract.

2. That the infection may be conveyed by means of the blood from its habitat or introduced from without, probably from the soil.

3. That, while in pure infections the progress is extremely rapid and decidedly grave, in mixed in-

fection it is protracted and the prognosis is not so grave.

4. That the use of an antitoxic serum, or the infecting of cases of pure infection with the streptococcus, would at present seem justifiable.

5. That liberal incisions, with drainage, or early amputation, is demanded in all cases of infection with the bacillus *aerogenes capsulatus*.

Since writing this paper Dr. Halsted's open-bath method of treating cases of sepsis and cases of infection with this bacillus has come to the attention of the author, and, after seeing the experiments of Dr.

CASES REPORTED BY DRs. WELCH AND FLEXNER.

	Case of Dr.	Sex.	Injury.	Operation.	Result.	Pure.	Infection Mixed with	Bacilli Found	
								<i>Ante-mortem.</i>	<i>Post-mortem.</i>
	Halsted.	M.	Gun-shot of knee.	Amputation of thigh.	Recovered.	No.	Staphylococcus aureus and staphylococcus pyogenes.	Yes.	
II.	Halsted.	M.	Compound fracture of leg.	Amputation of thigh.	Recovered.	No.	Staphylococcus albus.	Yes.	
III.	Halsted.	M.	Injury of hip and wound of rectum.	Extensive incisions.	Died.	No.	Intestinal (?) bacilli and streptococci.	Yes.	
IV.	Tiffany.	M.	Compound comminuted fracture of patella.		Died.	Yes.		Not stated.	Not stated.
V.	Tiffany.	M.	Compound comminuted fracture of forearm.	Amputation of arm.	Recovered.	No.	Pyogenic cocci.	Yes.	Yes.
VI.	Mann.	F.	Gangrene (?) of hand and forearm.	Amputation of arm.	Recovered.	No.	Streptococci.		From the amputated arm.
VII.	Halsted.	F.	Phlegmon of hand and forearm.	Amputation.	Died.	No.	Streptococci and staphylococci.	None found before death.	Twenty-four hours after death.
XVII.	Halsted.	M.	Catheterization for retention of urine, stricture, sepsis.		Died.	No.	Colon and streptococci.	Not examined.	Three-quarters of an hour after death.
XVIII.	Halsted.	M.	Catheterization for enlarged prostate, retention.		Died.	No.	Colon and pyogenic.	Not examined.	Yes.
XII.	Kelly.	F.	Strangulated umbilical hernia.	Operation.	Died.	No.	Colon and pyogenic.	Not examined.	Yes.

CASES REPORTED BY DR. E. K. DUNHAM.

	Case of Dr.	Sex.	Injury.	Operation.	Result.	Pure.	Infection Mixed with	Bacilli Found.	
								<i>Ante-mortem.</i>	<i>Post-mortem.</i>
I.	Dennis.	F.	Cellular infection about the lower jaw.	Incision.	Died.	No.	Pyogenic cocci.	Yes.	Yes.
II.	Erdmann.	M.	Scalp wound, compound fracture of right arm.	Free incision.	Died.	No.	Pyogenic cocci.	Yes.	Not examined.
III.	Gouley.	M.	External urethrotomy primarily, passage of sterile sound secondarily.		Died.	Yes.		Yes.	Yes.
IV.	Hotchkiss.	M.	External urethrotomy primarily, passage of sterile sound secondarily.		Died.	No.	Coli communis (?)	Yes.	Yes.
V.	Abbe.	M.	Prostatic hypertrophy, catheterization.	Incision.	Died.	No.	Coli communis and streptococci.	Yes.	Not stated.
I.	Bryant. ¹	M.	Compound fracture of leg.	Incision, amputation.	Died.	No.	Streptococci and staphylococci.	Yes.	

¹ Unpublished.

Total, 16 cases; 12 males, 4 females. Died, 12; recovered, 4. Pure, 2. Infection mixed in 14; 6 with colon bacilli.

E. K. Dunham and hearing his discussion of this paper, the author advocates most heartily the open-bath treatment, as far as possible, in these cases.

DISCUSSION BY DR. EDWARD K. DUNHAM.

Infection with the bacillus *aerogenes capsulatus* (Welch) differs from the infections with the ordinary pyogenic cocci in that the bacillus is a strict anaërobe; *i.e.*, is incapable of growing in the presence of free oxygen. It appears to me that advantage might be taken of this fact in contriving an appropriate treatment for cases of infection by this bacillus. If we can so arrange matters that the bacilli within the tissues are exposed to a sufficient amount of oxygen, we shall be able to check their growth and arrest the progress of the destruction they occasion.¹

In devising a mode of treatment with this end in view, the question of how much oxygen must be present to stop the development of the bacillus is of prime importance. I have endeavored to approach this question by means of the following experiment, suggested by the procedure followed by Dr. Halsted of the Johns Hopkins Hospital in his treatment of cases of severe infection with full and continuous hot baths:

A series of six test-tubes, provided with a small inner tube entering at the side and extending nearly to the bottom, was filled to various heights with nutrient bouillon and then sterilized by moist heat. Into each tube a number of short threads containing spores of the bacillus *aerogenes capsulatus* were then introduced, and hydrogen was passed through the bouillon, by means of the small inner tube, for half an hour. The object of this was to displace the oxygen in the bouillon. The tubes were then placed in an incubator kept at 35° C. The depth of bouillon in the tubes was 3, 2¾, 2¼, 2, 1½, and ¾ inches respectively.

After the expiration of fifteen hours the tubes were taken from the incubator and examined. An abundant growth was found in the two tubes containing the most bouillon, the latter being very cloudy throughout. There was a moderate sediment of bacilli in the bottom of these tubes, and minute bubbles of gas could be seen rising through the bouillon and collecting in foam on its surface. The other four tubes, containing less bouillon, appeared clear. (See Fig. 1.)

I inferred from these results that the bouillon at the bottom of the two tubes containing the most broth remained sufficiently free from oxygen, after the flow of hydrogen had been stopped, for the spores which

were present to develop into bacilli and for the latter to grow with a luxuriance ample enough to maintain anaërobic conditions in the bouillon by the production of the gas generated by the bacillus itself. This gas we know to consist chiefly of hydrogen and carbon dioxid (hydrogen, sixty-four per cent.; carbon dioxid, twenty-eight per cent.), so that its constant evolution within the culture-medium would be equivalent to the continuous passage of a moderate amount of those gases through the broth. In the case before us this evidently sufficed to maintain anaërobic conditions within the tubes containing the largest amount of bouillon.

In the tubes which appeared to be clear the absorption of atmospheric oxygen by the bouillon had extended sufficiently deep and had been abundant enough to check the development of the spores at the bottoms of the tubes. In the two middle tubes of the series a very slight clouding of the bouillon in

FIG. 1.

Test-tubes containing different quantities of bouillon, showing extent of growth of the bacillus *aerogenes capsulatus*.

the small inner tube could be detected. It appeared, then, that the penetration of the oxygen into this inner tube was more tardy than its penetration through the surrounding broth. This may have been due to the tightness of the cotton plugs in the outer ends of the small tubes, for it was noticed that a considerable pressure was necessary in order to force the hydrogen through those plugs when the cultures were being prepared.

If we assume that the rate at which water will take up oxygen from the air is the same as the rate at which bouillon will absorb it, it appears to me that the results of this simple experiment throw some light upon the efficacy of the full-bath treatment of cases of infection by this bacillus. If incisions into the infected parts can be made free enough to expose the tissues containing the bacillus to the close

¹ The mere presence of oxygen does not *kill* the bacillus, but it prevents its growth, and therefore the advance of the infectious process, allowing time for further measures tending to the destruction of the bacterium to be put into practice.

action of water, the oxygen which the latter contains may be sufficient to check the growth of the bacillus.

There is one factor which is left out of consideration in this experiment, namely: the influence which might be exerted by the tissues to impede the passage of oxygen from water surrounding the tissues to the bacilli which they contain.

In order to gain some information on this point, I made the following experiment: About 5 c.cm. of a twenty-four-hour bouillon culture of the bacillus was injected into a vein of a rabbit, and, after a few minutes, the animal was killed. The liver was at once removed and pieces of it placed in dishes containing recently boiled water. These dishes, with their contents, were placed in an incubator. The fragments of liver must have contained many bacilli disseminated throughout their substance by the blood circulating in the hepatic capillaries during the life of the animal. The water in which the pieces of liver were immersed had been deprived of at least a large proportion of the oxygen it had contained in solution by the boiling, but its surface was freely exposed to the atmosphere. The least measurement of the pieces of liver ranged between one-half and one centimeter, and they were covered by from one to two centimeters of water.

After seven hours all the pieces of liver were crowded with small bubbles of gas, which so diminished their specific gravities that they floated upon the water with an immersion of only about two-thirds of their bulk. They were surrounded by a coarse foam, due to gas which had escaped from them and become imprisoned in the albuminous fluid resulting from the maceration of the tissues.

This experiment shows that the bits of tissue sufficiently impeded the passage of oxygen from the air and water to the bacilli to enable the latter to develop and evolve enough gas to maintain anaërobic conditions suited to their further and rapid multiplication.

Thinking that the deoxygenation of the water in which the pieces of liver were immersed in the last experiment might be the cause of the unfavorable results, I repeated the experiment, using water containing five and ten per cent. of peroxid of hydrogen in the place of boiled water. The results of this experiment were almost identical with those of the preceding one. At the end of eight hours all the pieces of liver were floating on the surface of the liquid in the dishes, and contained bubbles of gas readily discernible through the peritoneal covering.

In the first experiment, made with bouillon, the bacilli were placed under the least advantageous conditions for their development, for they were directly exposed to the action of whatever oxygen might be

present in the bouillon. In the other two sets of experiments the conditions were most favorable for the development of the bacillus, for not only were they protected from access of oxygen by a layer of tissue, but the tissue in which they were situated contained sugar, which we know would favor the production of abundant gas and so facilitate the continuance of anaërobic conditions.

In order to eliminate this last condition, I asked my friend Dr. Le Boutillier to repeat the last set of experiments, using bits of kidney instead of liver. His results were as follows: The pieces of kidney measured from $\frac{1}{2}$ to about $1\frac{1}{2}$ centimeters in their least diameters. They were placed in dishes containing $1\frac{1}{4}$ - and $2\frac{1}{2}$ -per-cent. aqueous solutions of peroxid of hydrogen, and were kept in an incubator

FIG. 2.

Section of liver infected by the bacillus *aerogenes capsulatus*, showing large spaces filled with gas as a result of the infection, and groups of bacilli.

for twenty-one hours. At the end of that time the pieces of tissue were removed from the dishes and placed in a five-per-cent. solution of formaldehyde. Sections made through the centers of these bits of kidney after they had been hardened failed to reveal the presence of spaces that would have demonstrated the production of gas in the tissues before they were hardened. That the bacilli were present in the tissues was shown on staining the sections, when a considerable number of bacilli could be seen in the renal capillaries. The bacilli were so scattered that it appeared highly improbable that they had multiplied.

These results are in sharp contrast with those obtained in the experiments with pieces of liver. Sections of those pieces revealed large spaces (Fig. 2) in the tissue, which had evidently been filled with gas, and

large groups of bacilli, the result of multiplication within the tissue. I ascribe this difference to the presence of glucose in the liver and its absence in the kidney, the glucose favoring the rapid and abundant evolution of gases free from oxygen.

A very striking and, it appears to me, very important result of the foregoing experiments is the demonstration which they afford of the unexpected ease with which these bacilli can establish and maintain anaërobic conditions when they have once begun to multiply in a medium suited to their growth. This fact enforces the necessity of prompt and thorough surgical treatment.

There is one factor in the problem of treatment the importance of which I have not been able to estimate in these experiments, and that is the inhibiting influence exerted upon the bacilli by living tissues. In the experiments which I have made the tissues have been dead, and whatever antagonism might have existed between living tissue and the bacilli was excluded. That such an antagonism exists and that it is considerable is shown by the fact that artificial cultures of the bacillus soon lose their virulence, and the bacilli they contain are incapable of multiplying in the bodies of living animals. How much the loosely combined oxygen carried to the tissues by the circulating blood may contribute to this result I am unable to say, but it is not improbable that it may have considerable influence.

Although the crucial test of modes of treating this alarming infection must rest on clinical experience, it appears to me that the few experiments I have made lead to the inferences that it would be wise to expose the tissues as freely as possible to the influence of oxygen, and especially to do away as thoroughly as possible with dead tissue, which would favor the multiplication of the bacillus, and the establishment of anaërobic conditions for its further increase. It appears not improbable that the immersion of the infected part or of the whole body in water, frequently renewed or oxygenated with peroxid of hydrogen, would meet these requirements, and, perhaps, by aiding the elimination of poisonous substances produced by the bacillus, diminish the intensity of the toxemia which seems to be a potent factor in causing the prostration observed in cases of this infection.

BACTERIOLOGIC REPORT BY DR. HARLOW BROOKS.

The material for examination was received at the Carnegie laboratory in a sterile test-tube in which it had been placed about seventy-two hours before. It was found to give off a very foul odor. Cover-slip preparations demonstrated the material to be made up of blood-clot and pus, in which were found many

cocci, together with a large bacillus somewhat resembling the bacillus anthracis. The ends of the bacillus were slightly rounded, and in places a distinct capsule was evident. It reacted to Gram's stain, also staining with the usual anilin dyes.

Inoculations were made on slant agar tubes, half of which were placed in the pyrogallate jar after the method of Buchner, and the remainder left under aërobic conditions. After forty-eight hours in the incubator the agar in both sets of tubes was covered with a profuse growth, those grown anaërobically being distinguished from the others by the very foul odor which emanated from them. Cover-glass preparations demonstrated the aërobic growth to be one of various cocci, while the growth in the anaërobic tubes was found to contain, in addition to the cocci, a large bacillus similar in form and staining reactions to that seen in the cover-glass preparations which had been made directly from the original material. In the growth, however, many of the bacilli were found in end-to-end pairs, in these pairs the length of each bacillus being somewhat less than the average length of the single bacillus. So active had been the production of gas in these tubes that in several the agar had been forced up from the bottom of the tube and the condensation-water was covered with small bubbles. The mixture with the cocci seems to have prevented the formation of any characteristic colonies.

Loops of the condensation-water which seemed most rich in the growth of the bacillus were inoculated into bouillon tubes, which, after being placed in the pyrogallate jar, were left in the incubator for twenty-four hours, at the end of which time the media was cloudy with growth, and the top of the fluid was covered with bubbles. Cover-slip preparations showed the same mixture as before, but the growth of the bacillus now predominated. One cubic centimeter of this mixed culture was injected subcutaneously into the abdominal wall of a large guinea-pig. After a few hours the animal became quite sick; it burrowed under the hay in the corner of its cage and cried and trembled when disturbed; the fur was ruffled and the eyes were kept closed. In a few days, however, full recovery apparently took place.

A few drops of the same culture was injected into the ear-vein of a rabbit, and five minutes later the animal was killed and placed on the incubator overnight. In the morning great emphysema of the subcutaneous connective tissue over the entire body was found to be present. The eyeballs were forced from their sockets, and a blood-stained, foul-smelling fluid was escaping from the nostrils and mouth. Puncture of the skin gave vent to a gas which smelled

like ammonium sulphid, and burned with a pale-blue flame.

At the autopsy the liver was found to be soft, of a dull clay color, and many air bubbles were present beneath the capsule and throughout the entire substance of the organ. On stripping off the capsule the surface of the organ was found pitted with these air spaces, which were apparently the much dilated vessels. The kidneys were edematous, soft, and pitted with air spaces similar to those seen in the liver. The mucous membranes of the bladder and stomach were edematous and covered with bleb-like elevations. In many places the walls of the intestine were completely broken down by the extensive *post-mortem* changes in them. The heart was distended by bloody foam and by blood-clot riddled with air spaces. The lungs showed extensive emphysema with edema. The subserous and subcutaneous connective tissues of the entire body were infiltrated with bubbles of gas.

Cover-glass preparations which were made from the various tissues showed in every instance the presence of the large bacilli in great numbers, but cocci were found, as before, in all of the preparations. Small portions of the culture were spread over large surfaces of culture-media, and by this means it was possible, after some trouble, to secure isolated colonies from which pure cultures of the bacillus were obtained. The bacillus was found to be a broad, straight rod, about five μ in length. The ends were slightly rounded. In cultures it was often found in end-to-end pairs, evidently dividing in this manner. The bacillus, when found in the tissues, is surrounded by a broad, indistinct capsule, but this was not the case in the cultures. It did not form spores on the media on which it was grown, although it was not cultivated on blood-serum, as Dr. Dunham has shown to be necessary for the production of spores in the bacillus *aerogenes capsulatus*. It grew most luxuriantly in alkaline bouillon, and fairly well on agar-agar.

The rapidity of growth varied greatly. It seemed to grow much more slowly and in a less characteristic manner as the number of implantations increased. It grew only under anaërobic conditions, and very slowly, unless at the incubator temperature. The colonies appeared on agar-agar as raised, grayish, opalescent spots. The growth was most luxuriant where the medium was moist. Some of the most characteristic colonies developed between the wall of the tube and the body of the medium. The bacillus accepted the ordinary anilin dyes, and gave a very positive reaction to Gram's stain. Motility was not present.

Injection of a pure culture of the bacillus into the

circulation of a rabbit a few moments before the animal was killed gave rise to the emphysema as described following the intravenous injection of the mixed culture. Subcutaneous inoculation of guinea-pigs failed to produce fatal results, although in every instance the animal showed considerable reaction to the inoculation.

The bacillus found in this case appears to be identical with that described by Welch and Nuttall as the bacillus *aerogenes capsulatus*. It is difficult to determine the exact position which the bacillus bore in this instance, since, as from the history, it is plainly shown that death was due to infection, yet the mixed cultures made directly from the original material, when inoculated into guinea-pigs, failed to produce fatal results; but it must be remembered that about seventy-two hours elapsed between the time when the material was procured and when the first tube was placed in the incubator. It has been shown by Dr. Dunham that the bacillus *aerogenes capsulatus*, when first taken from a subject dying of the disease, is very virulent, producing death when injected into animals within a few hours, but that it soon loses this intense virulence as the material grows old or as the number of successive implantations increases. Taking this fact into consideration, it may safely be assumed that the time elapsing between the removal of the material and the first inoculation was sufficient for the bacillus to become to a large extent attenuated; but, unfortunately, in the absence of an autopsy we are unable to say whether the lesions present in this case were those which have been shown to be characteristic of this infection.

THE OPERATION ITSELF IN APPENDICITIS.¹

By LEWIS S. M'MURTRY, M.D.,
OF LOUISVILLE, KY.;

PROFESSOR OF GYNECOLOGY AND ABDOMINAL SURGERY IN THE
HOSPITAL COLLEGE OF MEDICINE.

HITHERTO our discussions upon appendicitis have been directed for the most part to the pathologic condition as related to symptomatology with a view to early diagnosis and determination of the question of operative interference, with only brief and incidental consideration of the operative technic. The multifarious types presented by the disease, the variety in character and extent of the lesions, the several stages of progress in which operation is performed, the complications and sequelæ, compose a series of requirements in operating which may only be successfully met by the best surgical judgment and operative skill. In view of these facts, and the additional one that the profession has very generally

¹ Read at the Tenth Annual Meeting of the American Association of Obstetricians and Gynecologists, Niagara Falls, N.Y., August 17-20, 1897.

come to recognize appendicitis as a strictly surgical disease, cured only by operation, I have selected the operation itself as an appropriate and profitable theme for discussion at this time.

I propose to consider the subject under the following heads: (1) The incision. (2) Dealing with adhesions and with abscesses. (3) Removal of the appendix. (4) Drainage and isolation of the peritoneum by gauze.

The Incision.—Concerning the incision, three important considerations must be observed, the first being to obtain easy access to the *caput coli*, with sufficient working space, the second, to secure all natural advantages to facilitate drainage, and the third, to secure complete repair of the parietal structures incised and thereby prevent the occurrence of hernia.

The early operations for appendicitis were mostly undertaken in extreme cases, in which suppuration had occurred, and consisted in cutting into the abscess and evacuating and draining the same. For this purpose the vertical incision was adopted and is yet practised by many surgeons. This incision is made along the external border of the right rectus muscle, a little to the inner side of the right semilunar line. It should intersect a line drawn from the anterior superior iliac spine to the umbilicus, very nearly midway, and should be about three inches long. The sheath of the rectus had best be pushed aside slightly and not opened, so as to lessen the amount of bleeding. The muscles and fascia having been divided, the peritoneum is opened, and the *caput coli* found immediately beneath by the exploring finger. Kocher has called attention to the fact that a branch of the iliohypogastric nerve, which enters the sheath of the rectus, is divided by this incision. Atrophy of that part of the muscle supplied by this nerve has been observed after the operation. This incision furnishes good access to the parts involved; and when made and sutured under the protection of thorough asepsis, with proper management afterward, restores the integrity of the abdominal wall. In my early operations performed in this way, comprising a series of twenty-seven cases, mostly in the suppurative stage of the disease, the results were quite satisfactory. So far as I am aware, not one hernia occurred in the entire series.

The vertical incision does not, however, give as easy access to the appendix and to the outer and posterior areas adjacent thereto (which are so frequently involved) as does the oblique incision. The latter is preferable also for drainage, and affords an additional advantage by diminishing the danger of breaking through the inner wall when an abscess-cavity has formed about the appendix. This incision

is made parallel with Poupart's ligament and traverses the line from the anterior superior iliac spine to the umbilicus well over to the right side. It enables the operator to explore the right iliac fossa from the external boundary, thus giving protection to the general peritoneum which may already have been shut off by protecting adhesions. In my recent work I have operated altogether through this oblique incision.

A method of dividing the abdominal wall by a combination of incision and blunt dissection has been described by McBurney and commended by many writers on the surgery of the appendix. This is an oblique incision, in which, after dividing the skin and superficial fascia, the fibers of the parietal muscles are separated by a blunt instrument and held apart with retractors while the peritoneum is divided and the appendix removed. This incision is only applicable to non-suppurative cases, according to its author, though some operators claim to have advantageously extended its application to those in which suppuration has taken place. The theory of this incision, of course, is that by tearing apart the bundles of fibers of the abdominal muscles, instead of dividing them by incision, the natural crossing of fibers in the muscular structure of the abdominal parietes is preserved, thereby preventing hernia as a post-operative sequel. These refinements are not practicable in cases of perforative appendicitis in which the life of the patient depends upon thoroughness of operation and free drainage. Moreover, it is doubtful if separating muscular structures with a blunt instrument yields any advantage over the division of those structures by incision, provided all proper care is bestowed upon closure and retention of divided parts by suturing. In grave cases of appendicitis, in which the patient's life hangs trembling in the balance, the incision should be made with a view to gaining access to the parts with sufficient working space and free drainage, other considerations being secondary.

In cases of recurrent appendicitis, in all cases in which there is no pus outside the appendix, and in all cases in which the requirements are properly met by a single drain, the utmost care should be bestowed upon the suturing of the incision. In these cases I have used the through-and-through suture with silk-worm gut, together with immediate suture of divided muscle and aponeurosis with interrupted sutures of catgut. In these non-suppurative cases the silkworm-gut sutures should be allowed to remain for ten or twelve days. In suppurating cases, when extensive gauze packing and drainage prevent immediate closure of the incision, one angle of the wound should be brought together as far toward the middle of the

incision as practicable, and the remaining sutures of silkworm gut left untied until they may be utilized. The latter are the cases in which hernia is so often a sequel to operation and I do not see that any method of suture can overcome this danger. They are really cases in which the open treatment is an absolute necessity. Patients treated in this manner should be required to remain in bed much longer than is customary, until organization and consolidation of the new tissue formation uniting the incised parieties are complete. This will do more toward the prevention of hernia in this class of cases than any particular method of incision or partial closure of the same.

Adhesions and Abscesses.—In dealing with adhesions and abscesses the same general rules of surgical treatment should be observed in appendicitis as in similar conditions affecting other organs enclosed within the peritoneum. Whenever practicable, adhesions should be separated, abscesses emptied, disintegrated structures composing foci of infection removed, and cleansing and drainage secured by measures of assured efficiency. It is an established procedure in pelvic surgery to incise and drain accumulations of pus in exhausted subjects as an operation of expediency, looking to improved conditions for radical operation and permanent cure. In a limited proportion of cases, Nature completes the cure after such an incomplete operation. The same methods and similar results obtain in the treatment of appendicitis. The function of surgery is to save life; the attainment of ideals should be altogether subordinate to this supreme indication of all surgical operations. This axiom is eminently applicable to the disease under consideration, and, at the same time, we must concede that incomplete operations do not, as a rule, beget cures. In all operations for appendicitis, in all stages and varieties of the disease, the appendix should be removed whenever the patient's condition will permit completion of the operation. I am aware that many excellent surgeons endorse and pursue the practice of evacuating an appendicular abscess-cavity, affording drainage, and partially closing the incision without any attempt to remove the appendix and close the cecum at the point of sloughing. Though this may be the better practice for the occasional operator, it is far from safe to leave within the abdomen a perforated and sloughing appendix. While a certain proportion of these patients recover under an incomplete operation, the aggregate of results, including cases of fecal fistulæ and secondary operations, is not equal to that of completed operations. This conviction has not been formed from theory or by analogy. I have opened appendicular abscesses which

have burrowed along the intermuscular planes to a point in the lumbar region, and other remote points and in numerous instances the patients have recovered after protracted convalescence. On the other hand, I can cite numerous instances in which this procedure has failed. Four years ago I operated on a young woman, aged twenty-four, with suppurative appendicitis. Her condition was critical when first seen and operation was promptly performed. On opening the peritoneum through the usual incision and introducing the finger, pus poured from the wound. The insertion of a drain completed the operation. Convalescence was imperfect and ten days later the pulse, temperature, and general symptoms gave unmistakable evidence of continued suppuration. A second operation was performed and an abscess posterior to the cecum evacuated. The abscess-cavity was irrigated and deep drainage established. The patient made an incomplete recovery and suffered another attack three months later, when I again operated and removed the inflamed stump of an appendix. Recovery was prompt and the cure complete. Much suffering and no small risk to life would have been avoided had it been practicable to complete the operation with safety the first time. I do not mean to question the wisdom of refraining from searching for accumulations of pus by separating adhesions, from searching for the appendix, and from completion of all details when the patient is too feeble to bear such an operation. But when it is practicable to do so, I am sure the patient's welfare is best subserved by a complete operation.

In some cases of appendicitis, known as the fulminant type of the disease, the progress is so rapid that no confining wall of lymph is formed. In such cases the peritoneum is filled with serous effusion mingled with flakes of lymph, and general septic symptoms proceed with great rapidity. A perforated and gangrenous appendix will be found. Thorough irrigation of the peritoneum far and near, with drainage, constitutes the essential parts of the operative procedure.

The most common abscess location, in my experience, is posterior to the cecum. The exploring finger, passed down beside the external surface of the cecum, will enter the abscess-cavity. Less frequently the abscess will be found anteriorly. The omentum, cecum, and coils of intestine, with the parietal peritoneum compose the confining area. The appendix will be readily found in the abscess-cavity. Again, the pus may be confined by adhesions within the pelvis. These are the cases in which fluctuation may be detected by rectal palpation.

In these several locations the general peritoneum, preparatory to evacuation, should be isolated by

careful packing of gauze. When the abscess is post-cecal, long strips of gauze should be carefully tucked in position before carrying the exploration to evacuation of the abscess. There are three directions for gauze packing under these circumstances—in the pelvis, toward the median line, and toward the lumbar region. As the pus is evacuated, the patient is turned toward the right side and the pus carefully wiped away with loose gauze pads. The cleansing should be completed by thorough irrigation with warm salt solution, using for this purpose a small glass nozzle attached to the irrigator. Careful and gentle exploration should be made for additional accumulations of pus. When the abscess formation is localized in the other regions indicated, the same methods of evacuating and cleansing, with proper protection of the outlying peritoneum by gauze, must be observed. My experience compels me to look to thorough irrigation as the most potent of all our resources in this all-important part of the operative procedure. I place no reliance upon the use of peroxid of hydrogen, iodoform, or other chemic germicides here, but believe mechanical cleansing by washing, with the accompanying attenuation, will do more to arrest septic processes and save the patient than all other agencies combined.

Removal of the Appendix.—The cecum appears in several types in the adult, four distinct typical forms being described by anatomists generally. The appendix in man is the cecum of some lower animals in an undeveloped state. In the early period of fetal life the cecum with its vermiform appendix is near the umbilicus and descends into the right iliac fossa about the sixth month. Abnormal positions of the appendix, such as to the left of the median line and other similar displacements, are due to failure of descent of the cecum. The average length of the human appendix is about three and one-half inches, but it may vary from one to nine inches. While the cecum may in exceptional cases be only partially invested by the peritoneum, as a rule it is entirely covered by peritoneum and hence free and mobile in the abdominal cavity. The triangular folds of peritoneum forming the meso-appendix are reflected from the ileum to the appendix. The artery, vein, and lymphatics which supply the organ pass between the two layers of the meso-appendix. This process of the peritoneum varies in length and thickness, and also in the extent of its infolding of the appendix. The mobility of the appendix depends upon the length and breadth of the meso-appendix, and hence has a varying range of movement in various subjects within physiologic limitations. In the female there is a prolongation of the meso-appendix extending to the right ovary, which conveys an additional vascu-

lar supply to the appendix and which has been called the appendiculo-ovarian ligament. To this additional blood-supply has been attributed an increased vitality, rendering women less disposed to appendicitis than men. The appendiculo-ovarian ligament may also facilitate the extension of inflammatory processes between the appendix and ovary, which I have frequently found to obtain.

From this cursory recital of some of the important anatomic relations of the cecum and its appendix, it is apparent that the latter is normally endowed with an extensive and varying range of mobility. It would be more accurate to say of the appendix that it may normally occupy various positions and possess varying degrees of mobility in these several locations. It has been attempted by Bristow, Fowler, and others, to make a definite numerical classification of the normal positions of the appendix. Such refinement of description is of doubtful value as a working basis under pathologic conditions. Normally it is about the *caput coli*, often found toward the median line, below the pelvic brim, alongside the cecum externally, and even underneath the cecum.

When fixed by adhesions and surrounded with inflammatory deposits, agglutinating adjacent serous surfaces, it becomes a difficult task to find and isolate the appendix. In many instances of suppurative appendicitis, that organ will have died, appearing in the abscess as a black slough. In other instances it will have been disintegrated by the destructive process and only a stump will be found to mark its site. The corrosive process of suppuration will, in some cases, erode in spots the structures of the cecum; in more than one such case I have found it necessary to pare away the rotten tissues and suture the openings in the gut.

When the incision has been completed through the peritoneum, the cecum and appendix should be brought up through the wound. In non-suppurative cases, by following familiar anatomic guides, the exploring finger will usually detect the appendix before bringing forward the cecum. In suppurative cases the greatest difficulties will be encountered. The anatomic and pathologic facts already given, together with the careful guide of an educated touch, must be utilized to discover and deliver the organs. When the appendix is in hand, the cecum should be returned into the abdomen, and gauze wrung out in hot water placed around it. In my early operations I ligated the appendix with the meso-appendix, using fine sterilized silk, cut away the appendix, and applied pure carbolic acid to the stump. Later, I adopted the modern method of transfixing the meso-appendix at its base, cutting it away, stripping back a cuff of peritoneum from the appendix down to its

junction with the cecum, ligating the appendix with fine silk and cutting it away, afterward sterilizing the stump, invaginating the stump into the cecum, and covering it with peritoneum by careful stitching after the Lembert method. Nothing in the progress of healing or in ultimate results indicated any advantage of the latter method over the former simple ligature, excision, and cauterization. Careful study of the method of invagination from time to time persuaded me that its advantages were more theoretic than practical. Indeed, if carefully studied with the parts in sight, it will be seen that the invagination is only into the coats of the cecum. An infected ligature would more readily find its way into the peritoneum than into the lumen of the gut. More recently I have adopted a method of treating the stump, which, after I had applied it for some time, I found had been published by Dawbarn. It consists in passing an interrupted suture of fine silk in a circular manner around the stump, catching up the peritoneum and bringing it over the stump as with a purse-string. I deem this preferable to the method of invagination. The silk used for ligature of the appendix and meso-appendix, and for suturing, should be of the size that will supply requisite strength with the least bulk. In cases of recurrent and relapsing appendicitis, wherein there is no pus outside the appendix, this part of the operation can be most satisfactorily completed; in suppurative cases there must be thorough cleansing, and the ligature and sutures must be placed in tissues of good vitality if we would avoid the troubles of infected ligature and a sinus afterward.

In cases in which the appendix is necrotic, it is not sufficient to leave the stump to separate under the protection of drainage, *provided the patient's condition will permit prolongation of the operation sufficiently* for proper closure of the point of separation. In these cases the necrotic process extends to the coats of the cecum and fecal fistula is a common sequel. While such a fistula will usually heal spontaneously, it does not always do so, and, when practicable, this complication should be averted by excision and suture of the gut. In these cases the dead tissue about the stump should be trimmed away with scissors and the opening thus made closed with two rows of fine silk sutures. When the patient's condition is extremely bad from progressive sepsis, the operation should not embrace these detailed attentions to the stump; but there is a certain proportion of suppurative cases wherein with rapid (not hasty) work such completed operative work may be most advantageously applied.

In all suppurative cases the clean peritoneum must be protected by gauze during the manipulations upon

the appendix and its stump, both from the foul appendix and the bed in which it lay. Throughout the entire operation the highest skill of the operator will be brought to bear upon the protection of the outlying area of peritoneum from infection.

Drainage and Isolation of the Peritoneum by Gauze.—In no class of intraperitoneal operations does drainage perform more essential functions than in operations for suppurative appendicitis. In cases of recurrent appendicitis operated upon in the interval of course drainage will not be required. That class of cases, also, in which suppuration is confined within the coats of the appendix, permitting accurate sterilization and infolding of the stump, will not need drainage. But in the cases in which perforation and suppuration have obtained, either with or without a limiting wall of exudate, drainage will be a most essential part of the operative technic.

The right iliac fossa is not the most dependent pouch of the peritoneum and hence glass tubular drainage supplemented by suction cannot be applied as in pelvic surgery. Here we must rely upon tubular drainage with rubber and capillary drainage with gauze. Rubber tubing of firm material which will bear considerable compression without closure should be selected; and sterilized gauze, untreated by any chemicals, is best adapted to this purpose. Gauze which has been iodoformized drains very inefficiently, its capillarity being impaired by the filling of its meshes with the chemic agent.

The extent of drainage must necessarily vary within wide limits. In certain cases only a small strip of gauze passed down to the bed formerly occupied by the infected appendix to prevent too quick closure of the parietal incision may be all that is required. In cases in which no adhesions had been formed between anterior peritoneum, omentum, and visceral peritoneum beneath, strips of gauze must be placed in different directions so as to assure drainage of the general peritoneum. These strips should be placed endwise, especial care being given to drainage from the direction of the deep pelvis, the spleen, and region beneath the liver. The ends must, of course, be brought out of the most dependent angle of the incision. This drainage had best be supplemented by a rubber tube passed down to the area immediately about the *caput coli* where the focus of infection was localized.

After removal of the appendix, and cleansing of the peritoneum, strips of gauze should be placed for the double purpose of drainage and forming a wall between the infected area and the general peritoneum. Within twenty-four hours the meshes of the gauze will be filled with lymph, forming a protecting wall. This is a most important function of gauze

and is utilized with greater advantage here than in any other class of operations. The gauze should not be removed before the third day, and then one strip at a time, beginning with the central piece and preserving the outlying barriers, until the fourth day. After the general peritoneum is securely shut off it is only necessary to maintain drainage down to the focal area about the head of the cecum. Should discharge therefrom appear at this time, the drainage-track should be frequently washed out. Fecal fistula will require constant care to cleanse and protect the wound. A fecal fistula which otherwise would heal may be kept open indefinitely by persistent efforts at drainage. Throughout the period of drainage the patient should remain in bed and union of the incised parietes should be facilitated by adhesive straps and bandages, with constant recognition of the possibility of the occurrence of hernia.

THE TREATMENT OF FORTY-THREE CASES OF DIPHTHERIA WITH ANTITOXIN.

By IRA D. PAYNE, M.D.,
OF LINDEN, IOWA.

HAVING read with interest the reports in THE MEDICAL NEWS of the treatment of diphtheria with antitoxin, I wish to add the results of its use in forty-three cases of the disease which have been treated by me since February 19, 1896. The report by Dr. Biggs of New York of more than 1200 cases of diphtheria, treated by means of serotherapeutics, might not be conclusive to one inexperienced in the use of the serum, but to one who has used it the tabulated cases are of marked interest.

I treated my first case with antitoxin February 19, 1896. The patient was a baby nine months old who had been sick four days with what the parents termed a very bad cold. Examination revealed a membranous deposit in the larynx with indications of an invasion of the trachea. Temperature 100° F., pulse 140, respirations very labored and slow, with marked cyanosis. The baby had not nursed for twenty-four hours. I injected under the skin over the abdomen 1000 (10 c.c.) units of antitoxin prepared recently by Dr. Walter L. Biering of the Medical Department of the State University of Iowa. I gave internally $\frac{1}{30}$ of a grain of bichlorid of mercury every three hours. After twenty hours I again visited my patient. Examination revealed a membranous deposit in the pharynx, and in each tonsil. Temperature 100 $\frac{1}{4}$ ° F., pulse 140, breathing still labored, patient cyanotic, had not taken any nourishment since my previous visit. I injected another 1000 units of antitoxin, continued the bichlorid of mercury as before, and made an application every hour of per-

manganate of potash, 10 grains to 1 ounce of distilled water, to the membrane.

February 24th, I found marked improvement. Temperature 99° F., pulse 140, breathing quite normal, no cyanosis. Baby had taken nourishment five times. I now made one more injection of 500 units, after which the patient had an uninterrupted convalescence.

On my second visit I removed from one of the tonsils a small section of membrane and subjected the same to a microscopic examination at the Medical Department, State University of Iowa, which confirmed the diagnosis. Following this case I treated five other patients with antitoxin, all of whom made a good recovery. In no case has more than three injections of antitoxin been necessary, and while my notes do not show the number, I feel quite sure that two-thirds of the patients required but one injection of 1000 units.

Five of the forty-three cases treated were of well-defined diphtheritic croup, all of which would probably have proved fatal under other treatment. About one-fourth of these cases I treated with antitoxin only, and could not see but that convalescence followed as early and as rapidly as when other remedies were used in conjunction with it.

The initial dose I have employed has in no case been less than 1000 units, and in one case, a little girl three years old, the initial dose was 2000 units, followed after eighteen hours by 1000 units more, with a favorable result. I have used for immunizing purposes about 150 injections of antitoxin from the following laboratories: Behring's of Germany, Mulford's of Philadelphia, and Biering's of the State University of Iowa. About one-half came from Mulford's laboratory. In no case have I seen any bad results follow, other than a slight urticaria, and only five cases of this, four of which followed the use of antitoxin which had been prepared ten months before.

My experience has led me to believe that the fresher the preparation of antitoxin the more rapid the effect. The mistake usually made in the treatment of many cases of diphtheria is in the use of too small a quantity of antitoxin for the initial dose. In any malignant form of the disease I would deem it rational treatment to use, with patients from two to ten years old, anywhere from 2000 to 4000 units as the initial dose; to be repeated in fifteen hours if symptoms indicated it. In cases of diphtheritic croup, when death seems imminent, I believe it advisable to first use antitoxin, and then intubate or perform tracheotomy.

We are warranted in the statement that what would be a mild form of diphtheria elsewhere, in the larynx and trachea would probably prove fatal.

Hence I can see the good results from tracheotomy or intubation in such a case, and by so doing save the life of the child.

Forty-two of the forty-three patients treated by me recovered. The fatal case was that of a child two years old, sick three days with diphtheritic croup. When first visited, 1000 units of antitoxin was injected; twenty hours later the child died.

Through the kindness of Drs. Noel and Thornburg of Redfield, Iowa, I was permitted to visit in February, 1896, five cases of diphtheria, all of which proved fatal. They had treated seventeen cases of diphtheria without antitoxin and eleven of the patients had died. With this record before them they commenced the use of antitoxin, and have treated since February, 1896, until the present time, about thirty-five cases with no deaths. The letter of Dr. S. E. Blaisdell of Brooklyn, N. Y., to Dr. Joseph E. Winters of New York, in which he states he has used antitoxin in thirty-one cases of diphtheria, and has yet to see a single case, either mild or severe, benefited by it, is an experience widely different from the results we have had following its use. While slow to believe in specific medication, we are forced to admit that in antitoxin properly prepared and rightly handled, we have as near a specific for the treatment of diphtheria as we have in quinin for malaria.

AMAUROSIS FOLLOWING INTRANASAL OPERATION, WITH A REVIEW OF SOME OF THE UNCOMMON RESULTS OF OPERATIONS WITHIN THE NOSE.

BY FRANCIS R. PACKARD, M.D.,
OF PHILADELPHIA.

A MAN, thirty-six years of age, came under my care for a hypertrophic rhinitis of very severe type. He had been treated by several specialists for the nose and throat, and had undergone many minor operations during the past few years. The hypertrophic tissue had been treated by galvanocautery, caustics, and by the cold-wire snare.

During February of this year I used the cold-wire snare (under cocain anesthesia) to remove a small piece of hypertrophied tissue from the anterior extremity of the middle turbinate bone of the left side. Two days later the patient returned and informed me that on the day following the operation he had, while writing, suddenly become blind in the left eye. He had gone at once to the office of a well-known oculist, and while waiting there had found that his vision was beginning to return. Before the doctor had finished his examination it was almost completely restored. The period of complete left-sided blindness was stated by the patient to have been between

twenty and thirty minutes. The oculist has informed me that careful examination failed to reveal a cause for the disturbance of vision. When I saw the patient the site of operation presented a perfectly normal appearance. Since that time I have frequently used the cold-wire snare in the further treatment of the patient, and have also employed chromic acid for cauterization, but no further unusual circumstances have attended the case.

The first to direct the attention of the profession to the occasional evil consequences of minor intranasal operations was Ziem.¹ He reported two cases of violent delirium following the application of the galvanocautery to hypertrophic nasal mucous membrane, and one case in which delirium occurred after the evacuation of an abscess of the antrum of Highmore. His fourth case was that of a woman who, on the day subsequent to galvanocauterization of hypertrophied tissue over the posterior extremity of the lower turbinate bone, was suddenly stricken with dimness of vision on the corresponding side. Ophthalmoscopic examination revealed hyperemia of the optic papilla with very marked venous pulsation. He also reported the case of a woman, twenty-five years of age, of very nervous temperament, who, for one week following the application of the galvanocautery to the anterior extremity of the left lower turbinate bone, suffered from diminution of the field of vision of the left eye, accompanied by considerable hyperemia of the eyeground. In Ziem's last case, that of a woman twenty-four years of age, marked congestion and venous pulsation of both optic papillæ were noted after similar treatment of the lower turbinate bones on both sides. Later, Ziem² reported three further cases of one-sided dimness of vision following the use of the galvanocautery in the nasal cavity of the same side.

Lermoyez,³ in a very exhaustive article, has classified the casualties or complications which follow intranasal operations as follows:

1. *Of Infectious Origin.*—Diffuse rhinitis, submucous abscess, diphtheria of the wound, conjunctivitis, otitis media, tonsillitis, facial erysipelas, meningitis, arthritis, pyemia, unclassified infections, post-operative scarlatina, awakening of diatheses.

2. *Of Nervous Origin.*—Neuralgias, migrains, syncope and vertigo, visual disturbances, asthma, laryngeal spasm, exophthalmic goiter, general depression.

3. *Of Mechanical Origin.*—Hemorrhage from the nose and permanent redness of the nose.

Lermoyez also considers these casualties severally. In regard to meningitis, he points out that it may be a result either of metastasis or of direct extension of an inflammation of the nasal mucous membrane.

He states it to be invariably fatal. Voltolini⁴ was the first to record this complication as occurring after the removal of nasal polypi. Lermoyez quotes Kraukauer's observation of an acute arthritis of the left elbow consecutive to the removal of a sarcoma from Rosenmüller's fossa. Pyemia, he states, was reported by Schneider⁵ to have followed the removal of a nasal polypus in an epileptic. Under the term "unclassified infections" Lermoyez includes headache, malaise, irritability, pyrexia, and anorexia. As an instance of the "awakening of a diathesis" he cites the well-known case reported by Curtis,⁶ in which a minor intranasal operation caused the outbreak of an attack of gout.

My case, with the cases of Ziem and with some others yet to be mentioned, should, of course, be placed among the visual disturbances under the head of nervous complications. Lermoyez quotes Rosenberg's⁷ report of a very mild galvanocauterization for vasomotor rhinitis which resulted in complete loss of vision, lasting seven minutes. Lemon's⁸ case of exophthalmic goiter following nasal cauterization is the only instance of this character noted by Lermoyez. His one case of permanent reddening of the nose was observed in a woman in whom the condition was induced by galvanocauterization.

Bresgen⁹ has reported a case of necrosis of the nasal bones and diminution of the field of vision consequent to the unskilful use of the galvanocautery. Ophthalmoscopic examination was negative in this instance.

Cheatham¹⁰ has seen two cases in which intranasal cauterization by chromic acid was followed by edema of the lids and conjunctivæ. He remarks that after this treatment patients are more apt to complain of pain in the eyes than in the nose.

Rethi¹¹ has noted persistent sneezing and vertigo as sequels to galvanocauterization, relieved only by excision of the scar-tissue. In another case laryngeal spasm was similarly caused and cured. In two other cases seen by Rethi vertigo and supra-orbital neuralgia following intranasal cauterization persisted in spite of excision of the scar.

Aronsohn¹² tells of the occurrence of asthma subsequent to the removal of a fibrous polypus from the middle turbinate bone. A cure was effected by excision of the scar.

Laurent¹³ had as a patient a man twenty-six years old, suffering from hypertrophic rhinitis. The obstruction to nasal respiration was removed by applications of chromic acid and the galvanocautery, but the man subsequently suffered from asthmatic attacks, attributed by Laurent to the contraction of the scar-tissue upon the terminal fibers of the trigeminus in the nose.

C. H. Knight¹⁴ reports the case of a girl nine years old, in poor physical condition, from whose nasopharynx adenoids were removed by the curette, under ether. Twenty hours after the operation she developed well-marked torticollis, accompanied by a mild febrile condition. Examination of the nasopharynx forty-eight hours after operation showed the wound to have a sloughing surface, with swollen and angry-looking margins. The child, however, improved rapidly, and in ten days the rigidity of the neck and all traces of the operation had disappeared. Knight attributed the torticollis to reflex irritation.

Max Thorner¹⁵ records a case much resembling my own in some of its details, in a man forty years of age. Numerous polypi had been removed from his nose by means of the cold-wire snare, and to the few which still remained between the middle and lower turbinate bones on the right side Thorner applied the galvanocautery. On one occasion the right eye became affected on the day following such a cauterization; the patient was conscious of light, but could not count fingers at five feet. Ophthalmoscopic examination was negative. Vision improved after five days, and was entirely restored within four or five weeks. Thorner also reports the development of a curious mental condition, with loss of memory, in a boy from whose middle turbinate bone some hypertrophied tissue had been removed. He recovered completely in a few months, and his subsequent treatment was uneventful. In another instance the removal by snare of an hypertrophy from the anterior end of the left middle turbinate bone produced an intense neuralgia of the left side of the face, lasting several days, and a severe spasmodic cough, which persisted for two weeks.

J. F. Ingalls¹⁶ concludes, from a large number of interesting statistics, that intranasal galvanocauterization is almost free from ill results if due care be observed by the operator in the manipulation of his instruments and in the details of his antisepsis. Inflammation of the Eustachian tubes and middle ear he attributes to a burn of the orifice of the tube, to the excessive inflammatory reaction of an over-large wound, or to a lack of antiseptic precautions. Ingalls has never known tonsillitis to result from intranasal cauterization. In 4 cases out of 2600 the procedure was followed by an erysipelatous eruption on the face. He has records of 1900 cases of hypertrophic rhinitis, with 2800 cauterizations, none of which had a complication of any consequence.

In conclusion, I would briefly call attention to the anatomic relation between the parts concerned in these intranasal operations and their sequelæ. The arterial supply of the nose is derived chiefly from branches of the ophthalmic and internal maxillary

arteries, which form a mesh beneath the mucous membrane. Some of the veins from the nose empty into the ophthalmic vein, others into the facial vein, and some terminate in the veins within the cranium. For the nerve-supply there are the olfactory, the nasal branch of the ophthalmic division of the fifth, and numerous filaments from Meckel's ganglion. It is thus readily seen how close is the arterial, venous, and nervous connection between the eyes and the nasal fossæ, direct communication being afforded in addition by means of the nasal duct.

CLINICAL MEMORANDA.

SARCOMA OF THE KIDNEY—ABDOMINAL NEPHRECTOMY—RECURRENCE AFTER FIVE MONTHS—DEATH IN ONE YEAR.

By WILLIAM B. COLEY, M.D.,
OF NEW YORK;

ATTENDING SURGEON TO THE NEW YORK CANCER AND POST-GRADUATE HOSPITALS; ASSISTANT SURGEON TO THE HOSPITAL FOR RUPTURED AND CRIPPLED.

E. Z., female, aged five years, was referred to me by Dr. J. S. Brown of Montclair, N. J. The general health of the child had been good up to about four months before I saw her, when her mother first noticed an enlargement of the abdomen. This had steadily increased until her health became seriously affected, and as the condition was looked upon as inoperable, it was hoped that inoculation of erysipelas toxins would prove of benefit.

I found upon examination that the abdomen was nearly filled by a firmly fixed, hard tumor, that apparently had its origin in the region of the left kidney, and which extended beyond the median line and down into the pelvis. A diagnosis of sarcoma of the kidney was made, and, as it seemed possible to remove the growth, with the assistance of Dr. B. Farquhar Curtis, I operated on September 25, 1894.

An incision four inches long was made parallel with the outer border of the rectus muscle, and from the center of this a transverse incision was made, extending about three inches to the left. The tumor was found to be adherent to the overlying colon, but was shelled out with but little

difficulty. Only a very small quantity of blood was lost, and the shock was slight. The pedicle, not more than three-eighths of an inch in diameter, was found and ligated with silk, the peritoneum closed, and a gauze drain introduced which passed down to the stump, but outside of the peritoneum. With the exception of a sinus which persisted for two or three months, the wound healed promptly and satisfactorily. The patient gained rapidly in flesh and strength, and was presented before the New York Surgical Society on November 14, 1894. The weight of the tumor was three pounds. Microscopic examination by Dr. H. T. Brooks, pathologist to the Post-Graduate Hospital, showed the tumor to be a mixed-cell sarcoma, with spindle-cells predominating.

The patient continued in perfect health until the early part of May, 1895, when a small tumor was detected, apparently originating in the retroperitoneal glands near

FIG. 1.

Sarcoma of the kidney in a child five years of age.

the site formerly occupied by the kidney. The tumor increased very rapidly in size. The quantity of urine passed by the patient was much diminished, was of high color, and contained some albumin and blood. She was put upon small doses of the filtered toxins of erysipelas and bacillus prodigiosus, which were injected every other day into the gluteal region. Her general health quickly began to improve, and her urine increased in quantity and became nearly normal. The injections were continued during May, June, and July, 1895, but not in sufficient doses to produce a chill. Treatment had to be carried out at my office, hence only small doses could be given.

In August there was a well-marked increase in the size of the tumor, and the health of the patient again became

impaired. The use of the toxins was discontinued. The growth of the tumor was enormously rapid, and by the latter part of September the abdomen was filled by it. Emaciation was progressive and rapid, and the patient

FIG. 2.

Spindle- and round-celled sarcoma of the kidney. Weight, 1400 grams.

died in the middle of October, 1895. The accompanying illustration shows the condition of the tumor prior to operation.

Sarcoma of the kidney has long been regarded, and rightly so, as very nearly a hopeless condition; hence, much difference of opinion is entertained by surgeons as to the advisability of subjecting such patients to an operation. The brilliant results reported by Dr. Abbe before the New York Surgical Society (two of his cases having remained well for more than three years) are certainly most encouraging. However, the fact that Dr. Abbe's experience has been so different from that of most other surgeons, together with the circumstance that one of his patients has had a recurrence of the disease more than four years after operation, force us to conclude that, in spite of improved methods, we must still give a very grave prognosis in cases of sarcoma of the kidney.

Lotheisen, in his admirable article on "Surgery of the Kidney,"¹ states that, of eleven patients operated upon for malignant tumor of the kidney, only one was well beyond two years, and the growth was an adenocarcinoma. Of the five cases of sarcoma, all the patients died of recurrence.

THE DIURETIC ACTION OF MERCURY IN CARDIAC DROPSY.²

By LAWRENCE JENCKES, M.D.,
OF GALENA, ILL.;

ATTENDING PHYSICIAN TO THE JO DAVIESS COUNTY ALMSHOUSE.

RECENT authorities universally agree that dropsical accumulations arising from obstruction to the circulation from valvular disease are best treated with cardiac tonics and stimulants, and that chief among these remedies are digitalis, strophanthus, diuretin, and caffeine. Most writers assert that digitalis acts best after a calomel purge. I

have frequently seen digitalis and iron fail utterly until the patient was thoroughly purged with a mercurial, after which the former remedy could be resumed with benefit.

The following cases in the writer's practice will illustrate not only the diuretic action of mercury, but also the disadvantages attending its continuous use:

During 1893 and 1894, Mrs. W. had been troubled with palpitation and irregular action of the heart, and marked dyspnea upon slight exertion. Failure of compensation, however, did not set in until the fall of 1895. A careful examination at this time revealed a moderately enlarged heart, acting feebly and irregularly. A mitral presystolic murmur could be heard near the apex, and serious pulmonary complications were also present. The abdomen contained a moderate amount of fluid, and the lower extremities were dropsical. The stomach was very irritable, and the digitalis and caffeine which she took was more often vomited than retained. The heart was acting so feebly and irregularly that strychnin was given hypodermically thrice daily for several days, but the attacks of dyspnea and cyanosis persisted.

These distressing symptoms were partially relieved by hypodermic injections of morphin and atrophin. The cardiac stimulant was discontinued, and three grains of calomel with soda was given thrice daily. Its purgative action was quite pronounced, and the effect seemed beneficial. Opium was often prescribed with the calomel in order to control the looseness of the bowels. After a few days it was noticed that the amount of urine was greatly increased, and twice when measured it was found to be more than eighty ounces per day. At the expiration of ten days of the treatment all of her symptoms had improved. The dropsy was rapidly decreasing, the pulse was more regular, and the breathing more natural. At this time, however, the calomel began to affect her gums, and she refused positively to continue its use. Her condition gradually became worse in spite of tonics and diuretic remedies, and several months later she succumbed to the disease. The diuretic action of calomel in this case was marked, and it was more efficient in this respect than were the remedies which were subsequently employed.

The next case was one of cirrhosis of the liver, with marked ascites. As Palma³ had reported the diuretic action of calomel in this condition I determined to make use of it in this instance. During a week the patient took ten grains of calomel daily. The purgative action was severe; but no diuretic action was noted, and, the gums becoming affected, the treatment was discontinued. He was tapped several times before he died.

Mercury was given Mr. W., a man about sixty years of age. His heart was greatly enlarged. A systolic murmur was heard in the second right interspace, and was traceable over the ascending arch. Palpitation was annoying, and the pulsation of the vessels in the neck was plainly noticeable. Failure of compensation had existed for some time. The abdomen and limbs were extremely dropsical. Breathing was superficial and difficult, and cough and expectoration annoying. The various diuretics he had been taking during several months seemed

¹ *Archiv. f. klin. Chirurgie*, Band 52, S. 721.

² Read before the Dubuque (Iowa) Medical Society, June 30, 1897.

³ Quoted by Pepper, *THE MEDICAL NEWS*, December 15, 1894.

to afford him no relief, and as the accumulation of fluid was increasing, the remedies were discontinued. He was now given 8 grains of calomel daily for four or five days. The remedy acted moderately on the bowels, but produced so much griping pain and distress that the dose was reduced to 3 grains, with soda and jalap, and this was given for several days. There being no perceptible increase in the amount of urine passed this line of treatment was stopped. A few months after this he succumbed to the disease. The use of calomel in this case was a *dernier ressort*, but it produced no benefit.

Mr. B. was seen in consultation. The examination showed enlargement of the heart, with feeble and irregular action. A mitral systolic murmur was heard in the sixth interspace. The abdomen contained fluid, the limbs were dropsical, and a hacking cough was incessant. He was unable to lie down and could sleep for only a few minutes at a time. His condition was so serious that his death was expected at any moment. During four months he had been under treatment, chiefly with digitalis. I saw him in December, 1896, and it was agreed to discontinue the use of digitalis. Sufficient morphin was given hypodermically to secure him several hours sleep. This afforded so much relief that the drug was given nightly for a number of nights. Ten grains of calomel was administered, and this was followed in three hours by a dose of jalap. The action upon the bowels was prompt and beneficial. Six grains of calomel was now given daily. The nightly doses of morphin probably restrained the purgative action of the mercury. He began shortly to pass more urine, and, while it was not measured, it was thought to amount to four or five pints daily. During two weeks he continued to take from four to eight grains of calomel a day. Antiseptic mouth washes were constantly used. The dropsy subsided gradually, his stomach was no longer irritable, and his breathing became freer and easier. He was soon able to be up and about, and, I believe, is still living.

This report has been condensed as much as possible, and but passing reference has been made to the action of other remedies used before resorting to mercury. Much of the benefit obtained from the use of this drug no doubt arises from unloading the bowels, relieving the engorged and congested condition of the liver, and removing impurities from the system. Nor is this all; it undoubtedly causes diuresis in dropsical patients by causing serum to be reabsorbed and eliminated by the kidneys. Mercury differs from digitalis as a diuretic in the fact that its action in this respect is sooner lost. When the remedy is resumed, however, after having been suspended, it again causes diuresis. Murray states that this remedy acts, not only as an eliminative and alterative, but also upon the heart itself. I have seen nothing to warrant me in accepting this conclusion.

It must be borne in mind in estimating the value of mercury as a diuretic that several disadvantages attend its continuous use. Among these are its pronounced purgative action and the griping pain which it causes, both of which are controlled with difficulty. Even with the most careful management stomatitis will often result,

and, furthermore, the diuretic action is not uniformly produced. Notwithstanding these drawbacks, however, mercury has a place as a diuretic. In most cases in which a diuretic is necessary the use of mercury is not indicated, but in those in which other remedies have been administered during so long a time that they have lost their effect it may be administered, often with benefit.

A CASE OF CHYLOUS ASCITES.

By J. A. DAY, M.D.,
OF WINCHESTER, ILL.

I DESIRE to report a case which is unusual, judging from the limited amount of literature bearing upon the subject. The case in question is one of ascites, the fluid of which I believe to be of a chylous nature.

My attention was attracted to the patient whose case I present about two and one-half years ago, and the following history elicited: Mr. J. H., aged fifty-four years; height, 5 feet 10 inches; weight, 160 pounds; family history, good. His previous health had been excellent until about twelve years before, when he had an attack of what his attending physician termed catarrhal fever, which, as he states, was attended with dull pain in the left hypogastric region, and a feeling of fullness and oppression all over the abdomen. Shortly following this attack he had edema of both lower extremities, penis, and scrotum, which varied in intensity from time to time, and has continued until the present, although his general health has remained good, and he has always led the active life of a farmer until about three years ago, when he was obliged to abandon hard work in consequence of an enormously distended abdomen. He was ignorant of the true nature of his condition, which in reality was caused by a large accumulation of fluid in the abdominal cavity. The attending physician seemed to have overlooked this very distressing condition, which persisted until about the middle of February, 1895, when he consulted another physician in a neighboring town, who made a diagnosis of ascites, and drew several quarts of yellowish-white fluid resembling milk from the abdominal cavity. He had undergone this procedure twice before coming under my observation.

Paracentesis was performed April 6, 1895, by my father and myself, and we removed about three gallons of fluid resembling rich milk, of a specific gravity of 1010, with entire relief to the patient for the time being. After this operation the abdominal walls returned to a normal level. Upon careful examination after paracentesis, we could find no evidence of disease of the heart, liver, spleen, or kidneys, neither was there any tumor to be discovered by means of deep pressure over the abdomen. In about three weeks a subsequent tapping was performed, obtaining about the same quantity of fluid. The patient has undergone this operation on an average of once every three weeks, each time having from two to three gallons of fluid of the same character withdrawn. He has been tapped in all forty-nine times, the aggregate amount of fluid removed from his abdominal cavity being 976 pints.

The fluid is strongly alkaline, odorless, of salty taste, specific gravity ranging from 1008 to 1014, depending

upon the kind of fluid ingested, and diet seems to influence the amount of the accumulation as well as its specific gravity. During the summer when he is indulging in a vegetable diet, the fluid accumulates very rapidly and is of lower specific gravity; and in winter, when diet is mostly of foods rich in fats, the opposite condition obtains. Upon standing this fluid undergoes separation imitating milk, the rich fatty elements coming to the top like cream. Chemic analysis proves it to consist of many of the same elements as chyle, and the microscope shows an abundance of fat globules and granules of different, but minute sizes, in suspension. There are also numbers of crystals of what appears to be salts of the ammoniophosphates. No leucocytes, blood-corpuscles or epithelial cells were to be found.

The patient is at this time in excellent health. His appetite is good, there is no dyspepsia or pain, the bowels are regular, and but for the inconvenience occasioned by the enormous distention of the abdomen, and edema of the lower extremities, which disappears at once on tapping, he is apparently well.

I have used an ordinary trocar and cannula for this operation, and have always observed the strictest anti-septic precautions; as a consequence, he has never suffered the least inconvenience from it, the punctures invariably healing rapidly. As to location of the punctures, I have not observed any particular rule, except to avoid tapping above the umbilicus, or in the extreme groin, taking care to see that the bladder is empty.

This case is no doubt of a chylous nature, being of especial interest only on account of its rarity, the long duration of the disease, and the continued good health of the patient. The exact pathologic lesion is obscure and will probably never be revealed short of an autopsy, but the author believes there exists that variety of ascites which is due to an effusion of chyle into the peritoneal cavity, resulting from some obstruction situated in the lymphatic vessels, lymphatic glands, or the thoracic duct. The chyle finds its way into the peritoneal cavity by the rupture of the lymphatic vessels or transudation through them, the nutrition of the body being carried on by anastomosis. In a fairly careful search of literature, I have been able to find only eight recorded cases of chylous ascites.

MEDICAL PROGRESS.

The Question of Allowing a Woman Who Has an Eruptive Fever to Nurse Her Child.—ROGER (*Med. Week*, September 3, 1897), from statistics kept at one of the Isolation Hospitals in Paris, answers the above question in the affirmative. Of quite a large number of new-born infants breast-fed by mothers who suffered at the time from either measles or scarlet fever, none contracted scarlet fever, and only two measles, and in both of them the disease was of a mild type. So that one need not feel any uneasiness in allowing an infant to continue at the breast of the mother who manifests the symptoms of one of these diseases. This immunity is explained by Roger on the supposition that the children are rendered immune to the

disease, by ingesting the toxins or attenuated germs in the milk.

Ultimate Results of Operations for Hernia.—In the *Rev. Med. de la Suisse Rom.*, July 20, 1897, there is a *résumé* by TAILLENS of 324 cases of hernia operated upon in the hospital service of Roux, which affords opportunity for fruitful study, the more so, that only cases which have gone over two years since the operation and which have been personally traced are included in the tables. These herniæ were 288 inguinal, 22 femoral, and 14 umbilical, and the recurrences were respectively 16.7, 27.3, and 0 per cent. Taking the inguinal cases alone the influence of age was most apparent, the recurrences for each decade of life being 5, 10, 15, 25, and 32 per cent., the latter including all cases over forty years of age.

Two methods of operations were employed, *viz.*, that of Bassini fifty-three times, and simple suture of the pillars either in one or two layers; the operation of Ferrari, in 235 cases. Cases operated upon by the former method recurred to the extent of 39 per cent., while following the latter only 12 per cent. relapsed. This is directly opposed to the experience of some American surgeons.

The cases which healed primarily did better than those which healed by granulation, the figures being respectively 15 and 22 per cent. Atrophy of the testicle occurred in 4 per cent. of the Ferrari operations, and in 7 per cent. of the Bassini's. An attempt was made to ascertain the virility of those having double herniæ, but the replies were unsatisfactory partly because many of the men were not married, and also because it could not be definitely shown that they were the fathers of the children attributed to them. The author gained the impression, however, that these men were less fertile than normal.

The Rapid Estimation of Uric Acid in Urine.—BARTLEY (*Brooklyn Med. Jour.*, August, 1897), has devised a method of estimating the amount of uric acid in the urine which may be completed in about half an hour. The solutions required are: (1) A 1-50 silver nitrate solution. (2) A mixture containing 8 grams of crystalized magnesium sulphate and 12 grams of ammonium chlorid in 100 c.c. of aqua ammoniæ (U.S.P.). (3) A solution of ammonium sulphohydrate of such a strength that its color is nearly that of the urine. Fifty cubic centimeters of the urine are poured into a beaker, with 5 c.c. of the magnesium fluid, and the whole is warmed over a water bath to prevent the precipitation of the xanthin bodies by the silver.

The silver solution is run into the warm mixture from a burette. From time to time a drop is removed from the beaker by means of a dropper over whose end a piece of absorbent cotton has been tightly wound, thus acting as a filter. After removal of the cotton the drop of the solution is brought into contact with a drop of the ammonium sulphohydrate solution on a white slab or a piece of glass placed over white paper. If a dark ring is observed at the line of contact of the two fluids, there is an excess of silver nitrate, and when this point is reached no more silver is added. Each cubic centimeter of silver

solution used, precipitates 0.00336 grams of uric acid. This factor multiplied by the number of cubic centimeters used gives the uric acid in the 50 c.c. of urine. To obtain the number of grains in an ounce, multiply this result by 9.12. Fifty cubic centimeters of urine require usually from 6 to 10 c.c. of the silver solution to precipitate all of the acid present; if more than 12 c.c. are required, it is better to dilute the urine with an equal amount of water before taking the final reading. If albumen is present, it must be precipitated by acetic acid and boiling before the uric-acid test is made. If there is a sediment of uric acid or urates this must be dissolved by heat, with or without the addition of sodic hydrate, and diluted with an equal quantity of water before the urine is tested.

The amount of xanthin may be determined by testing one portion of the urine warm and another cold; the difference in amount of the silver solution required in the two instances being that necessary for the precipitation of the xanthin. One cubic centimeter of the silver solution will precipitate 0.00158 grams of xanthin.

On the Occurrence of Nasopharyngeal Adenoids.—ARROWSMITH (*N. Y. Med. Jour.*, August 28, 1897) reports in tabular form 701 cases of nasopharyngeal adenoids observed in 2000 dispensary patients. Contrary to the experience of many Continental observers, in not a single one of these 701 cases was there the slightest evidence on gross inspection of a tuberculous tendency. In twelve consecutive unselected cases, histologic, bacteriologic, and inoculation examinations, were absolutely negative. Of 255 operations, 204 were performed under general anesthesia, which is greatly to be recommended in young subjects as it lessens nervous shock, saves time, and above all else enables the operator to perform his work with a greater thoroughness than is otherwise possible.

Dyspepsia in Children.—MAGNIAUX (*La Presse Médicale*, May 19, 1897), says that dyspepsia is very common in childhood but is frequently overlooked; its victims being treated for anemia, beginning tuberculosis, etc. In consequence, iron, creosote, quinin, and wine, all which are irritants of the mucous membrane of the stomach, are given often with unpleasant results. The author having examined eleven children presenting the symptoms of dyspepsia draws the following conclusions: all were badly nourished during the first years of life; eight were bottle-fed; three were allowed a mixed milk diet; and all were rachitic to a variable degree.

A dyspeptic child may be abnormally thin, or large and fat, the two types representing only two successive stages of dyspepsia. In all of these cases the stomach resonance extended down to, or even below the umbilicus. There was always excessive thirst, and usually loss of appetite, though in two of the children the appetite was abnormally great. Constipation was frequent, often alternating with diarrhea. Nausea, vomiting, and heart-burn, were frequently observed. At times the gastralgia was so marked that it might easily be thought to be due to ulcer of the stomach. Headache and night terrors were common.

Hydrochloric acid was usually found to be in excess, although it was entirely absent in certain cases, and at times it was normal in amount. As a general rule alteration in the gastric juice played a secondary part while muscular atony was the most important feature of the disease.

Treatment was for the most part dietetic. Medicines were prescribed in only four of the eleven cases, and consisted of bicarbonate of soda, powdered nux vomica, and hydrochloric acid. In all cases the treatment employed had but one object, that of permitting the overworked stomach to rest as much as possible. This was accomplished by reducing the number of meals, by establishing their regularity, their character, the fine division of the food, and the regulation of the amount of liquid. The results obtained were very satisfactory.

Bichlorid Catgut Better Than Kangaroo Tendon.—BORDEN (*New York Med. Jour.*, September 18, 1897), as a result of his personal experiments makes the statement that catgut boiled in a 1-to-500 solution of bichlorid of mercury in alcohol over a water bath for one and one-half hours is cheaper, stronger, more regular in size and will last longer in the tissues than kangaroo tendon. In a skin wound sutured partly with kangaroo tendon and partly with heat-sterilized catgut, it was found at the end of five days that some of the sutures of tendon were cut quite through by the leucocytes, while the catgut sutures were all divided by their action. This wound healed aseptically. In another wound which suppurated catgut and tendon, both of which had been steeped in bichlorid solution, were used. At the end of four days a microscopic examination was made, and it was discovered that the action of the leucocytes had penetrated the tendon to its center, while the bichlorid catgut, in this case No. 8, was eaten only half way through. The superiority of the catgut was thus clearly shown.

Borden prepares his catgut in the following manner: Coils of gut are placed in clean Petri dishes, or short strands in long glass tubes the ends of which are stopped with cotton, and kept for three hours in a dry sterilizer which is slowly raised from 100° to 140° C. The gut is then removed with sterilized forceps to a sterilized pint fruit jar, which contains the alcoholic solution of bichlorid of mercury, 1 to 500. In this it is slowly boiled on a water bath for one and one-half hours. It is kept in the bichlorid solution until wanted.

Borden now uses catgut prepared in this way in cases in which he would formerly have trusted only to kangaroo tendon, or, indeed, in which he would have thought the use of silver wire or silkworm gut indispensable. He has had the best of results from its use in hernia, and in appendicitis with suppuration, when it was possible to close the wound only partially, deep sutures of this catgut kept the edges in apposition for a sufficient length of time, and suppuration did not extend to the stitches, as would have been the case if silkworm gut had been employed. The most serviceable sizes are Nos. 1 and 2 for fine sutures and ligatures, and Nos. 8 and 9 when strength is required.

The Country Slaughter-House as a Factor in the Spread of Disease.—In the *Med. and Surg. Reporter*, September 11, 1897, STILES, one of the Zoologists of the United States Department of Agriculture, points out how the country slaughter-house is a factor in the spread of disease. Whether the animals used for food are killed by the farmers or by the butchers in their own slaughter-houses, the offal is almost always fed to hogs. If the slaughter-houses are permanent, they are usually infested by rats, which are frequently eaten by hogs. As a result of these practises, many hogs become infected with trichinæ. Of seventy-two rats taken from slaughter-houses, meat-shops, and packing-houses, fifty-four per cent. were found to have the disease, while of seventy-five rats from barns, feed-stores, etc., only three per cent. were infected. The probabilities are, therefore, if a hog eats a rat at a slaughter-house it will contract trichinosis. It is not to be expected that hogs which eat offal will escape infection any more than will the rats, so it is no cause for surprise that from one to two per cent. of the hogs at large abattoirs are trichinous, for in some localities from one to four per cent. of the hogs are offal fed. The offal of hogs ought never to be fed to these animals. There is no sanitary objection to feeding them the offal of healthy cattle and sheep, but cattle affected with tuberculosis and other diseases may transmit them to hogs, so that the practice ought to be abandoned altogether, and all the offal rendered. If the slaughter-houses were located near together in every locality, instead of being as at present far apart, this could easily be done. As a further precaution the houses should be kept free from rats, by the use of traps, not poison, as this drives them away.

A Supposed Case of Bismuth Poisoning.—MAXSON (*Ann. of Gyn. and Pediat.*, July, 1897) describes an instance of poisoning by bismuth. Fifteen grains of the subnitrate was given every two hours to each of a pair of twins three weeks old, to allay diarrhea. The children became dark-colored, sleepy, and the breath had a garlicky odor. The bismuth passed from the bowels unchanged in color. The administration of the medicine was discontinued and the symptoms of poisoning quickly disappeared. Two weeks later, owing to a recurrence of the diarrhea, one of the children was again given the same preparation of bismuth, and the symptoms again developed.

Some Facts About the Origin of Malaria.—BATTEN (*Four. Amer. Med. Ass'n*, August 14, 1897) denies that the poison of malaria enters the system wholly by way of the stomach, and in support of the theory that an entrance may also be effected through the respiratory tract he mentions his experience on the vessel *Valley City* during 1864-5. The ship was cruising along the coast of North Carolina, and although all the water used on board, either for drinking or cooking purposes, was boiled and filtered, yet the number of cases of malaria invariably increased whenever a long stay was made in any river. Again, in the Western States and in Pennsylvania, malarial fever has actually been ploughed out of existence, those who

first turned the soil suffering the most from its effects. Was it in the food or water of these early settlers that the *plasmodium malariae* was contained, or was it in the air they breathed?

THERAPEUTIC NOTES.

Proper Use of Colchicum in Gout.—SCHULZ (*Med. Week.*, September 3, 1897) believes that the failures in the use of colchicum in gout are due to two causes, *viz.*, the employment of the drug at a period of the disease when it is inefficient, and secondly, to the use of excessive doses. It is especially indicated in cases in which there is pain in the joints, fever, and copious perspiration, quick breathing, and a full pulse. The dose should be small, from 20 to 40 drops daily of a mixture of the tincture of colchicum seeds and alcohol in the proportion of one part to ten.

Acute Pulmonary Affections Treated by Warm Baths.—In the *Centralbl. für Innere Med.*, July 10, 1897, there is an abstract of an article by VERDY on the treatment of acute affections of the lungs by warm baths. The baths should be given at from 36 to 38° C. (97 to 100° F.) and should last during ten minutes, the usual precautions against congestion of the brain being carried out. From two to three baths are given daily according to the necessities of the case. After a bath there is a quiet, restful sleep, while the respiration and pulse become less frequent and more regular, and expectoration is facilitated. Upon awaking, the patient is delighted to find the pain less severe, and in the case of children the playthings are asked for, and the appetite is almost immediately restored. In some cases mustard is added to the baths.

Practical Points in the Treatment of Chancres.—FOURNIER (*La Presse Med.*, July 7, 1897) has an excellent paper upon the treatment of chancres, from which the following practical points are taken: (1) Forbid sexual intercourse. (2) Forbid a stimulating diet. (3) Counsel moderation in exercise. (4) Prescribe frequent warm baths, local and general, and a simple ointment for local application. Irritating substances such as alum, ferric chlorid, carbolic acid, etc., should never be used. Iodoform, though an excellent application, had better be dispensed with on account of its odor. Nitrate of silver is much abused, and should never be used except to stimulate healing in chancres which remain stubbornly covered with a crust; or upon indolent ulcers or exuberant granulations. In these cases the application ought not to be repeated oftener than every five days. If the chancre is at the meatus, the same rules of treatment apply, but they are to be carried out with the greatest pains on account of the tendency to inflammation of a chancre in this situation. If the chancre is situated within the urethra, aside from the local and general baths and the administration of diluents, nothing is to be done, as in such cases the introduction of foreign substances, either fluid or solid, within the urethra, only aggravates the trouble.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor : J. RIDDLE GOFFE, M.D.,
NO. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

SATURDAY, OCTOBER 9, 1897.

MERCANTILISM VS. MEDICINE.

ABOUT fourteen years ago President White of Cornell University published an article sharply calling the attention of thinking men to the fact that the relations of the business and the professional worlds were rapidly being reversed; that the varied opportunities for making money in different mercantile pursuits in this great commercial nation of ours were draining the brightest minds from the learned professions. He explained the fact by showing how much more wealth could be amassed by the exertion of a certain amount of brain power in a mercantile pursuit than by the exercise of equal brain power in one of the professions.

The church, the bar, and medicine have all equally suffered by this change. And not only have many brilliant minds been drawn away from our profession; more disastrous still, the ease with which a person can become legally qualified to practice medicine in almost all parts of this country has opened the flood-gates of mediocrity and over-supply. Indeed, the mercantile spirit has helped in more ways than one to cause an over-supply of physicians, many of whom are necessarily of ordinary ability. Few cities of

more than 100,000 inhabitants in this country are without a fairly well-equipped medical college, which takes the raw material and, in an incredibly short time, turns out a machine-made product of medium attainment—with exceptions of course—but all of them warranted to wear awhile and compete in the race. The mercantile spirit is at the bottom of this condition. The professors and teachers expect an augmentation of both reputation and practice to accrue from the nature of the position occupied. If the size of the school increases, each receives a gradually increasing salary. Of course some of the instructors, the writer, and a few other sainted ones attend at the free dispensary for glory and love of study; but none the less, every one of the faculty is blindly but laboriously adding complication to complication in the problem which menaces our profession.

This over-supply of men of but average ability has produced the same business conditions that exist in commercial life—that is, the competition which fifty years ago served as a wholesome stimulus has to-day become a deadly struggle. The fight was on in the trading world some years before we felt it keenly in the professional, so that business men are necessarily in advance of us, both in theory and in practice.

The time has been when single-handed effort brought its just and proportionate reward, but the American system of individualism has bred such a ruinous competition that far-seeing men have been driven to combine. A late writer, Otis Kendall Stuart, himself a large manufacturer, demonstrates conclusively that to all thinking men the logical step in business is the foundation of a trust. The man nowadays who attempts to struggle along alone is forced to the wall by a multitude of rivals. The only logical resource is to combine individual strength with that of his competitors—the trust thus formed being to the practical advantage of all concerned, reducing expenses to the lowest possible limit and maintaining profits at the highest. We of the medical profession are now face to face with the question whether we shall not be driven to the same methods in coping with these conditions. We are practically still working upon the system of individualism, with at the same time an indistinct, albeit semi-blind, reaching out after the new methods of the business fraternity. The lodges, the great public hospitals, the dispensaries, and the sharp competition are a quartet

that is steadily and surely forcing down prices to the starvation point. Cannot some practical remedy for this condition be found in the formation of a trust on the part of the profession, a good common-sense working trust or union that shall have some solidarity of purpose and some cohesion among its members?

THE LUETGERT CASE AND EXPERT TESTIMONY.

THE battle royal now on in Chicago, in which the experts for the prosecution assert their scientific belief that every particle of bone found in or about the now famous sausage-vat belonged to a human adult female, bids fair to be enrolled as one of the most monstrous exhibitions of the century. The experts for the defense, no less than their opponents, have thus far demonstrated the utter fallibility of testimony called expert. Indeed, the experts on both sides have made so many contradictory and impertinent statements about bones in general, especially about phalanges, ribs, sesamoids, femurs, and temporals, that the profession, the public, and especially the jurors, are so confused that, if any consideration is to be given to this feature of the evidence, it will result only in uncertainty and doubt.

Furthermore, it will not be surprising if all concerned—judges, lawyers, and jurors—lose all respect for expert testimony. Professor Os Calcis swears that a bone he now holds in his hand is that of a woman, while Professor Trapezium affirms that the same bone belongs to the hog family. How ungallant of you, Professor Trapezium! But never mind, gentlemen, you have illustrated what has been demonstrated over and over again in New York—that it is perfectly absurd to go on hiring so-called experts, as the courts are doing in all cases of a criminal nature. Too long has this sad condition been a reproach and a shameful stigma not only upon the courts of justice, but also upon the medical profession. I will venture to say now that every man of the “twelve good and true” sitting in judgment in this case has concluded that a just verdict can be reached only by entirely eliminating the testimony of the experts. Their verdict will certainly brand the one or the other set of experts as veritable humbugs, for certainly those for the defense have thus far contradicted every point depended upon by the State for a conviction.

Astounding as the expert testimony has been in this case, it is only equaled by the brazenness of the opposing counsels. The medical witness must answer “yes” or “no” or be ridiculed beyond the limit of toleration. Pleading lawyers and cross-examiners never respect a medical witness; confusion worse confounded in a few moments takes the place of the direct and forceful statements the medical witness wishes to make. The expert may be perfectly correct in saying that a given bone is a human femur, but before the opposing counsel gets through with him he is unable to swear to the identity of his own nose. He is simply to be confused, in order the more certainly to confuse the jury.

These astonishing exhibitions in courts of justice will but hasten the day when a decided revolution shall be inaugurated in the method of selection of medical experts and the giving of medical expert testimony. Certainly such a witness is justly made light of in many cases; he is amusing at times, but he winks the other eye, for he has a fee.

Appalling as all the contradictory testimony has been in this case, one fact will stand after all else has vanished, and that is, sufficient experiments in the boiling of bodies have been made to suffice for all time. The State boils a body and finds that it entirely dissolves in a certain specified time; the defense boils two to their one, with entirely opposite results. A human body, male or female, thrown into a vat before life is extinct, and subjected to prolonged boiling in a caustic solution takes on changes more or less rapidly in proportion to the strength of the caustic and the temperature of the solution. The experts in this case have agreed, disagreed, and even flatly contradicted their brethren of the same side on the above points.

The scientific mind of the anatomist has been placed in a peculiar position. The gray matter of his left hemisphere must be having a terrible time trying to convince the gray matter of his right hemisphere that a contemptible sesamoid bone has been the initial cause of the femur of a dog refusing to be recognized as the femur of a female adult. The osteologist is certain, when upon the witness-stand, that the femur he holds in his hand, the largest and strongest of the bones, is that of a human; you cannot fool him. He goes still further; he testifies that it at one time formed part of the bony frame-

work of a female human. Not satisfied with this, thinking he has routed the prosecuting attorney, he is confident that that particular female human who owned that femur in life was five feet four inches in height. He arrives at this latter conclusion by the length of the femur. Oh, God of mathematics, you have been made sponsor of a most egregious piece of logic! The expert steps down, smiles with satisfaction to himself until rebuttal testimony brings out positive proof that the aforesaid femur belonged to the bony framework of a gorilla, six feet six inches in height.

Even the poor little rib has been used in this case to puzzle court and jury. Not since the exsection of a rib from Adam in the Garden of Eden has it played so important a part as when flaunted in the court-room last week. I am not aware which rib was found, but the peculiarities of the first, second, tenth, eleventh, and twelfth ribs would not help the case in any manner. As if the case of the State had no leg to stand on, the prosecuting attorney promptly supplies a phalanx or two.

Weak spots have shown themselves in the case for the State. For instance, no testimony has been adduced to show that any one piece of bone fitted any other fragment. Corresponding bones would go far to prove whether the pieces belonged to one body or not, human or animal. Two femora, two temporals, several ribs, or a few inches of the spinal column would assist to clinch the case. To determine age from bones is almost impossible; the long bones and those especially, past the period of ossification would help in this direction. In any event, positive opinions must be guarded. Stature may be approximately stated by measurement of a long bone, but to state positively the probable nature and connection of an isolated bone is absurd.

The question of identification naturally arises, the defendant claiming that his wife left home; the State contends that the finding of finger-rings and bones in and about the vat points to the fact that the defendant's wife was placed therein and destroyed. Admitting this, there is not a particle of evidence to prove in what manner the wife of the defendant came to her death. It certainly is not a capital offence to place a dead body in a vat and destroy it. Whether the body in this case, admitting that a human adult female body was placed in the vat,

found its way therein before or after life was extinct is a question which cannot be solved by chemic or pathologic research; circumstantial evidence alone can decide this contention in the case.

The lessons derived from the Luetgert case point to a revolution in the methods of selecting and giving expert medical evidence. The medical profession should rise and demand the change before the ridicule heaped upon medical men brands them, when on the witness-stand, as blockheads.

JUSTIN HEROLD, M.D.

ECHOES AND NEWS.

Swallowed False Teeth.—The death of a man, aged sixty-eight, at East Hampton, Mass., was caused by swallowing two false teeth during sleep.

Fined for Illegal Practice.—A colored man employed in a drug-store in Washington, D. C., was recently fined \$50 in a police court for illegally practising medicine.

Prison Congress Postponed.—On account of the yellow fever the date of the Annual Prison Congress to be held at Galveston, Texas, has been postponed to December 2d to 6th, inclusive.

Influenza May Come.—The medical press of Europe is warning the public against a probable recurrence of influenza, which has been raging for months in a severe form in the district of Merv, Turkistan.

Appointment of Dr. Bates.—President McKinley has appointed Medical-director Newton L. Bates, Surgeon-general of the Navy Department, to succeed Surgeon-general J. Rufus Tryon of New York.

Vaccination Laws in England.—Vaccination laws are not enforced in England. At Norwich, with a population of over 100,000, the vaccination-officer's fees this year amounted to about \$40. He receives fifty cents for each case.

Bombay Again Stricken.—Sixty deaths from bubonic plague occurred in Bombay during the last week in September. The disease has reappeared in Kurrachee, and is gradually spreading. It is said that the government regards the situation as serious.

Typhoid Fever Attacks the Turks.—The news comes from Constantinople that typhoid fever is ravaging the Turkish troops in Thessaly. Six thousand men have already been invalided home, and four thousand others are awaiting transportation back to Turkey.

Typhoid Epidemic in Kent (England).—According to the *New York Times* there is an alarming outbreak of typhoid fever at Maidstone, Kent, due to the pollution of

water by drainage from a hop-pickers' encampment. Over 1300 cases have been reported.

Medal for Dr. Recamier.—The news comes from Paris that Dr. Recamier has been presented with one of the silver medals sent by the Czar to be distributed among those who distinguished themselves at the charity bazaar fire by saving others from perishing in the flames.

Professor Adami to Lecture at the New York University.—Professor Adami of McGill University has accepted the invitation of the New York University Medical College to deliver a course of lectures on general pathology. The course begins Friday morning, October 8th.

Obituary.—We regret to announce the death on September 20th of Dr. G. D. Ricketts at Proctorville, Ohio. He leaves a widow, one daughter, Mrs. G. D. Bush, and three sons, Edwin S., Merrill, and Joseph. All of the sons are physicians, practising in Cincinnati, Ohio.

The Restrictions of Medical Charities.—Dr. Stephen Smith, who was recently elected President of the Board of Charities of New York City, is reported as having said that hereafter not one person who is able to pay for medical aid will receive free treatment at any of the city institutions.

Yellow-Fever News.—It is reported that the yellow-fever epidemic is spreading in New Orleans. Many new cases have developed, five of which appeared in one of the fashionable avenues of the city. The mortality has decreased from fifteen to twelve per cent. No general alarm is as yet felt.

Fatal Railroad Crossing.—The wife of Dr. R. C. Gray of Springfield, Long Island, was instantly killed by a train at that place September 29th. The carriage in which she was driving with a friend and two children was demolished at a railroad crossing. The others were seriously injured but may recover.

Appointments Abroad.—Dr. T.W. Engelmann, Professor of the Medical Faculty of Utrecht, has been appointed ordinary professor of physiology, vice Professor du Bois-Reymond, deceased. Dr. Leopold Meyer, docent, has been appointed professor of obstetrics and gynecology at Copenhagen, vice Professor Stadfelt, deceased.

American Jubilee Fund Endows Hospital Beds.—Guy's Hospital (London) has received a donation of \$5000 from the Committee of the American Victoria Jubilee Fund to endow in perpetuity a "Queen Victoria Bed." The London Hospital and the Charing Cross Hospital have each received a similar donation.

Experimental Hygiene in the Argentine Republic.—It is reported that a laboratory, similar to the Instituto d'Igiene Sperimentale founded by Sanarelli in Montevideo, is to be opened in Buenos Ayres. It will be under the direction of Professor Ferruccio Mercanti, the sub-director of the laboratory over which Professor Sanarelli presides.

Bogus Doctor Convicted.—In a Brooklyn police court a

man named Siegfried Reubel has been convicted of practising medicine illegally. This is the individual who attempted to restore the sight of a little girl by placing about her head an iron band, which he tightened at intervals by means of thumb-screws with which the instrument was provided.

Death of Dr. Samuel Craig.—Dr. Samuel Craig died recently at the home of his parents in Brooklyn. During last year, while on duty at the Manhattan Hospital, Ward's Island, he contracted typhoid fever, followed by pneumonia, which speedily developed into phthisis, which latter disease ultimately caused his death. He was twenty-six years of age.

Veterinary College Open to Women.—The New York College of Veterinary Surgeons, the fall session of which began last week, has for the first time opened its doors to women, and one has already matriculated. The Board of Regents of the State University has recently placed the requirements for entering a veterinary college upon the same plane as those for entering a medical college.

Alcoholic Selection.—In a recent work, "The Present Evolution of Man," by Mr. G. Archdall Reid, an English writer, the theory is advanced that intemperance is an important factor in the elimination of the unfit, and in the consequent progress of the race, inasmuch as it kills off those persons who have an undue craving for alcohol. He calls this process of elimination "alcoholic selection."

Typhoid Fever Near Kingston, N. Y.—Many cases of typhoid fever are reported from various towns which lie near Esopus Creek, in Ulster County, N. Y. This stream, which is a popular fishing ground, has its source at the quarries at Malden, and its outlet at Kingston Point. It is claimed that the disease is caused by the pollution of the water by the Kingston sewer which empties into the creek.

Body Hidden in the Cargo.—The news comes from San Francisco that the dead body of a Chinaman was found stowed away in the hold of the ship "America," which recently arrived at that port from Prince William Sound with a cargo of salmon. It is supposed that the body was hidden there by other Chinamen in order to avoid a burial at sea. The appearance of the body indicated that the man had been dead for a week.

Honorary Degrees Conferred.—At the recent meeting of the British Medical Association in Montreal, McGill University announced that it had conferred honorary degrees upon the following: Lord Lister, Sir Walter Foster, Sir William Turner, Dr. H. Barnes, Dr. Michael Foster, Dr. Gaskell, Mr. Christopher Heath, Dr. Alexander Macalister, Dr. Saundby, and Mr. Wheelhouse, all of England, and Professor Richet of France.

Remarkable Recovery from Snake-bite.—The sting of the double-horned viper is said to be invariably fatal, yet a case is reported from Opobo, West Africa, where a man survived the bite of one of these reptiles. He was stung just above the right ankle, and within an hour the leg was three times its natural size. Iodin and potassium were

injected into the wound, and the man recovered after a desperate illness and some days of delirium.

Dr. Bermingham Appeals.—The local Board of Health of Liberty, Sullivan County, N. Y., refused Dr. Edward J. Bermingham permission to erect at that place a sanatorium for the care of consumptives. Dr. Bermingham appealed to the State Board of Health on the ground that the local officials have no authority to prevent the establishment of a hospital for the care of the sick. The question having been referred to Attorney-general Hancock, he sustained Dr. Bermingham's position.

Memorial to Marcello Malpighi.—The news comes from Rome that a monument to Marcello Malpighi, the great physician and biologist, has recently been unveiled in his native town, Crevalcore, in Italy. The monument is surmounted by a statue of Malpighi, sitting in profound meditation, book in hand, and is the work of the sculptor, Enrico Barberi. Among those present at the unveiling was Professor Kolliker of Würzburg, who spoke of Malpighi as "the founder of embryology."

Instantaneous Skiagraphy.—It is said in Paris that an important improvement in skiagraphy, as applied to medicine, has been brought before the Academy of Sciences of that city by M. Porche. It is proposed to make use of a fluorescent screen and to photograph the shadow on the screen. An extremely sensitive plate is required, and this plate must be protected from all other rays emanating from the Crookes' tube, except those which actuate the fluorescent screen.

The Astoria Water-Supply.—The Grand Jury of Queens County, L. I., which has been investigating the complaints against the water-supply of Astoria, reports that it is insufficient and sometimes unfit for use. It was recommended that larger mains be used to increase the supply. The report furthermore states that the Grand Jury deplores the lack of harmony in the different departments of Long Island City, which renders any concerted action for the benefit of the people impossible.

Pulmonary Phthisis in Europe.—At the recent meeting of the International Medical Congress at Moscow, Professor von Leyden read a paper on the important subject of the treatment of pulmonary phthisis in special establishments. He called attention to the enormously large number of persons who perish from this disease, and said that in Germany there are 1,200,000 consumptives, of whom 180,000 die every year, and estimated that the annual mortality from phthisis in Europe is upward of 1,000,000 persons.

Insanity in Prussia.—In connection with the increase of insanity in England, mentioned in an article in the last issue of THE MEDICAL NEWS, it is said that a similar, if not a worse, condition of affairs exists in Prussia, where the insane asylums are not large enough to accommodate those who require institutional care. In 1871 the total number of lunatics in Prussia was 55,063; in 1880 it had risen to 66,345, while in 1896 the number reached 82,-

850. It is interesting to note that more men than women are affected.

Hydrophobia in Scranton, Pa.—The death of a ten-year-old boy from hydrophobia is reported at Scranton, Pa. The boy was bitten by a rabid dog sometime last March. During delirium the boy's teeth grazed his father's finger. It was antiseptically treated at the time and no further attention paid to it. The hand and arm now show considerable swelling and are very painful, and the man has been advised to come to New York to undergo the Pasteur treatment. It is said that the dog bit seven persons, and the boy above mentioned is the second who has died.

Health Reports.—The following statistics concerning cholera, yellow fever, smallpox, and plague, have been received in the office of the United States Marine Hospital Service during the week ending October 2, 1897:

American Women Students at University of Zurich.—A society has been formed at Zurich, Switzerland, by Amer-

ican women who are studying for a doctorate at that place, and a circular has been issued containing information for those who intend to study in Europe. Among other things it states that no woman should go to Zurich with the immediate intention of university-study, unless she has not only a reading but a speaking knowledge of German, and furthermore, that Zurich is not the place to acquire this knowledge because of the dialect spoken there and because of the number of foreigners in the town.

Disinfection of Mails from Infected Localities.—There are different ways of disinfecting mail matter, but in the New York Post-office it is done in the following manner: A bag of letters upon being received at the quarantine station is turned over to an employee, who, with his hands carefully gloved, drops them one by one into the chute of a machine which punches a circular hole, about one-sixteenth of an inch in diameter, through each. As they emerge from the punching-machine the letters fall into a basket from which they are emptied into a huge circular tank inside of which is a cage of steel wire. This cage revolves rapidly by means of electricity, and for an hour the letters are shuffled up and turned about, during which time they are subjected to the fumes of sulphuric acid. When this is finished live steam is turned on, and the cage is again set in motion for a shorter space of time. The letters are then returned to the mail-bag, which has meanwhile been thoroughly fumigated in the steel cage, and are delivered in the usual way.

CORRESPONDENCE.

A HINT TO LIFE-INSURANCE EXAMINERS.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: If an applicant for life insurance on being examined states that he has some eye trouble, and is at the time under the treatment of a specialist, whose address he supplies, would you consider it the duty of the examiner to write to the specialist to ascertain the cause of the eye trouble, or the duty of the medical director of said insurance company?

Respectfully,
"E."

MANCHESTER, VA., June 1, 1897.

[The above letter was referred to Dr. E. W. Lambert, Medical Director of the Equitable Life Assurance Society, and the following reply received.]

DR. J. R. GOFFE.

MY DEAR DOCTOR: My answer to such an inquiry would be this: If an applicant came before us and should state that he was under treatment by any specialist, we would expect the applicant to furnish us with a certificate from the specialist as to what he was treating the applicant for, and also all the particulars relating to the case from the standpoint of the specialist. In other words, it is the duty of the applicant to furnish the company with all the facts in regard to his present and past history, and not our business to hunt up and find out what has been the matter with him.

Yours very truly,

E. W. LAMBERT, M.D., Medical Director.

NEW YORK, August 2, 1897.

KEROSENE-OIL POISONING.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: In the issue of THE MEDICAL NEWS of September 18th, I read with interest the report of a case of kerosene-oil poisoning by Dr. G. Edgar Hoffman of Rochester, Indiana, as I had just observed a very similar case in which a boy aged seventeen months swallowed a mouthful of kerosene oil, and strangled severely. The mother ran into my office with the child, so that I saw him within one minute after the ingestion of the oil. I simply inverted the child—not entirely, but so that his head was lower than his body, and face down. I tapped him sharply on the back, which caused the sudden expulsion of air from the lungs and expelled the few drops of oil from the throat. I next applied pressure with my hand over the stomach, and in a very short time had him vomiting nicely. In fact his stomach was entirely emptied in about five minutes. The child became very pale and almost completely unconscious, in which condition he remained for nearly two hours. From this time on he improved quite rapidly and next evening was about as well as usual.

I would not have considered this case of sufficient importance to report had not Dr. Hoffman mentioned the scant literature upon the subject. In connection with this I might mention another case which occurred in my practice about four years ago. I was called in great haste to see a child that had swallowed coal-oil. This did not prove so serious. A dose of zinc sulphate caused immediate vomiting and the child apparently suffered little. There was no strangulation. At the time of the occurrence of my first case I was assured by Dr. J. H. Kinyoun of Centreville, that I need not be greatly alarmed as the oil was not, in itself, very dangerous, and the old doctor related that he himself had once taken nearly half an ordinary glassful of the same oil—kerosene—and never felt the least discomfort from it.

D. D. BARR, M.D.,

PRAIRIE HOME, ILL., September 22, 1897.

OUR BERLIN LETTER.

[From our Special Correspondent.]

THE LEPROSY CONGRESS AND THE ATTENDANCE OF SPECIALISTS—KOCH'S NEW TUBERCULIN AND THE RESULTS IN HIS OWN SERVICE; SOME REASONS FOR THE NON-SUCCESS REPORTED—OTHER SERUMS, PROPHYLACTIC AND CURATIVE, IN THE INFECTIOUS-DISEASE WARDS—THE GERMAN APOTHECARIES' UNION AND THE ADMISSION OF WOMEN.

BERLIN, September 27, 1897.

As the time approaches for the holding of the Leprosy Congress here, the interest shown in it by specialists becomes more apparent. Though so many congresses have been held during the last two months, this one will not suffer by comparison. It is clear that the practical experts in leprosy—the medical men who are living in actual contact with the disease where it is endemic—and the skin specialists whose writings on the subject have been the generally accepted teaching of the medical world are to meet at last under the most favorable circumstances

for the ventilation of discordant ideas. As is usual in most branches of medicine, the theorists and the practitioners have not been strikingly accordant in the general treatment of the subject. Some little fear was entertained that the French school might not be well represented, but some of the best known specialists have signified their intention of being present. There are to be two representatives of the Turkish government from Constantinople, and other delegates will be present from Turkey in Asia, Roumania, Alexandria, Algiers, the East, and Japan, all men of wide practical experience in dealing with the disease.

So much has been said and written recently on the subject of Koch's new tuberculin, and so much has been of an unfavorable nature, that it occurred to your correspondent that it would be worth while to find out what the present opinion of it is in the infectious wards of the Charité, where Koch's assistants are in charge. I found Professor Brieger, who, during Professor Koch's absence in South Africa, is acting director of the department, very ready to express an opinion on the matter. He knows how much that was unfavorable was said at the Moscow Congress, even by distinguished authorities from Berlin, and regrets that a representative of the Koch Institute was not present to state the other side of the case. Under the circumstances, however, with Professor Koch himself absent, this was impossible.

During the course of a walk through the wards with Professor Brieger I saw a number of patients who at present are under treatment with the new tuberculin. Not by any means are all the patients suffering from tuberculosis considered suitable subjects for the administration of the remedy. When the destructive process in the lung is at all advanced very little can be hoped for from the treatment. Regeneration of lung-tissue cannot be expected, and, besides, infection with other micro-organisms has inevitably taken place, and the process is eminently a progressive one. Unfortunately, it is just this class of patients which has been used in testing the new T. R. When all other means were hopeless and the patient seemed doomed anyhow, tuberculin was used as a last resort. The recollection of the unexpected dangers developing under the use of the old tuberculin is too vivid to allow most clinicians to use this in just the class of cases for which it is adapted. According to Koch it is in the subjects in whom the physical signs are scarcely more than suspicious, when there are few, if any, tubercle bacilli in the sputum, but when the febrile reaction after injection of the old tuberculin shows the indubitable presence of a tuberculous process that the new remedy can be depended on to effect a cure. As to the danger for such patients, not a single bad result, when a sluggish tuberculous process has been irritated into acute activity, has occurred in all the cases treated at the Institute. As to the possibility of the presence of any living tubercle bacilli in the new tuberculin, when properly prepared, it is the merest chimera, for, in almost countless cultures made by professors and assistants in the laboratories, it has been demonstrated beyond doubt that these have been thoroughly eliminated. As to the reported non-sterility

of certain samples of the new tuberculin which came from the factory at Höchet, this may have been true as regards the presence of certain non-pathogenic germs in the first issues from the factory. Large quantities of the agent were called for at once, and some of the minute precautions so necessary for absolute sterility, especially as regards molds and certain harmless air-germs, may have failed of fulfilment. None of the later products, however, is open to such an objection, unless through careless handling afterward.

Some of the cases in which striking improvement has been noted during the course of injection of the new tuberculin are those of external tuberculosis. Lupus, especially, is soon and favorably affected by the remedy, and the healing goes rapidly on to complete cure. Certain external eye diseases, too, when all other methods of treatment have been tried without success, yield to its influence. In the wards at present there is a patient, about to be dismissed as cured, who is a remarkable example of this. The case was one of multiple tuberculous ulcers of the cornea, which absolutely refused to heal under all manner of treatment at the hands of an experienced ophthalmic surgeon. The cure is absolute.

Such cases are very striking, because the results can be clearly seen. There is no question of auto-suggestion, with seeming improvement in symptoms and temporary arrest of the progress of the disease, only to be followed by inevitable relapse. Cases in which the physical signs have shown that the tuberculous areas in the lungs have become less in size during the course of the injections are not lacking, and this sometimes when the destructive process has been quite advanced. There is a remarkable case under treatment just now, of a well-to-do patient who insisted on receiving the injections, though his was evidently at a stage of the disease not considered suitable for the T.-R. treatment. Injections during several months have been followed by lessening of the physical signs in the lungs, and he has gained fifteen pounds in weight.

As to the serums in use at the Institute, reports are not very encouraging. A tuberculous antitoxic serum has been used without effect, and the impression seems to be that an antitoxin for tuberculosis is impracticable. A streptococcic serum, used in conjunction with tuberculin in cases of mixed infection, did not seem to produce any good result. Generally, the streptococcic serums have been unsatisfactory in their action. Recent work at the Institute has demonstrated that the streptococcus pyogenes and the streptococcus erysipalatosus are the same, but the specific virulence of various forms of the streptococcus for animals, and even for individuals, is so different that the preparation of a curative serum which will give results in any definite case seems a hopeless task as yet. Streptococcic serums for the treatment of carcinoma have not proved successful, and even Petruschky's preparation, which, for a time, at least, seemed to promise amelioration of symptoms and slower progress of the malignant invasion, has not continued to give such results as would encourage further experimentation. Cascarelli's serum

for the treatment of leprosy has been tried in several cases, but absolutely without effect.

At the meeting of the German Apothecaries' Union the other day, the resolution that "women had shown themselves to be capable mentally, as many of them were capable physically, of fulfilling the duties of apothecaries, and so should be admitted as members of the Union," was voted down by a large majority. The fact that it should have been presented at all is significant, for in Germany more than anywhere else at present are what may be called the intellectual rights of woman and the question of her employment on a plane at all equal to that of man a subject of derision. The heaven is evidently at work here also.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

THE SOCIAL SIDE OF THE COMING MEETING OF THE AMERICAN PUBLIC-HEALTH ASSOCIATION—OPENINGS OF THE MEDICAL SCHOOLS—DR. WILLIAM S. CARTER HONORED—DR. GEORGE W. PFROMM—DR. CHARLES W. BURR—VITAL STATISTICS FOR THE WEEK ENDING OCTOBER 2D.

PHILADELPHIA, October 4, 1897.

ARRANGEMENTS for the celebration of the twenty-fifth anniversary of the American Public-Health Association, which meets in this city on the 26th, 27th, 28th, and 29th of this month, have been almost completed by the local committee, of which Dr. Benjamin Lee is chairman, and sufficient progress in the details connected with the work of the gentlemen entrusted with the entertainment of the visitors has been made to indicate that the four hundred expected delegates will be fittingly entertained during their stay in Philadelphia. The headquarters of the Association will be at the Hotel Walton, where daily sessions will be held, and which is admirably adapted to the purpose. In addition to the receptions given the members of the Association by the various scientific and teaching bodies of the city, the Committee of Arrangements has planned visits to many places of interest throughout the city. The United States Government has also placed at the disposal of the delegates one of the revenue vessels stationed at this port, and two steamboats belonging to the Sanatorium Association have been secured by the Committee, whose intention it is to convey the visitors to the Government Quarantine Station some miles below the city, where a day will be spent in inspecting the hospital and disinfecting plant situated there.

The session of 1897-'98 of the Woman's Medical College of Pennsylvania was formally opened on September 29th. The opening exercises took place in the large lecture-room of the college, and were presided over by Dr. Clara Marshall, the Dean of the institution. After Dr. Marshall's usual announcements concerning the arrangements for the ensuing year, Dr. Anna M. Fullerton, Clinical Professor of Gynecology, the lecturer for the occasion, was introduced, who took for her theme, "Methods in the Study of Medicine." From present appearances, the outlook for the college year at the Woman's Medical College is exceedingly gratifying to the friends of this progressive institution.

The opening of the Medical Department of the University of Pennsylvania took place on October 1st the ushering in of the new term being marked by elaborate exercises, in which a prominent part was taken by the distinguished English prelate, Canon Gore, of Westminster Abbey, who made an address to the class. The changes made in the medical faculty since the last session have not been noteworthy, and the *personnel* of the teaching force remains practically unaltered. The enrolment of students for the present term indicates, as far as it is possible to do at this time, a full attendance in the medical school, in spite of the constantly increasing standard of requirements for admission—a standard which the University has gradually raised, year by year, to its present status.

The introductory lecture to the seventy-third annual course of lectures at the Jefferson Medical College will be delivered by Dr. G. E. de Schweinitz, Professor of Ophthalmology, on the evening of October 4th, in the amphitheater of the Jefferson Medical College Hospital. The exercises will be opened by an address by the Hon. William Potter, the President of the Board of Trustees of the college. The class at Jefferson this year far exceeds the expectation of the authorities of the institution, who naturally anticipated somewhat of a diminution in the number of matriculants, in consequence of the radical changes tending toward the high standard of education which the college demands of its prospective students. The faculty of this institution, its laboratory equipment, and its clinical facilities leave nothing to be desired by the seeker for a school offering every modern method for the study of his chosen profession, under the guidance of teachers whose views are authoritative on the subjects upon which they lecture.

The regular fall and winter term at the Medico-Chirurgical College will commence on October 4th with a registration in every department in excess over that of the preceding year. In addition to the elaborate clinical amphitheater erected by the college during last spring, many other improvements in the buildings have been completed. By a bequest of the late Professor William H. Pancoast, the Pancoast Library, consisting of nearly six thousand volumes of medical works, will be placed at the disposal of the students of the college.

Dr. William S. Carter has resigned his position as Assistant Professor of Comparative Physiology and Demonstrator of Physiology in the Medical Department of the University of Pennsylvania, to accept the Professorship of Physiology at the University of Texas, Galveston. A reception was tendered Dr. Carter by many of his colleagues and friends at the University on the eve of his departure, on September 28th.

Dr. George W. Pfromm has been elected Lecturer on Materia Medica and Therapeutics in the Medico-Chirurgical College, to succeed Dr. William B. Stewart.

Dr. Charles W. Burr delivered an address on "The Remote Results of Injuries on the Nerves" before the Philadelphia Hospital Medical Society, on September 27th.

The number of deaths in this city for the week ending October 2d was 342, a decrease of 10 from those of the preceding week, and a decrease of 59 from the correspond-

ing week of last year. The number of deaths from contagious diseases was 33, or 11 less than those reported last week. Cases of diphtheria numbered 97, with 27 deaths; scarlet fever, 25, with 2 deaths; and enteric fever, 31, with 4 deaths.

Paris.

RADICAL CURE OF HERNIA BY INJECTIONS OF THE CHLORID OF ZINC—NATURE AND TREATMENT OF EXOPHTHALMIC GOITER—PAINFUL HYPERTROPHY OF THE BREAST AND ITS CURE BY MASTOPEXY—FRACTURES OF THE PATELLA.

AT the session of the Academy of Medicine, July 6th, LANNELONGUE showed some children upon whom he had practised a *radical cure of hernia, by injections of a ten-per-cent. solution of chlorid of zinc*. Of forty-four children and youths, aged from four months to twenty years, treated in this manner, a perfect cure was obtained in forty-one. One of the failures was the very first patient operated upon, and who was insufficiently injected. A cure followed a repetition of the treatment. The other two were unsuitable, by reason of the size or density of the hernia, for this method of treatment. In seven adult cases, success was obtained five times. The essential points of this method of treatment are to avoid injection into the peritoneal cavity, by pressure of the finger over the internal ring, and to avoid injury of the cord, by isolating it at the moment that the injection is made. Two or three injections are usually required, of ten or twelve drops each, and as the pain is pretty sharp it is better to make them under chloroform narcosis.

ABADIE read a paper upon *the nature and treatment of exophthalmic goiter*. Three theories of its origin have been advanced—the hematic, nervous, and thyro-genous. The last is the most seductive and has been widely accepted. None the less, all surgical attacks upon the gland itself have proved uselessly dangerous. The most rational theory is that the disease is due to permanent excitation of the vasodilators of the cervical sympathetic. The benefit which follows division or resection of the cervical sympathetic between the superior and middle ganglia is proof of the correctness of this theory. In all cases in which such division has been made, the exophthalmus and goiter have decreased. If, later, there is a recurrence of these symptoms, this is doubtless due to a restoration of nerve-fibers. In the resections of a part of the gland, the exaggeration of symptoms which so often follows is apparently due to the irritation of torn nerves, and in exothyropexy this irritation reaches its maximum, and explains why patients die from an operation which in itself does not appear to be dangerous. This theory of a dilatation of the vessels also explains the formidable hemorrhage which is met with in partial resection of the gland.

The rational treatment, therefore, is section of the cervical sympathetic between the superior and middle ganglia. The inferior branch of the nerve is small, and may be neglected. If there is any doubt as to the diagnosis, before resorting to a surgical operation the patient

should be put on the thyroid extract for a few days. If there is improvement the proof is conclusive that the goiter is an atrophic one, and the medication is to be continued until a cure is obtained. If the goiter is truly exophthalmic, the symptoms will be aggravated, and the operation referred to should be performed.

POUSSON spoke of *painful hypertrophy of the breasts and its relief by mastopexy* before the Surgical Society, June 30th. The patient to whose case he referred was a very stout woman, whose breasts reached her groins, preventing her from wearing corsets and from doing work, and giving her in addition a great deal of pain. An elliptical incision was made along the inferior surface of each breast, and a large portion of skin and fat removed. The glands were sutured to the fascia of the greater pectoral muscles, and the wounds closed by sutures. Union was prompt, and the deformity, with its accompanying pain and disability, was permanently relieved.

In speaking of *fractures of the patella*, POIRIER said that the dimensions of the patella vary much according to the age of the individual, as successive layers of osseous tissue are added peripherally with advance in years, the central part of the bone meanwhile becoming very porous. The practical lesson from this observation is that the treatment of fractures of the patella by the open method is not alike in all cases, but that more solid patellæ are fitted for suture, while "cooperage" is the best for more porous bones.

BERGER mentioned a case of *primary melanotic sarcoma of a gland* in the subhyoid region. The most careful search failed to reveal any other source of the trouble.

MARCHAND mentioned a similar case in which the sarcoma was of the inguinal glands, and another in which the glands of the axilla alone were affected.

At the Medical Society of the Hospitals, July 2d, GAL-LIARD related the case of a man, aged forty-three years, who suffered from pleurisy, at first serofibrinous and then purulent. A pleurotomy was performed in the eighth intercostal space, and a drain left in position. Fifteen days later the drain was removed, and cicatrization rapidly followed. Some time later it was observed that with each expiration there appeared in the scar a soft tumor about the size of a nut, which was non-pulsile and non-crepitant and easily reducible. Under the influence of a compress and bandage, worn for some months, the little hernia of the lung permanently disappeared.

Vienna.

REPORT OF THE GERMAN COMMISSION UPON THE PLAGUE AT BOMBAY—SUPRARENAL EXTRACT USED LOCALLY TO CONTROL HEMORRHAGE.

AT the session of the Imperio-Royal Society, May 28th, ALBRECHT presented a *report of the German commission upon the Bombay plague*. The commonest form of the disease is the *septic-hemorrhagic* one. The buboes occur oftenest in the groins, and next in the axillæ and the neck, involving sometimes a single gland, sometimes a whole group. On cut section a gland shows a number of red and yellow areas, and these infarcts are often con-

tinued into the surrounding tissues. If death does not ensue, there usually results suppuration and breaking down of the skin with discharge of hemorrhagic and necrotic masses. The whole process is accompanied by marked edema, and often proceeds with great rapidity. In a few hours from the time of outbreak, vomiting, fever, etc., and infiltration of the tongue, pharynx, and gullet, are common.

In the vicinity of the original bubo, there frequently appear bullæ filled with clear or cloudy serum, and proceeding to carbuncle formation. These were supposed to be the result of lymphangitis, but although this cannot be proved, the fact that one of the physicians of the investigating party developed a bulla as the result of a scratch received at an autopsy supports this theory. This bulla became hemorrhagic, and its contents contained a pure culture of the pest bacillus.

Besides the buboes, the general lymph system shows infection, the throat, as already referred to, often presenting the appearance of diphtheria, while the spleen is so filled with the bacteria that they form a considerable part of its swelling.

Hemorrhages into the pleura and other serous membranes are the rule. They were also not wanting in the muscles of the neck, breast and abdomen.

Another form of the disease, the *septic-pyemic*, develops in those cases in which the poison has had time to produce embolic masses in the internal organs. These are especially noticeable in the lungs and liver and to a less extent in the kidney.

The third form is a *primary plague pneumonia*, and it is by this form that English doctors and nurses are chiefly attacked. The pneumonia occurs in patches, and these are indistinguishable from the pneumonic areas which occur in the second form. Cases of this type run a fearfully rapid course and quickly lead to death.

The infection reaches the system in most cases through the skin, but the numberless scratches on the bare legs and arms of the Hindus make it difficult to determine in most instances its exact point of entrance. Whether the stings of insects are responsible for the infection in any case could not be ascertained, though this is the popular belief among the natives. From the occurrence of primary plague pneumonias, it appears that infection by inhalation is possible, and doubtless infection sometimes takes place through the tonsils.

The plague bacillus discovered independently by Kitasato and Koch is easily isolated and may often be obtained in pure culture from the blood. The pus is usually sterile, or contains other germs, but not the plague bacillus. Animals artificially infected with the bacillus, quickly die with all the symptoms of the disease, but it does not occur spontaneously in any animal except the rat. The members of the commission did not see any benefit result from the use of a plague-serum. So far from being surprised at the high mortality of the plague, they expressed their wonder that more did not die of it, so bad are the conditions of life in which the natives are placed.

At the session of the Medical Club, June 16th, KONIGSTEIN said that the *extract of the suprarenal capsules*

is the only one of the animal extracts which has been used locally. Dropped into the eye, it is said to produce a profound anemia. Taking a suggestion from this, it has been used to control hemorrhage, but its working in this direction leaves much to be desired, as it dilates the larger vessels, while contracting the smaller ones and capillaries.

SOCIETY PROCEEDINGS.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Fourteenth Annual Meeting, Held at Washington, D. C., May 4, 5, and 6, 1897.

DR. ROBERT H. BABCOCK of Chicago presented a paper, entitled

A BRIEF CONSIDERATION OF SOME POINTS IN THE MANAGEMENT OF CONSUMPTION,

for the purpose of drawing forth discussion by the members of the Association. He inquired first whether the slight elevation of temperature in the early and unmixed forms of the disease is inflammatory in origin, as held by Jaccoud, or whether it is an expression of infection by the bacillus tuberculosis. For diagnostic purposes he attaches no importance to the occurrence of afternoon temperatures below 100° F., which should be regarded as subfebrile, fever not being present until the temperature reaches 101.3° F. For temperature below this point, and even when fever is moderate, *i.e.*, between this point and 103° F., he orders absolute rest in the open air when possible, regulates the diet, and promotes free expectoration. Solid food is only allowed at such times during the day as the temperature is subfebrile or normal—generally in the morning, of course. Liquid diet, such as milk properly diluted with some alkalin water, is allowed when the fever is present. Patients are instructed how to cough intelligently and efficiently, and if the sputum is tenacious terpin hydrate or some other equally efficient and harmless expectorant is administered; in the belief that at this stage febrile temperature is due largely to absorption and consequent sepsis. Dilute hydrochloric acid, pepsin, pancreatin, taka-diastase, and the like are administered to aid the enfeebled digestion. If such simple measures do not suffice, careful sponging is resorted to whenever well borne. He administers as little medicine as possible, apart from strychnin and the carbonates of guaiacol and creosote, relying chiefly on fresh air, rest, and nourishment. Whenever drugs are ordered they are usually in response to troublesome symptoms, such as cough and sweating, anorexia, diarrhea, and the like.

The second symptom discussed by the speaker was night-sweats. They are a phenomenon of sepsis, and the ideal treatment would be the removal of the cause. He gives picrotoxin, $\frac{1}{60}$ of a gram, in the late afternoon, and a like dose in the evening, so as to obtain the action of the remedy before the expected sweat occurs. He never uses atropin for this purpose, but sometimes orders camphoric acid in 15-gram doses, three times daily. The picrotoxin rarely fails.

Diarrhea is another symptom which, in advanced cases,

is often very obstinate, and requires skilful handling. He rarely prescribes opium, preferring intestinal antiseptics, as dermatol and other preparations, benzonaphthol, and salophen; but when he does resort to an anodyne he gives phosphate of codein. A tuberculous physician, now in Texas, related that after having had obstinate diarrhea for months while in Mexico, he obtained prompt and lasting relief from enteric pills of creosote. As this treatment was coincident with his removal to a somewhat lower altitude in Arizona, the query arises, How much is to be attributed to the creosote, and how much to the change of location?

The next query was, Should we send our patients to Colorado and New Mexico if the larynx is infiltrated, but not yet ulcerated?

Finally, what opinion should one give to a patient who has regained his health at a high altitude and then desires to return for permanent residence to his old home at the sea-level? The speaker has always regarded such a course unwise, if not actually unsafe, even in cases of incipient and circumscribed lesions. Aside from the fact that the climate of the patient's former home is less dry, equable, sunshiny, and pure, it has seemed a dangerous experiment, because the apices and borders of the lungs expanded under low atmospheric pressure are again likely to fall into comparative disuse at a low altitude. Will respiratory gymnastics prevent this? Is it safe for a patient, having nearly or quite regained health in Colorado or New Mexico, to remove permanently to even desirable localities in Southern California, Texas, or other comparatively salubrious climates of lower altitude? Is it necessary to impress patients who have not pronounced tubercular inheritance with the importance of changing residence permanently?

DISCUSSION.

DR. V. Y. BOWDITCH of Boston: In regard to what Dr. Babcock has said about it not being necessary to force down the temperature of phthical patients who do not complain of fever, I can heartily agree with him. Attend to the general condition of the patient, and leave the fever alone unless it causes great discomfort. As to the return to a lower altitude after a residence in a higher one, where health has been regained, my early teachings and my own experience have made me feel it is an experiment attended by much risk. We know of many exceptions, doubtless, but my usual advice to a phthical patient is to remain in or near the place where he regained his health.

DR. HANCE of Lakewood: As to the question of sending laryngeal patients away, I think that it depends upon the degree of laryngeal invasion. If they are in the last stage of phthisis, they might as well stay at home. I have found that Tully tablets, in combination with bismuth or salol, are very beneficial in the diarrhea of such patients. Instead of using morphin in the last stages of phthisis, codein will often carry the patient on for two or three weeks, or even months, after which we must fall back on morphin. There is one preparation of service in the early stages of the disease. Dr. Quinby spoke of it four years ago. It is aquazone, which improves the condition of the stomach. The last report of the sanatorium

at Saranac Lake refers to the use of tuberculin. There were many patients there to whom it was administered. During the time it has been in use at the sanatorium there have been twenty-four patients discharged "apparently cured." Their after-history has been followed, and it is reported that twenty-two are now well, that one died of chronic alcoholism, and one died in an insane asylum.

DR. NEWTON of Montclair: I should like to know why Dr. Babcock objects to the use of atropin to check night-sweats of phthisis. I have generally obtained good results from its use. I am now treating an advanced case of phthisis in which atropin in reasonable doses having apparently lost its power, I resorted to the use of agaricin, and afterward to camphoric acid. Neither of these drugs proving to be satisfactory, I tried sulphonal in $7\frac{1}{2}$ -grain doses every six or eight hours, and was much pleased with the result.

DR. HARE of Philadelphia: The results of the experiments of those who have done laboratory work prove that guinea-pigs confined in laboratories are naturally subject to tuberculosis. The great objection to the use of atropin in the treatment of night-sweats is the fact that it disorders the digestion by stopping the secretion of gastric juice. I have for a number of years used camphoric acid with very great satisfaction. It should be given in the dose of at least 20 grains three or four hours before the usual time of the sweat, so that it may be absorbed from the stomach in time to exert its physiologic action. It dissolves very slowly, and is best given in a cachet. I have recently been engaged in studying the rapidity of absorption of various drugs, and I believe that the condition of the gastro-intestinal mucous membrane in relation to the absorption of remedies is not sufficiently studied. Briefly, I may state that if a small quantity of some gastric stimulant, such as capsicum, is added to the camphoric acid in the capsule, it will aid very materially in the absorption of this antisudorific remedy.

DR. HANCE: My experience has not been such as Dr. Hare describes. I have used at least 200 guinea-pigs in experimental work. By far the largest proportion of these were found free from any tuberculous infection after they had been subjected to inoculation, and only those were tuberculous in which we had reason to suspect the presence of the tubercle bacilli previous to inoculation. If guinea-pigs are found tuberculous without any inoculation, they have either been inoculated by reason of bad breeding-quarters or lack of care in looking after them in the laboratories where the experiments are performed.

DR. SOLLY of Colorado Springs: Some physicians think that because the patient worries about the night-sweats and feels that the doctor should be giving him something to stop them, they should fall in with the patient's mood. I would let the night-sweats take care of themselves and devote myself to building up the system. It is generally a question of food. The intelligent use of whisky is to be commended, but the patient should not be allowed to drink all the whisky he can.

Concerning tuberculous laryngitis, I am convinced that the delusion ought to be put to one side that high altitudes exert an unfavorable effect. If altitude is good for

tuberculosis, it will be good for the other complaint also, but not otherwise. Another point is that tuberculous laryngitis in the ulcerative stage should be treated locally.

DR. W. H. DALY of Pittsburgh: In the belief that we would all like to hear of the experience of others upon this interesting subject, I would state that for three years I have been administering doses of $\frac{1}{2}$ to 1 drop of pure carbolic acid, with 1 to 2 drops of compound liquor of iodine in water, one-half hour before meals, followed by as much hot water as the patient can drink, with very beneficial effects; in fact, in some cases I have succeeded in arresting the progress of the disease. I found some of the more fickle-minded patients objected to taking this solution. I therefore had some tablets made representing the same, or supposed to represent the same drugs and dose, but equally good results did not follow their use. I also keep the air of the bed-chamber saturated with iodoform, and find that patients soon become accustomed to the odor. If I were to be denied all remedies but one for the abatement of cough, I should choose laudanum in the minimum adequate dose. Another valuable remedy for the cough of phthisis is sulphate of codein in 1-grain doses at bedtime; it will carry the patient through the night without cough, and disturb the secretion but slightly.

DR. KNIGHT of Boston: I think that it is important to treat easily accessible laryngeal ulcerations locally. The present method is by curetting and the application of lactic acid. This will often prove very satisfactory, and should be tried, especially when the ulceration seems superficial and there is no perichondritis. I use iodoform internally, 1 to 3 grains of this taking the place of creosote. I have found that patients will tolerate from 3 to 6 grains of it a day. I would like to ask Dr. Daly what effect he wished to obtain from the use of iodoform, and whether he used it for its antiseptic effect.

DR. DALY: In my opinion, iodoform is the best and safest germicide which can be used in the air-passages. I am in the habit of cleansing, as far as I can, the gray mass from the ulcers of laryngeal phthisis and then covering the surface with iodoform powder, and I instruct the nurse or attendant to repeat this often, and always after free expectoration by the patient. I endeavor to bring the patient as completely and quickly as possible under the influence of iodoform, and maintain the influence, and if this can be done, and foolish objections of friends as to the odor overcome, an arrest of the disease and, in many instances, a cure may be expected. I have had some phthisical patients that lived six, eight, and ten years, apparently well, and died from other causes. I have also given iodoform internally, in from 1- to 5-grain doses, as an antiseptic and alterative in other diseases, especially those of the digestive organs.

DR. BABCOCK: Concerning the danger of allowing tuberculous patients to return to their old homes, I may say that this question has troubled me more than any other. Dr. Hare's objection to the use of atropin seems to me a sufficient one, and its unpleasant physiologic effects are enough to influence us to try some other remedy. I cannot pass by the remarks of Dr. Daly concerning the use of laudanum. Of course, we are sometimes compelled

to use opium in cases of consumption, but I think its use should be put off as long as is possible, and that the codein preparations should be employed instead, since they are devoid of the unpleasant effects of other opiates.

THERAPEUTIC HINTS.

For Eczema of the Genital Organs.—In this disease, so remarkable for the severity of the subjective symptoms, for its tendency to persistence, recrudescence, and nocturnal exacerbation, the following formulæ are highly recommended by Finny of Dublin, to allay irritation:

℞	Lin. calcis	f 3 iv
	Ext. belladonnæ	gr. xii
	Zinci oxidi	3 ii
	Glycerini	f 3 ii
	Aq. calcis	f 3 iv.

M. Sig. Lotion, to be applied at night after bathing the parts in hot water.

℞	Lin. calcis	f 3 iv
	Ac. hydrocyan. dil.	f 3 i
	Sig. plumbi subacetat.	f 3 ii
	Glycerini	f 3 ii
	Aq. rosæ, q.s. ad.	3 viii.

M. Sig. Cream, for application on strips of old linen.

For Exophthalmic Goiter.—HUTCHINSON advocates the use of potassium bromid, in 20-grain doses, three times a day. The salt should be taken an hour or two after meals in half a tumblerful of water.

For Galactorrhea.—

℞	Atropinæ sulph.	gr. iv
	Aquæ rosæ	3 i.

M. Sig. Apply on lint or cotton over the breast and remove when the throat becomes dry.—*Bartholow.*

For Fætor of the Breath, due to carious teeth.

℞	Sodii bichloratis	gr. xv
	Thymol	gr. vii
	Aq. dest.	3 lxxv.

M. Sig. Mouth-wash.

For Acute Gout.—

℞	Ext. colchici acetici	} aa	gr. i
	Ext. aloes		
	Pulv. ipecac.		
	Hydrarg. chlor. mitis		
	Ext. nucis vomicæ		gr. ¼.

M. Ft. pil. No. i. Sig. One such pill to be taken every four hours until purgation ensues.—*Loomis.*

For Gonorrhea in Females.—

℞	Zinci sulphatis	3 i
	Aluminis	3 iii.

M. Sig. Dissolve one teaspoonful of the powder in one pint of warm water and use as an injection, three times daily.—*Ringer.*

Another excellent mixture for the same purpose is the following:

℞	Creolin	m. xxx
	Ext. hydrast. Canad. fluid.	3 iiss.

M. Sig. Two teaspoonfuls in a pint of warm water, to be used as an injection, two or three times daily.—*Lutaud.*

APPENDICITIS IN RELATION TO DISEASE OF THE UTERINE ADNEXA AND PREGNANCY.¹

By JOHN B. DEEVER, M.D.,
OF PHILADELPHIA;

ASSISTANT PROFESSOR OF APPLIED ANATOMY IN THE UNIVERSITY OF PENNSYLVANIA; SURGEON-IN-CHIEF TO THE GERMAN HOSPITAL.

THE subject of appendicitis, with its fatality and many complications, and the close relationship which it may bear to contiguous organs and structures, cannot fail to be of particular interest to this body of obstetricians and gynecologists. You will no doubt agree with me that acute appendicitis is the most common, and one of the most fatal, of all acute intra-abdominal affections, and, furthermore, that its mortality is in a great measure due to a failure to make an early diagnosis, and to the character of the treatment instituted. The position which I have held, namely, to operate as soon as the diagnosis is made, I still maintain, assuming that this is done very shortly after the onset of the attack. I know that this course is attended by the least mortality. My experience in the operative treatment of this dangerous, treacherous, and fatal disease, embraces several hundred cases, and I am prepared to make the statement that I have never seen a human life lost when operation was performed immediately following the onset of the disease. While I am aware that to discriminate between cases, and to be able to determine from the onset which are operative cases and which will recover without operation, or to be able to defer operation with absolute safety for two, three, or more days, rather than to rush in, as some put it, and remove the diseased appendix as soon as the diagnosis is made, may be more scientific, yet I know positively that this course is taken at the cost of many human lives. When, therefore, it becomes a question of following the lines of theory or of experience, which teaches practical facts and which when instituted will bring practical and favorable results, the decision permits of no choice.

The ultimate results of inflammation of this organ more than justify early operative interference. Let us consider for a moment some of the results of appendic inflammation. First and most important, because of the high mortality, is perforation of the

appendix, with general septic peritonitis; next, perforation, with localized abscess formation, which if not evacuated early produces general sepsis, a tedious convalescence, a granulating wound, and in many instances ventral hernia or fecal fistula. Appendicitis followed by a large localized abscess means necessarily the destruction of a great deal of tissue which oftentimes Nature fails to repair, to say nothing of the loss of life when it occurs in the young or feeble. I consider the formation of a localized abscess, occurring as the result of appendicitis, anything but the most fortunate culmination of the attack and for the following reasons: because the inflammation should not be allowed to reach that stage; that in the hands of the majority of operators it is an excuse to leave the appendix, believing that with the evacuation of the abscess they have accomplished all that can be expected. This practice not only offers an opportunity in too many instances for leaving behind an organ which is more liable to be the cause of subsequent and less favorable attacks, but also exposes the patient to the risk of an undiscovered secondary collection which in my experience is a frequent cause of death.

Before a body of operators, comprising the members of this Association, it would be presumptuous for me to draw a comparison between operation in the absence of, and in the presence of, pus. I may, however, bring to your attention some complications of pus-formation which I have observed. The presence of pus increases the danger of lymphatic infection. This is also true of infection through the portal system (pyelophlebitis) resulting in miliary abscess of the liver, and consequent death. The complications which may arise from an undisturbed localized appendic abscess are its rupture into the bladder, thus occasioning an enterovesical fistula; rupture into a bronchus and evacuation by way of the mouth; rupture into the ascending colon, rectum or vagina, which is not to be considered a favorable termination and does not preclude the possibility of a recurrence of the inflammation; rupture into the ureter with evacuation of pus through the bladder. A complication which is not an uncommon sequence of the formation of a localized abscess is intestinal obstruction due to adhesions which have been formed in the process of localization. Again, secondary obstruction may follow the evacuation of an abscess, due to the subsequent contraction of its walls.

¹ Read by title at the Tenth Annual Meeting of the American Association of Obstetricians and Gynecologists, Niagara Falls, New York, August 17-20, 1897.

A septic phlebitis (phlegmasia alba dolens) is not an uncommon sequence of localized abscess formation. A condition of affairs which may arise as the result of a small collection which has remained undisturbed is a cheesy degeneration of the abscess wall, involving contiguous structures in the process. When the gut has been thus included an attempt to remove the degenerated mass will frequently bring to light a perforation of the bowel, often so large as to necessitate excision, enterorrhaphy, or anastomosis. In operating for appendicitis the multiplication of the difficulties induced by pus-formation must prepare the surgeon to meet and handle any of the complications of abdominal surgery.

To recapitulate: the large mortality in appendicitis, as I have previously stated, is the result of too conservative measures in the early stage of the disease. Surgeons whose experience in the treatment of appendicitis has been large, I am sure will to a man agree with me in this statement. To be brief, I have yet to see a human life lost when in an acute attack of appendicitis the appendix has been removed within six to eight hours after the onset of the disease, while on the other hand, I regret to say that I have seen many lives lost by adopting the so-called conservative methods, namely, opium to relieve the pain, allowing the bowels to remain confined, leeches, fly-blisters, turpentine stupes, any or all of which are not only useless but harmful. I cannot impress this fact too strongly as I have seen five deaths from appendicitis in as many days, in all of which cases I am morally certain that had the appendix been removed immediately after the onset of the first pain all the patients would have recovered.

The question naturally arises, Who is largely responsible for this high mortality? Is it our teachers? Personally, I feel that it is their fault. What is the alternative? I would suggest that our professors in the different teaching institutions should witness a number of operations performed early, and I know there no longer would be the list of skeptics there is now. This, too, would be a healthful diet for the so-called surgical critic who writes articles condemning too frequent operation. The last-mentioned class is evidently wanting in experience; otherwise they could not but entertain different views.

The conditions in women which call for careful thought in differentiating between one or other of the diseases of the uterine adnexa and acute or chronic appendicitis, are the following:

1. *Acute Salpingitis*.—There frequently is a close relationship between acute catarrhal appendicitis and right-sided acute salpingitis, and the symptoms may closely resemble one another. The great points of difference, however, are the history of infection, the

slight degrees of abdominal tenderness and rigidity, the location of the pain, and the absence of vomiting, and in the case of appendicitis the pain migrating from the epigastric or peri-umbilical region to the right iliac fossa, the decided tenderness and rigidity of the lower right quadrant of the abdominal wall, suddenness of attack, accompanied by vomiting, no history of infection, and the absence of signs by vaginal examination and the pressure of a palpably enlarged appendix.

2. *Pyosalpinx and Ovarian Abscess*.—The presence in the recto-uterine cul-de-sac of an inflammatory mass in intimate relation with the uterus, which renders it partially or completely immovable, and which may be clearly outlined by vaginal, bimanual, or combined vaginal and rectal examination, together with the history of a vagino-uterine infection, and the presence of septic fever, establish the diagnosis of pyosalpinx or ovarian abscess. The essential points in the differentiation between these two affections and appendicitis are the suddenness of onset in the latter, accompanied by vomiting, and the characteristic rigidity and tenderness following general abdominal pain.

Inflammation of the right ovary may be confounded with appendicitis, as it is attended by pain, tenderness in the right iliac fossa, nausea, and fever. It is, however, always accompanied by disturbances of the uterine function, is accompanied by the characteristic ovarian pain, and is demonstrable by vaginal or bimanual examination. The tenderness is never so intense on superficial palpation as in appendicitis and is not accompanied by a perceptibly enlarged appendix.

3. *Extra-uterine Pregnancy*.—The history in these cases is usually that of partial or complete cessation of the menstrual flow for one, two, or more periods, generally accompanied by other symptoms of pregnancy, with collapse supervening upon an attack of acute abdominal pain. The pain is long-continued and paroxysmal, but not colicky. An irregular, bloody, vaginal discharge, generally lighter in color than the normal menstrual flow, and containing shreds of tissue, portions of the decidua, etc., is present. Vaginal examination will detect a tender and sensitive mass in the posterior cul-de-sac, unless the pregnancy be an abdominal one. In the majority of these cases there is a history of sterility for five or six years previous to the abnormal conception.

When the product of conception occupies the fimbriated extremity of the right tube, the points of differentiation are more difficult, owing to the close proximity of the lesion to the appendix, and to the negative result of examination *per vaginam* prior to rupture. Should the two conditions occur coinci-

dently it will be well nigh impossible to differentiate between them. The chief points to be borne in mind, however, if such is not the case, are the history and the absence of inflammatory symptoms prior to the rupture of the extra-uterine sac and the presence of inflammatory symptoms in appendicitis.

4. *Suppurating Ovarian Cyst.*—An appendic abscess and a small suppurating ovarian cyst on the right side present some symptoms in common which may give rise to difficulties in diagnosis. These symptoms are: Painful tumor in the right iliac fossa, which may be made out by vaginal, bimanual, rectal, and external examination; symptoms of septicemia; hectic temperature, and history of previous gastric and urinary irritation. The differences, however, are marked and may be distinguished by careful consideration. In ovarian cyst the onset is gradual and a history of infection may generally be elicited. The pain is constant and of a dull character; by pressure the significant "ovarian pain" may be produced, differing from the colicky and paroxysmal pain of appendicitis. The rigidity of the abdominal wall is not so marked as in appendicitis, while the tumor itself is more elastic, apparently having thinner walls and a more regular outline.

5. *Ovarian Cyst with Twisted Pedicle.*—An ovarian cyst with a twisted pedicle, gives, as a rule, a history of a slowly growing tumor, which is so frequently unaccompanied by pain that its presence has been unsuspected until the accident occurs. The onset of the acute symptoms of a cyst with a twisted pedicle is sudden and is usually caused by excessive peristalsis of the intestines or by sudden changes of the position of the body, causing the tumor to revolve. If the twisting be complete enough to shut off the circulation, the walls of the cyst will rapidly become gangrenous and the patient profoundly septic, with localized peritonitis soon becoming general. Here, again, is seen a resemblance to an attack of appendicitis with abscess formation, but the difference in shape, elasticity, the slow growth, if noted, preceding the sudden onset, the difference in the character of the pain and tenderness, and the lessened degree of rigidity should enable one of experience to distinguish between the two. If, however, for any reason it is impossible to make a differential diagnosis, I would advise the lateral incision as the one to be chosen, because appendicitis is so much more common an affection that the chances are in favor of its being the latter. If it is an ovarian cyst the lateral opening may be closed and a median incision made for its removal. The median incision for appendicitis is illogical, unwise, and in many instances will present anatomic impossibilities. Where the appendix lies behind the

cecum and observes one of the northerly directions, if adherent, it will present difficulties in the removal through the ordinary incision. It is, therefore, plain to be seen how much more difficult it would be to attempt its removal through a median opening. These difficulties are greatly enhanced when there is pus formation, and, further, the danger of peritoneal infection is greatly multiplied.

6. *Fibroid Tumor.*—Appendicitis has been confounded with a local inflammation of a portion of the broad ligament overlying an intraligamentous fibroid tumor. The main points in the differential diagnosis are the history of metrorrhagia, the presence of a growth detected upon vaginal examination, tenderness and pain, which is elicited upon abdominal palpation and is confined to the part of the wall overlying the mass.

7. *A varicose condition of the veins of the broad ligament* may simulate chronic appendicitis. A differential diagnosis should be easy to make, however, because there is an absence of inflammatory symptoms, and a characteristic dull aching pain, with nausea, which disappears when the veins are emptied, as the patient assumes the recumbent position. Again, in chronic appendicitis there is a history of one or more acute attacks, with a palpably enlarged organ and the symptoms of chronic inflammation.

8. *Painful Menstruation.*—A condition which may be misleading in the differentiation of appendicitis, is the sudden onset of pain occurring in young unmarried women of a neurotic temperament at the ushering in of the menstrual period. The onset is sudden, the pain is paroxysmal, and is accompanied by nausea. There may be more or less rigidity of the lower abdominal walls, which is most frequently bilateral. The presence and the degree of the rigidity of the abdominal walls depend upon the amount of congestion of the ovaries, and whether one or both are involved. The pain, at first paroxysmal, is most severe during the first day of the menstrual flow. After this it may become continuous, and, in some instances, last during the entire period. The tenderness and rigidity corresponds to the amount of ovarian congestion. If both ovaries are involved the tenderness will be bilateral. The pain at the onset differs, however, from that of appendicitis, being non-inflammatory and localized from the beginning, while in appendicitis there is general abdominal pain, which later becomes localized in the right iliac fossa, while marked intestinal symptoms are present.

Some women, during the climacteric, occasionally complain of symptoms resembling appendicitis. They suffer from localized pain in the right side, gastric and intestinal disturbances, and irregular

temperature. As absence of the menstrual flow often exists, some difficulty may be experienced in reaching a correct diagnosis, particularly in those cases associated with obesity. A correct diagnosis as to the condition present may be established by careful inquiry into the previous history and by local examination; the latter means will demonstrate the absence of rigidity of the abdominal walls and no palpable enlargement of the appendix. The flushes, back-aches, and mental symptoms incident to the menopause will clear up the diagnosis. The mere mention, however, of the nervous affection, with its ubiquitous symptoms, will suffice.

I recently met with a unique case which presented a typical history of acute appendicitis, followed by abscess formation. At operation the appendix was found in relation with the right ovary, to which it was bound by strong adhesions. The ovary was the seat of an abscess which had evidently been infected by the perforated appendix.

Appendicitis and Pregnancy.—Pregnancy complicating appendicitis forms one of the most serious conditions which may come under the consideration of the surgeon. Ordinarily, appendicitis involves the risk of life. Under this condition, however, the lives of both mother and child must be taken into consideration. It is claimed by some obstetricians that this (appendicitis) is an infrequent occurrence as a complication of pregnancy. While this may be the case, it is of such great importance that I believe, from its rarity, it should receive even more earnest consideration on account of the disastrous results which are likely to follow the formation of an abscess of appendic origin at any period near the completion of the term of gestation. When we consider that the gravid uterus occupies the abdomen to a large extent, and that there is a likelihood of the uterus forming a portion of the abscess-wall, involving the risk of miscarriage and subsequent shrinking in the size of the uterus, and the consequent likelihood of adhesions being torn and the escape of the contents of the abscess into the general peritoneal cavity, it is easy to imagine the risk in allowing such a condition of affairs to occur. In addition to the likelihood of breaking up adhesions following the emptying of the uterine cavity, there is equal danger of peritoneal infection. If the adhesions have become organized so that, owing to fixation, contraction of the uterus fails to occur after miscarriage, *post-partum* hemorrhage may result, the arrest of which would be attended by unusual difficulties.

Women who present the history of previous attacks of appendicitis and complain of local pains and distress in the right iliac fossa, with all the symptoms

of chronic appendicitis conjointly with pregnancy, should, in my opinion, be relieved of a chronically diseased appendix in order to avoid the likelihood of suffering from a condition of affairs as above outlined. Although in many cases the condition may not go on to the formation of pus, still the great uncertainty which hangs over chronic disease of the appendix, and the indefiniteness as to the ultimate outcome, when complicated by pregnancy, make it imperative that we should not be too conservative, and thus endanger the life of the patient.

A question may arise as to the differential diagnosis between peritonitis from a perforated appendix or ruptured appendic abscess and peritonitis resulting from endometritis following abortion, miscarriage, or labor at full term. The principal points of differentiation are the history of sudden onset, accompanied by nausea or vomiting, and pain, rigidity, and tenderness in the case of appendicitis, while in the latter there is a history of uterine infection prior to the inflammatory invasion of the peritoneal cavity, as well as an absence, early in the history of the case, of localized rigidity and tenderness, which is diffuse in purulent peritonitis.

The rupture of the appendic abscess or perforation of the appendix may be followed by a temporary cessation of the more pronounced subjective symptoms previous to general septic peritoneal infection. This may be accompanied by shock. In puerperal peritonitis the symptoms appear slowly and are progressive and without amelioration.

The symptoms of appendicitis complicating pregnancy are those common to uncomplicated appendicitis, although there may be vomiting throughout the entire period of gestation, not associated with evidences of an inflammatory condition. What is true of appendicitis in general is also true when it is associated with pregnancy. The likelihood of referred pain, not necessarily confined to the region of the right iliac fossa, is also true when complicated by pregnancy. The diagnosis is rendered more difficult when pregnancy is advanced and the abdomen is filled with the uterus and its contents. The ability to elicit rigidity of the recti muscles is marked on this account, although tenderness will be more pronounced when pus is present. The cases reported of appendicitis complicating pregnancy I believe, without exception have presented a history of previous attacks of inflammation of the organ in question.

Appendicitis, associated with or complicating pregnancy during the early months of gestation, is not as serious by far as when it occurs later. The danger of involvement of the uterine wall, as a part of the abscess wall, when such is present, is in distinct relation with the elevation of the uterus from

the pelvis. The danger of miscarriage increases also as pregnancy advances for the same reason. Changes occur in the placenta when the uterine muscle is included as a part of the abscess wall, especially if the placental attachment corresponds with that portion of the uterine wall forming a portion of the abscess wall. It has been conclusively shown in several instances that degeneration of the placenta has followed abscess formation. In one case the placenta had undergone partial calcareous change, and miscarriage followed the evacuation of the abscess. The calcification was noted after the expulsion of the after-birth.

There may be some doubt created in these cases from the fact that the patient has had disturbance of digestion, with nausea, and vomiting. This condition, however, should not be confounded with nausea and vomiting at the first onset of appendicitis, as this is associated with evidence of inflammation. A primary acute attack of appendicitis in a pregnant woman might be mistaken for an approaching miscarriage. In the latter instance, however, the symptoms are not ushered in by severe abdominal pain, and as a rule there is no nausea attending the onset of local pain.

Acute appendicitis complicating the later months of pregnancy is a far more dangerous condition to deal with. The appendix, if holding any of the southerly or easterly directions, is bound to be in relation with the uterus, and if pus be present the uterus is readily included in the mass of lymph thrown out to wall off the forming pus. Here lies the danger in appendicitis if it is allowed to go on to pus formation. If the appendix is removed before pus is formed, there is a decreased likelihood of miscarriage, and a lessened possibility of peritoneal involvement, adhesions, and peritonitis.

A serious question arises after pus has formed and the uterus is included as a part of the inner wall of the abscess cavity. We must face two important considerations: first, the likelihood of infecting the peritoneum primarily, and second, whether it is proper at the time of evacuating the abscess cavity to induce a miscarriage, or to allow Nature to take its course, and run the chance of avoiding an abortion. If we choose the former alternative and evacuate the uterus, after emptying the abscess cavity it would seem as if the surgeon would be in a position to control the possible infection of the peritoneum by the tearing loose of the adhesions to the uterine wall following the contraction of this organ, and by a proper disposition of gauze prevent infection of the cavity. If we are to choose the other alternative and leave the fetus *in utero*, then there exists a double menace to the future welfare of the patient—a probable infection of the peritoneum, a possible miscar-

riage, or the likelihood of carrying a dead child, with the attending risk of uterine infection, and the danger of septic endometritis, and peritonitis.

The salient points which I particularly wish to bring to your attention I will summarize in the closing paragraph of this paper:

The many difficulties of diagnosis between disease of the uterine adnexa, pregnancy, and appendicitis, and the probability of their co-existence in the same case, bring us face to face with the general rule that "he who opens an abdominal cavity must be prepared to meet any or all the complications which may arise in this most complex portion of the human anatomy." The first and most important point is the necessity for an early diagnosis, because the good results of an operation for appendicitis depend upon the time of operation. The danger increases in direct ratio with the progress of an attack. In women who are liable to become pregnant and who have had an attack, or attacks of appendicitis, the appendix should be taken out in order that the dangerous complication of pregnancy and appendicitis may be avoided. This is particularly true if an attack of appendicitis supervenes upon pregnancy. The latter condition does not contra-indicate operation under the circumstances, but rather, on the other hand, makes operation more imperative. Another point is one based upon a rich personal experience, covering both operative and non-operative cases. It is that the number of patients with appendicitis who become perfectly well, patients who do not suffer during the interval between attacks, and who are not subject to the certainty of future attacks, are so extremely rare that the question of curative treatment resolves itself *into the time of operation*.

THE DIAGNOSIS OF PRIMARY SARCOMA OF THE PLEURA FROM THE CELLS FOUND IN THE PLEURITIC EXUDATE.

By ALDRED SCOTT WARTHIN, M.D.,
OF ANN ARBOR, MICH.;

INSTRUCTOR IN PATHOLOGY IN THE UNIVERSITY OF MICHIGAN.

THE microscopic examination of the sediment of pleural and peritoneal effusions for the purpose of establishing the diagnosis of new growths of these membranes before a clinical diagnosis can be determined is a diagnostic measure but rarely instituted, if the scantiness of the literature upon the subject is to be taken as an index. Much has been done with the chemistry of these fluids, but few careful investigations have been reported of the cellular constituents in those cases in which malignant tumors of the pleura or peritoneum were present.

Such examinations have been much more frequently made of the urine, sputum, stomach-contents, feces,

and vaginal discharges in the hope of establishing at the bedside the diagnosis of new growth, and not a few cases have been reported in which a correct diagnosis was made from the presence of tumor-cells or tumor-tissue in these excretions and secretions. Though in these days, when exploratory aspiration of almost every case of pleural or peritoneal effusion is made as a matter of course, and when the centrifugating-machine is so frequently utilized in the examination of the sediment, few cases of malignant growth diagnosed in this way have been reported. This seems strange when one considers the large number of cases of ascites due to peritoneal metastases in ovarian and gastric carcinoma, and the frequent cases of pleuritic effusion due to secondary carcinoma of the pleura following primary tumors of the mammary gland, etc.

It is evident that the possibility of diagnosing new growths from the microscopic examination of effusions before a successful clinical diagnosis can be made would be a very important advance. The question then stands, To what extent is it possible, from the examination of the cellular elements of effusions, to establish the diagnosis of new growth of pleura or peritoneum?

The usual examination of the sediment of these fluids is confined to the direct microscopic examination of the fresh specimen, or to the examination of stained preparations for bacteria. In the majority of cases the search is limited to leucocytes and red blood-cells; and more emphasis is laid upon these than upon the character of other cells which may happen to be present. In addition to the blood-corpuscles, note is also made of endothelial cells, fat drops, fatty acid crystals, Charcot-Leyden crystals, cholesterol, pigment, fibrin threads, micro-organisms, and foreign material.

The presence of large numbers of large polymorphous cells, having numerous vacuoles or containing fat droplets, has led to the assumption in many cases that these cells were carcinoma cells, but from the fact that the endothelial cells in effusions exhibit such diversity of size and shape, and show also a similar degree of vacuolation and fatty degeneration, some investigators have declared it impossible to diagnose with certainty the existence of a new growth unless bits of tissue showing definite structure can be found.

Quincke¹ endeavored to establish the principle that carcinoma cells can be distinguished from endothelial cells by their size, their number, their grouping into masses, and perhaps by their glycogen reaction. Later Rieder,² after a careful study of carcinoma cells

in peritoneal and pleuritic fluids, concluded that the most important differential point between them and endothelial cells is in the large number of mitoses, especially asymmetrical division forms, which are found in the cells of tumors and not at all, or to a very slight degree in endothelial cells. The finding of many cells showing division figures he believed to speak conclusively for malignant growth. Neelsen, quoted by Rieder in the same article, diagnosed carcinoma of the kidney from bits of tissue discharged in the urine, and which contained cells showing many asymmetrical mitoses.

Since Rieder's article, I have not been able to find any work bearing upon this point. The tumors which have been diagnosed by a microscopic examination of cells found in effusions have been in all cases carcinoma, or, as in Rieder's case, atypical growths (*sarcoma carcinomatosum*), probably a mixed tumor arising from an ovarian teratoma. I have not been able to find any statement of a typical sarcoma of the peritoneal or pleural cavity, diagnosed from the cells found in the effusion, but I have not been fortunate enough to secure all of the literature on primary endothelioma of the pleura, so that my search must be looked upon as incomplete. The evident rarity of such cases makes the report of the one which came under my observation some time ago very important because of its bearing upon the question of diagnosis. As far as I know, it is the only case in which sarcoma of the pleura has been correctly diagnosed by an examination of the pleuritic exudate.

I am not at liberty to give the full clinical history of the case, my connection with it being limited to the examination of the effusion and the material obtained at the autopsy. The most important facts are as follows:

X., a German, male, about forty-five years of age, gave an indefinite history of dyspnea, pain in the right side of the thorax, cough, and progressive weakness. He also had irregular fever. The exact duration of these symptoms could not be ascertained because of the clouded mental condition of the patient when first seen.

The physical examination showed increased fulness of the right side of the thorax, with entire absence of movement. There was slight bulging in the fourth and fifth intercostal spaces between the nipple and sternal lines on the right side. There was a weak apex-beat in the left anterior axillary line in the fifth interspace. Vocal fremitus was absent over the right side. There was no friction fremitus. On percussion, dullness was found below the fourth rib on the right, rising to the level of the second rib when in a sitting position. Above this, there was dull tympanitic resonance. Over the area of dullness there was no breath-sounds and no adventitious sounds. Above the second rib there were faint blowing breath

¹ *Deutsch. Archiv. f. Klin. Med.*, vol. xxx.

² *Ibid.*, vol. liv.

sounds. The voice-sounds were only faintly transmitted above the second rib.

A diagnosis of pleurisy with effusion was made, the patient was aspirated, and the fluid sent to the pathologic laboratory for examination.

Pleuritic Exudate.—The fluid was brownish-red in color, with many yellowish or grayish flakes which settled quickly after agitation. The fluid was thick, but the amount obtained was not sufficient for the estimation of its specific gravity. On standing, fibrin was formed. The fluid coagulated solidly on boiling. The fresh sediment was examined, numerous stains and reagents being applied. Cover-glass preparations were made and a portion of the sediment was hardened for future examination.

The examination of the sediment, stained by allowing a drop of dilute methylene-blue solution to run under the cover-glass, showed the field to be full of spindle-cells of about the same shape and size, mostly single, but lying also in groups. There were numerous red blood-cells, leucocytes (mostly lymphocytes), fibrin threads, blood-pigment, and an abundance of fine granules, supposed to be cell *débris*. The leucocytes were not present in such numbers as to admit of the fluid being called purulent. Endothelial cells were present in only a very small number. They showed various degrees of vacuolation.

From the great number of spindle-cells present, the diagnosis of small spindle-cell sarcoma was made. The diagnostic points considered were the number of the cells and their character. The one alternative set against this diagnosis was a pleuritic effusion containing large numbers of fibroblasts, but the regular size and shape of the cells were opposed to this view.

The patient gradually became worse. A rapidly progressing anemia and weakness, with constant delirium, were the most marked symptoms up to the time of death. The bulging on the right side between the nipple and sternal lines became more prominent before death.

The *post-mortem* examination was held four hours after death. The subject was very anemic and much emaciated. The pathologic conditions were confined to the thorax. The right half of the thoracic cavity was filled with a thick brownish-red effusion containing many large flakes and stringy masses. To these, blood-clots were attached. There were also large blood-clots floating in the fluid. The entire surface of the mediastinal pleura and of the anterior parietal pleura as far as the anterior axillary line was covered by a velvety growth; in some places the surface of the growth was covered by long strings of fibrin and blood-clot, firmly adherent to the tumor mass. In many areas the tumor itself consisted of

long strings extending out into the pleuritic cavity. The greatest thickness of the growth (about three inches) was at the level of the fourth and fifth intercostal spaces between the right nipple and sternal lines, corresponding to the area of prominence in the chest-wall. The right lung was completely atelectatic; the visceral pleural was covered with fibrin, but there were no evidences of a new growth. The heart was pushed to the left, the right edge being at the left sternal line. The left lung and pleura were normal, as were also the pericardium and heart. No metastases were found.

Tumor.—The tumor was mottled red and grayish-white. It was so soft that it could easily be crumbled between the fingers, and so fragile that it could hardly be cut without falling to pieces. The surface was uniform, homogeneous, without stroma, but rich in large blood-vessels, having very thin walls. There were numerous hemorrhagic areas, also areas of necrosis, grayish-yellow in color. In the stringy areas, the blood-vessels were surrounded by the grayish-white tissue of the tumor, giving to the naked eye the appearance of a perivascular growth.

Scrapings were made from the freshly cut surface of the tumor, and it was found to consist of medium-sized spindle-cells like those found in the effusion. The fluid obtained from the thoracic cavity was very rich in the same cells, so rich that it was not necessary to collect the sediment for examination. The specific gravity of the fluid was not taken.

Pieces of the tumor were hardened in alcohol and Müller's fluid. Sections were prepared from these, and the growth was found to consist of spindle-cells grouped about the large but thin-walled blood-vessels. Only a single layer of endothelium separated the blood from the cells. That the tumor-cells arose from the endothelium there can be no doubt; they were crowded more closely just around the endothelium, and here the nuclei stained more deeply than those away from the vessels. In specimens hardened in alcohol, dividing endothelial cells were seen, and in some cases the cells grew into the lumen, forming buds on the inner wall of the vessels. In other cases, free masses of cells were found in the vessels. In the stringy areas covering the surface of the growth, all stages of development of the tumor tissue could be found, from the small capillary growing out into the fibrin with only a single layer of endothelium forming its walls and with no tumor tissue about it, up to the large blood-vessel surrounded by a large cylindric mass of cells. Throughout the tumor the structure was essentially perivascular, so that the tumor consisted of cellular cylinders surrounding the blood-vessels. Mitoses were abundant throughout; for the most part they were symmetrical.

From its histologic structure the tumor should be styled a spindle-celled hemangiosarcoma; from its origin it should be classed with the endotheliomata.

The hardened cover-glass preparations of the sediment were not examined thoroughly until some time afterward. These were stained in hemalum and examined with an oil-immersion lens. The finer structure of the cells was then carefully studied. The cells were spindle-shaped with rather long and slender polar processes which did not branch as is commonly the case with the spindle-cells found in inflammatory exudates. The nucleus stained rather heavily; was oval, as a rule, but in many cells was slightly curved. The chromatin was very abundant, but had a very simple structure. Numerous mitoses were found, but in all cases they were regular and symmetrical. They showed all stages of development.

As a rule, the cells were found singly, but groups were very common. They did not contain vacuoles, neither was any vacuolation of the nucleus observed. The rather abundant protoplasm was finely granular. The epithelioid appearance of the nucleus so common to fibroblasts was not seen. Numerous necrotic cells were found, the protoplasm being more coarsely granular and the nucleus staining very poorly or not at all.

The pleural endothelial cells were relatively scanty. They were very irregular in size and shape, and showed various degrees of vacuolation. They presented no characteristics differing from the same cells found in ordinary pleuritic effusions.

In Fig. 1 the character and relative proportion of the cellular elements (blood-cells excepted) of the effusion in this case are shown.

FIG. 1.

Cells from effusion in primary sarcoma of the pleura. (a) Endothelial cells, all the others are tumor-cells, some showing cell division. (One-twelfth oil-immersion lens; ocular No. 2.)

Since the examination of this case I have made a study of the cells found in the sediment of the exudate in a large number of cases of diseased conditions

of serous membranes—pleura, peritoneum, and pericardium. A description and comparison of the cells found under different conditions may be very valu-

FIG. 2.

Endothelial cells from sediment of effusion in early stage of acute serous pleurisy. (One-twelfth oil-immersion lens; ocular No. 2.)

able in itself and of aid in establishing a basis for diagnosis, if such be possible. The specimens were taken from cases in which the diagnosis was confirmed *post-mortem*; in some instances the fluid was obtained directly from the body-cavities, in others by puncture previous to death and also at the *post-mortem* examination. The cells were examined fresh, and fixed cover-glass preparations were made according to the method usually employed for the examination of blood. The cleaned cover-glasses were spread with a thin film of the sediment, allowed to dry in the air for a few minutes, and then fixed in a mixture of equal parts of absolute alcohol and ether (one to two hours in the fixing fluid is sufficient). After fixing, the covers were dried in the air and stained at convenience. Hemalum or hematoxylin was the stains used most frequently.

Acute Serous Pleurisy (Fig. 2).—The fluid was obtained in this case on the second day of the disease. It was clear, pale yellow, and contained numerous small whitish particles. These, when examined microscopically, were found to be masses of endothelial cells. From the large number of these desquamated groups of cells the pleurisy might be styled as desquamative. It is, however, the rule to find these in the very early stages of pleurisy. In these groups of cells the cell-membranes could not be made out. The cells were also found in great numbers isolated or in smaller groups of two or three.

As seen in Fig. 2, the cells were large, irregularly oval or round, and had an oval nucleus which stained less heavily than the nuclei of leucocytes or fibro-

blasts. They were for the most part vacuolated, the vacuoles being due to hydropic degeneration and not to fatty change. Some of the nuclei were also vacuolated. In many cases the vacuole occupied the entire cell, with the exception of the nucleus. In some cases the nuclei were partially extruded from the cell. Though the polymorphic character of the cells was very striking, no spindle forms were found in the early stage of simple pleurisy, though in the later stages they become abundant. No mitotic forms were observed.

Acute Fibrinous Pleurisy (Fig. 3).—The effusion of both early and late stages of fibrinous pleurisy was examined. In all cases the fluid was cloudy, light yellow, and contained numerous flakes and strings of fibrin. The pleuræ were covered by a thick layer of stringy fibrin. In both early and late

FIG. 3.

Cells from the sediment of acute fibrinous pleurisy, third week. Endothelial cells and various forms of fibroblasts. (One-twelfth oil-immersion lens; ocular No. 2.)

stages the sediment contained vacuolated endothelial cells and numerous irregular spindle-cells, having in many cases finely branched polar processes. These cells had nuclei which stained more deeply than the endothelial cells, but in some cases they were epithelioid in character. Some of the nuclei of these irregular cells were vacuolated. In the early stage the endothelial cells predominated, but in the older cases of fibrinous pleurisy the spindle forms were much more numerous. They are to be looked upon, I think without doubt, as fibroblasts. No mitoses were found in these cells.

Tuberculous Pleurisy.—The exudate was obtained *post-mortem*. It was fibrinous, and similar in character to that found in simple fibrinous pleurisy. The sediment of the fluid differed in no respect from that

shown in Fig. 3, being made up of endothelial cells and fibroblasts. No mitoses were found.

Acute Fibrinous Pericarditis (Fig. 4).—The case examined was seen *post-mortem*, death having oc-

FIG. 4.

Cells, probably fibroblasts wholly, from the sediment of pericardial fluid in the third week of acute fibrinous pericarditis. (One-twelfth oil-immersion lens; ocular No. 2.)

curred during the third week. Both layers of the pericardium were covered by a thick layer of fibrin; in many places there were fresh adhesions which were easily separated by the fingers. There was a small quantity of thick grayish fluid between the

FIG. 5.

Cells from scraping of normal pleura. Endothelial cells, with a few connective-tissue cells from basement structure. (One-twelfth oil-immersion lens; ocular No. 2.)

layers. On examination, no endothelial cells were found in this fluid, but numerous fibroblastic forms. These were much more branching than the cells

found in the pleuritic exudates. No mitoses were found.

Scraping from Normal Pleura (Fig. 5).—For the sake of comparison, the cells obtained by scrapings from normal pleuræ were also studied. The surface of the membrane was gently scraped with the edge of a sharp knife so as not to loosen the cells of the basement structure. As seen in Fig. 5, the cells obtained in this manner are almost wholly characteristic polymorphic endothelial cells; the few spindle-cells found were doubtless from the basement connective tissue.

After a study of the sediment of many cases of effusion into peritoneal, pleural, and pericardial cavities, the following points seem to me to be worthy of emphasis:

1. In all cases of this kind, when fluid can be obtained by exploratory puncture, cover-glass preparations should be made by fixing in absolute alcohol and ether as described above. This should be done immediately after the withdrawal of the fluid from the body in order that the mitoses may be preserved.

2. In early stages of simple pleurisy the sediment contains endothelial cells and no fibroblasts. The endothelial cells may be desquamated in large pieces.

3. In fibrinous pleurisy, tuberculous or septic, the sediment contains, in addition to endothelial cells, numerous fibroblastic forms. In later stages, when adhesions are forming, the endothelial cells may be entirely absent, and only fibroblasts be found.

4. In the diagnosis of sarcoma of serous cavities, the character and number of the cells and the presence of numerous mitoses are the points upon which the diagnosis must be based. It is, of course, evident that the quickly growing and soft forms of sarcomata are the ones most apt to lead to the presence of cells in the fluid. The tendency of all sarcomata to break down after reaching a certain growth makes it extremely likely that in most cases free cells will be found. The diagnosis of spindle-celled sarcoma is easy, from the occurrence of large numbers of spindle-cells of similar size and shape, showing fewer branching processes than fibroblasts, and containing more mitoses. In the round-cell forms, the tumor cells are to be distinguished from the endothelial cells by their size, character of nucleus, and the relation of the nucleus to the protoplasm. The presence of mitotic forms will again be the most important point; in the small round-cell sarcoma, these are not so easily seen. The greatest difficulty will be in the differentiation of the cells of a polymorphous-celled sarcoma from the fibroblastic forms found in fibrinous exudates. Aside from the general character of cell and nucleus, the presence of division forms must in

all cases be looked upon as being the most important point.

In conclusion, therefore, the presence of numerous cell-division forms in the cells of the sediment of serous exudates may be taken as strong (perhaps conclusive) evidence that the effusion is due to the presence of a new growth, inasmuch as mitoses are but rarely found in the cells of purely inflammatory exudates.

CERTAIN SOURCES OF NEUROSES IN WOMEN.¹

BY EGBERT H. GRANDIN, M.D.,
OF NEW YORK.

THERE are few studies in medicine more interesting than that of the neuroses. It appears to me that I cannot do better than consider, from a clinical standpoint, certain forms of disease subsequent to which neuroses occur in women, tracing possibly obvious and yet frequently overlooked sources of their manifestation. The term neuroses is vague, and means in reality that the user is uncertain as to what he desires to express. It too often is a mere cloak for ignorance, and yet I trust to prove to you that at times this is the result of either faulty examination, or of the fact that the sufferer has consulted a specialist who is not broad enough to look beyond the organs which it is his custom to observe, forgetful of the truism that rarely is one organ of the body diseased without reflex manifestations, and inversely that symptoms pointing to one organ in reality may emanate from another. With this brief preface, I will endeavor to exemplify the subject by relating, with comment, instances of neuroses which have passed under my observation.

CASE I.—A few years ago a gentleman brought his wife to me, and stated, that, although he had been married for a number of months, sexual commerce with his wife had been impossible. Intromission was accomplished, but beyond this such intense pain was evoked that he was obliged to desist. The woman was intensely neurotic, complaining of pain in almost every portion of the body. The pelvic organs were normal; ovarian prolapse, which I had expected to find, did not exist. Had the examination ended here I would have been obliged to confess inability to relieve a condition which was causing much marital infelicity. It has been my custom, however, never to stop short after examination of the uterus and its appendages. It was not necessary to seek beyond the vesical neck, for here I found a fissure, evidently the cause of the trouble. Dilatation and the application of phenic acid completed the cure.

Even, as in man pain at the tip of the penis is a frequent symptom of bladder disease, so will the

¹ Read before the Medical Society of the County of New York, September 27, 1897. Discussion on page 510.

practitioner find, on careful sifting of the symptom-complex presented by his female patients, that signs apparently referable to the pelvic organs will find explanation in fissure of the vesical sphincter.

It is probably unnecessary at this day to refer to the manifold neurotic symptoms which may emanate from preputial adhesions of the penis and clitoris. I have elsewhere recorded some interesting examples of the effects of this condition, and I desire here simply to call renewed attention to the fact, that insignificant as the clitoris appears, it exercises a vast influence upon the organism. It is my routine practice never to consider an examination complete unless the condition of this organ has been investigated, and further still, it is the exception rather than the rule not to find adhesions concealing a greater or less collection of smegma, and, of course, acting as a constant irritant. Many an instance of masturbation, nymphomania, and of bedwetting will find explanation in this condition. I have elsewhere entered a plea for the careful routine examination of the clitoris shortly after birth, feeling assured, that if adhesions are found and relieved, neurotic and pseudo-epileptic children will diminish in number.

An instance of the effect of clitoridal adhesions in the causation of reflex symptoms is the following:

CASE II.—A lady, aged 35 years, consulted me for the relief of an intolerable pruritus of the vagina. Urinary examination negative; endometritis did not exist, and yet, she was driven almost to distraction, having employed nearly every remedy without avail. The prepuce of the clitoris was found to be firmly adherent, and underneath its base was a collection of acrid smegma. Thorough separation of the adhesions effected a cure.

In this instance a good result would long before have been obtained had I not overlooked the clitoris. This is the case, seen many years since, which taught me the lesson that this organ is worthy of the most careful scrutiny.

I am inclined to think that the rôle of a diseased sphincter ani muscle in the production of neuroses in women is not fully appreciated. I am satisfied that many reflex symptoms may be explained by ulceration just at the sphincter. Recalling the anatomy of the parts, in particular the manner in which the fibers of this muscle inosculate, it is at once clear why irritation at one point may give rise to symptoms suggestive of disease at another. In the course of time constant irritation of the sphincter ani may cause congestion of the uterus of such a degree, that the hasty diagnostician may conclude that possibly curetting, or even extirpation of the appendages may be necessary for a cure of the aggravated symptomatology. All the more reason, then, why the examina-

tion of women should never be deemed complete unless the anus and rectum have been explored as well as the pelvic organs proper. The symptoms referable to the uterus, tubes or ovaries, as the result of long-continued irritation, may be so pronounced as to mislead both patient and examiner, and still, as has happened to me and, I presume, to others, the causal factor of the symptomatology lies not in the uterus, tubes or ovaries, but in the rectum.

Of a number of cases, the essentials of the following have been selected to illustrate the point:

CASE III.—An intensely neurotic woman consulted me after two years of married life for the relief of the following symptoms: Intense dysmenorrhea; dyspareunia of such an aggravated type that the sexual act had never been performed, and ovarian pain, chiefly on the left side. The spasm of the hymen was so intense that I was unable to make a vaginal examination without anesthesia, but upon the employment of an anesthetic it disappeared. The uterus and adnexa were normal as far as could be determined. Inspection of the rectum revealed a deep ulcer at the sphincter. Dilation of the sphincter, incision and cauterization of the ulcer relieved the symptoms within two weeks. The patient has continued well, and to-day is the mother of two children.

If, in this case, the anal examination had been omitted, I would doubtless have been tempted to thoroughly dilate and curette the uterus, and, notwithstanding, would have failed to give relief. This is simply an example of many cases which I have observed, and together they justify an earnest plea for a careful rectal examination before the diagnosis is considered complete.

Attention is next invited to the coccyx—relatively a frequent source of neuroses. This bone is peculiarly susceptible to injury in women; should conception occur at an age past twenty-five, and should the child be proportionately large or the pelvis small, or should instrumental delivery be necessary, it is likely that the coccyx will be injured. It may be possible to secure a history of a fall on the end of the spine. Neither a fall nor childbirth may cause actual disease, but fracture of the bone, even though caries does not result, quite frequently gives rise to almost constant pressure on the nerve filaments it contains, and hence the occurrence of obscure reflex symptoms. Remembering the anatomic distribution of the sphincter ani muscle, it is apparent how irritation of the coccyx is readily reflected to the anus and vulva. Investigation of my records reveals seven cases in which I have removed the coccyx, either because of the presence of actual disease, or because fracture apparently accounted for reflex nervous phenomena not otherwise to be understood. In

not one instance have I been disappointed in the result, and further, in every case, irrespective of actual caries, neuroses were prominent in the symptomatology.

As an instance—a very marked one—the following is cited :

CASE IV.—A woman sought relief from pelvic symptoms of a vague character. She also presented prominent signs of spinal irritability, even the slightest touch causing an attack of hysteria, which she claimed was due to the spinal pain. Vaginal examination revealed nothing abnormal, and both rectum and bladder appeared healthy. During the manipulations I touched the coccyx, causing the most aggravated attack of hysteria I have ever witnessed. Inquiry elicited the fact that this bone had at one time been fractured. It was my opinion that the symptoms might depend upon an abnormal condition of the coccyx, at any rate, extirpation was worth trying in the absence of a lesion of more definite character. At the operation caries was found to exist, and the bone was embedded in a mass of adhesions. The result was magical—all the reflex symptoms promptly disappeared.

In another instance the symptoms apparently were ovarian, and in still another dyspareunia was the principal complaint. In both cases removal of the fractured or diseased coccyx was followed by cure. The lesson is that it may be necessary to investigate the condition of this bone before a satisfactory explanation of the symptomatology is discoverable. One or two points in regard to the technic of the operation for extirpation of the coccyx are offered : Drainage is unnecessary, even though many textbooks direct the contrary. Let the assistant press the bone firmly backward by means of a finger in the rectum, and the operator will have little difficulty in exposing it. After removal, if a large Hagedorn needle is employed, the sutures may be made to travel entirely around the wound, thus securing close apposition of the surfaces when the sutures are tied. The operation having been aseptic there is no reason for drainage.

The next and last source of neuroses which will be considered is the tubes and ovaries, and here, as it were, the dark continent is entered. So far, operations of a simple type have been considered. Ground is now approached where, if operation be performed for the relief of neuroses, it must be with the utmost circumspection and with a full understanding on the part of those most interested that the result is problematic, because operation is empiric. I am not speaking of operations performed in the presence of definite pathologic lesions of the tubes and ovaries. I have in mind those instances where careful examination fails to reveal disease, and yet where the symptomatology points, apparently unerringly, to

the uterus, tubes and ovaries as causal factors for which no other explanation may be found. Many and ghastly were the failures fifteen years ago when it was customary more than it is to-day to remove these organs, and yet, on the other hand, the results secured through empiric operating of this type are very brilliant. When it is considered that after all there is little information of a definite character in regard to that function which assists in differentiating woman from man—I refer to menstruation, its cause and purpose—little wonder that it is dangerous to assume that a nervous manifestation, even though aggravated, may depend upon this function. I have observed menstruation reappear with regularity of rhythm in three instances when I am positive that both tubes and ovaries had been completely removed by me, and in one a secondary abdominal section enabled me to be certain that a third ovary did not exist. Under the circumstances it seems pardonable to term menstruation the most obscure of all feminine neuroses. Paradoxically too, the cessation of this function—as at menopause—is accompanied by aggravated neurotic symptoms—hot flashes, cold sweats, melancholia with suicidal tendencies, etc. Why then, in order to cure a supposed neurosis, should we be tempted to cause menstruation to cease? unless that supreme paradox “like cures like” be accepted. Still, in my experience, as doubtless in that of every operator, empiric removal of the tubes and ovaries has at times wrought wondrous changes for the better. I will give in outline two histories bearing upon this point:

CASE V.—A woman was brought to me from a retreat for the insane, where she had been placed by a neurologist. She was about thirty years of age and the mother of two children. The symptoms were severe melancholia, erotomania, and suicidal tendency. Evidences of endometritis and pelvic peritonitis were found. The husband was informed that, while it was impossible to state definitely that the condition depended upon the findings, I would be willing to curette the uterus and remove the appendages if the moral support of a consultant could be secured. Receiving this, the operation was performed; convalescence was uneventful, and the woman has enjoyed continued good health, two years having passed since the appendages were removed. The adnexa was not markedly diseased, the lumina of the tubes being patent and the ovaries only enlarged to a degree usual in multiparæ.

CASE VI.—A young girl, aged eighteen years, during her menstrual life had been subject to attacks of hystero-epilepsy, which had not yielded to treatment. Examination revealed an infantile condition of the pelvic organs. The attacks were aggravated during the menstrual periods, and were so violent as to require anesthesia for their control. Drugs having failed, and since the attacks were usually coinci-

dent with a menstrual period, extirpation of the appendages was advised, but with a clear understanding that the operation would be empiric, and that no hope of cure could be offered. The operation occurred nearly three years ago. The attacks at once diminished, both in frequency and severity, and none have occurred during the past two years.

In this patient the tubes and ovaries were not diseased, but together with the uterus were undeveloped, and this condition may have been the causal factor in the production of hysterio-epilepsy. At any rate had we possessed any means for causing the development of infantile organs, I would have tested them before emasculating the patient.

In this connection I will give the notes of a case possessing great interest, and in which a similar operation failed :

CASE VII.—A woman past thirty years of age came to me for an opinion as to the advisability of extirpation of the adnexa for the cure of epilepsy. The appendages, though markedly enlarged, were freely movable. No data could be secured indicating augmentation of the symptoms during the menstrual periods, but a number of years previously during pregnancy, when, of course, menstruation was in abeyance, the seizures were very infrequent. Nothing was promised as regards a cure, indeed entire skepticism was expressed as to the result, but the operation was requested on the ground that everything else had been tested and that this might succeed. Convalescence was uneventful, and for a few months after the operation the attacks diminished in frequency. The patient began to have a pseudo-menstrual flux, and the seizure recurred as before the operation.

This patient did not have a third ovary, as the technic employed—ligation of the ovarian arteries in sections and removal of the entire tube—eliminated such a possibility as a factor in the production of the recurrent menstrual flux. This was, unquestionably, a case of essential epilepsy, and the result secured is the one constantly obtained after operations upon the pelvic organs for the relief of this disease.

Certain of the neuroses observed in women have been sketched, at times insignificant as regards lesion, though major as regards symptoms. Time forbids reference to the obstetric neuroses and those accompanying lesions of the cervix. Aside from laying stress on certain factors in the production of neuroses, I have entered a plea for the more careful examination of the body as a whole before attention is centered upon a special set of organs. While the wide specialization of medicine which has marked the age in which most of us have lived has redounded greatly to the advance of knowledge and the relief of suffering, it is an open question if there does not exist an overspecialization, so to speak, too many immature

specialists, with the result that often the wrong organs are treated or too many are unavailingly treated in turn. You are all aware how hard hobbies are ridden. Oftentimes the eyes, nose, tubes, and ovaries are each investigated with failure, and the case remains uncured until it reaches the man of broader mind, reared, perhaps, in an older school, who administers a dose of calomel, and cures the hitherto intractable neurosis. The deduction is, that the best specialist is he who for years has been a general practitioner.

THE ETIOLOGY AND TREATMENT OF ACUTE NEPHRITIS IN CHILDREN.

BY A. ROBERT TAFT, M.D.,

OF CHARLESTON, S. C.;

DEMONSTRATOR OF ANATOMY IN THE SOUTH CAROLINA MEDICAL COLLEGE.

AN experience covering a number of years in the treatment of diseases of children has led to a belief that the generally accepted idea of the acute infectious fevers being mainly responsible for the occurrence of acute nephritis in children is an erroneous one; that a great number of such cases do occur in which it is impossible to trace a history of acute infection. To record these instances of nephritis as "causative factor unknown," when, to my mind, it is possible to explain the cause of the disease, seems hardly a logical course.

Among the causes may be cited: (1) Improper food and hygienic environment; (2) hereditary syphilis and the inherited tendency to tuberculous disease; (3) inherited weakness of the kidneys. That improper food and hygiene play a prominent part may be assumed from the fact that such affections are much more common among the poor than among the well-to-do. Though the children of the former are more often exposed to infection, the relative number of cases of infective disease occurring in the two classes is not sufficient to account for the difference; while, on the other hand, the dietetic and hygienic conditions are woefully dissimilar. Examples of the affection under consideration are comparatively rare in the rural districts, where the food and environments are better and the parents more healthy. Under such circumstances cases occur in about equal proportion in the two classes mentioned. These patients have usually presented a history of repeated attacks of diarrhea, and the fact that the urine frequently contains an excess of indican indicates fermentative processes in the intestinal canal. That abnormal alimentary changes often stand in the relation of cause to effect in the nephritis of children seems to be proved from the fact, that such patients do better on a properly regulated diet than on any other form of

treatment, the dropsy disappearing, the bowels becoming regular and the urine normal.

The changes in the intestinal contents give rise to a toxin or toxins which act injuriously upon the kidneys, just as do the toxins of the infective fevers. Thompson explains this action by attributing to the poison an effect upon the general health followed by a change in the density of the blood, which in turn modifies the rate of osmosis so that albumin is filtered through the kidneys. A solution of albumin injected into the rectum of a dog will pass almost unaltered through the kidneys. It appears to be a rational conclusion that if an infant is placed upon an albuminous diet, which, of course, it cannot assimilate, that an albuminuria, continuing during the employment of such a diet, will occur.

According to Yeo, the ingestion of too great a quantity of albuminous material necessitates the excretion by the kidneys of so large an amount of nitrogenous waste that a temporary functional hyperemia of the organs in question is excited, and this leads to a slight leakage of albumin from the blood. Thus it is seen, that given an improper diet to begin with, there exists the first factor in a chain of events which may ultimately lead to organic disease of the kidneys.

The victim of inherited syphilis or of the tuberculous diathesis is apt to develop nephritis. This is especially so among the negroes—a fact well-known to Southern physicians—and particularly applies to those having an urban environment. Both of these diseases act in a manner analogous to that of the infectious fevers. Other cases have come under my observation to which no causative factor could be assigned; but the family history would show one or two near relatives who died of nephritis. Some persons certainly evidence a marked tendency to albuminuria from slight dietetic errors, which in time may be followed by structural lesions of the kidney, and in children, on account of the age and an undeveloped digestive system, this condition could easily be brought about.

The treatment, of course, depends upon the cause. Should the history elicit evidence of the presence of the toxin of an infective fever, the aim should be to eliminate the poison from the system. This is accomplished by promoting physiologic action of the kidneys, and for this purpose our most effective means is a properly regulated diet. The same principles are true in the case of syphilis or tuberculosis, although in the former, of course, the specific treatment of the disease would be applied as well. Milk, modified to suit the exigencies of the case, is the best means we have for the accomplishment of the purpose. Heart stimulants and diuretics are sometimes

necessary, though administered as a routine practice they do more harm than good.

I append a brief account of a few cases, and, although my efforts have not always been successful, I attribute the failures not to incorrect methods, but to the impossibility of carrying out the treatment thoroughly in many instances, and to the fact that the disease had often passed to an advanced stage before the patient came under observation.

CASE I.—W. J., negro, aged two years and nine months. Family history good; no history of infectious fever. The examination revealed general edema. The urine was supposed to be diminished, but it was impossible to get total amount; specific gravity, 1028; albumin present; urea, six grains to one ounce; indican present, though not in excess. A diet was ordered, which consisted of modified milk, fruits, gruel, etc. The child gradually improved, and finally passed from observation, when things were doubtless allowed to continue as before. Called to see the child two months later. Coma complete. Administered digitalis and nitroglycerin hypodermically; no reaction. Child died within a few hours.

CASE II.—R. H., female, light mulatto, aged twelve years. Had been under treatment by various physicians for about two months. General dropsy. Almost constant headache. Visual abnormalities, such as floating particles in the air, etc. Mother died from nephritis and father from tuberculosis; no history of infectious fever. Urine: Amount, twenty ounces; urea, seven grains to one ounce; albumin present in large quantities. Patient very anemic. Medication, cod-liver oil and syrup of the iodid of iron. Slight improvement. Occasional convulsions, and finally death ensued during an attack.

CASE III.—H. S., negro, female, aged eight months. History of repeated attacks of diarrhea, and symptoms of syphilis. General edema present. The mother was ordered to nurse the child, and inunctions of mercury followed by iodid of potassium were prescribed. Child improved steadily, and at present appears to be perfectly well.

On consulting Quain's "Dictionary of Medicine," I find that views identical with mine are held by Stokins and Sir George Johnson. These, while detracting from the originality of the ideas presented, coming from such eminent authority add greatly to the weight of the argument.

Donation to Veterinary College.—Ex-Governor Flower has donated \$5000 to Cornell University to purchase books for the Veterinary College library.

Suicide in New York.—During the year 1896 there were 384 suicides in New York City, of which 295 were men and 89 women. Shooting constituted the favorite method; 58 swallowed carbolic acid; 54 hanged themselves, and 35 inhaled illuminating gas.

CLINICAL MEMORANDA.

A CASE OF GASTRIC ULCER, TERMINATING IN HEMORRHAGE AND DEATH.

By ELEANOR C. JONES, M.D.,

OF PHILADELPHIA;

CLINICAL INSTRUCTOR IN PEDIATRICS AT THE WOMAN'S
MEDICAL COLLEGE.

MR. J. C., aged eighty-four years, an unusually well-preserved and apparently healthy old man, gave the following history: He had always been very temperate in the use of alcohol, but had been a habitual smoker. As a young man he enjoyed excellent health, with the exception of the occurrence of what he called recurrent bilious attacks. These attacks consisted of gastric pain followed by nausea and vomiting, and, later, by diarrhea; they occurred at irregular intervals, and sometimes several months elapsed between them. During the intervals, as a rule, he was free from any stomach symptoms; his appetite was good and his bowels regular. About thirty years ago he suffered from his first gastric hemorrhage, which was said to be profuse, and was so ill that death seemed imminent, but he recovered perfectly. Between the date of the first hemorrhage and January of the present year he had three or four recurrences of the hemorrhage, but the attacks were not so severe as the first. On January 30th, another hemorrhage occurred, being preceded a day or two by abdominal pain and fever, but unaccompanied by nausea.

I saw him immediately after this attack, and calculated that he vomited at least a pint of coffee-colored blood. The hemorrhage was followed by large tarry stools. He became very wild and delirious, so that on the night of January 31st, he had to be held in bed. The delirium subsided after a few days and he soon was up and about again, taking a walk every day as usual, and despite an appearance of anemia and a considerable loss of flesh, seemed fairly well. On April 23d, he had another profuse hemorrhage, and afterward became very anemic and weak, although he remained entirely rational. On April 26th another hemorrhage occurred. He never entirely rallied from this, his pulse remaining very feeble, his lips bloodless, and complexion ashy. He suffered from "air-hunger," and tossed his arms about, but remained conscious and knew that he was dying. Death occurred on the afternoon of April 26th. He was conscious until within a few minutes of the end.

A *post-mortem* examination was made by Dr. C. T. Dercum and myself. We found all the tissues very anemic. The stomach was small and there were no adhesions or perforation. On removing the viscus and opening it along the lesser curvature, we found that it contained about half a pint of coffee-colored blood. On the anterior wall of the lesser curvature, near the cardiac end of the stomach, there was one open ulcer, containing the remains of a small thrombosed vessel, and two cicatrices. The cicatrices were very irregular in shape, the greatest diameter being about two centimeters. The ulcer was about the size of a 10-cent piece, sharply defined, but very shallow, extending only to the submucous structure.

The stomach wall in this locality was thickened, showing that there had been considerable inflammatory infiltration. The wall at the pyloric end along the greater curvature was very thin. The veins on the anterior wall were large and tortuous.

The intestines were entirely normal in appearance, with the exception of about twelve inches of the lower part of the colon, which was studded with little sac-like protrusions filled with inspissated blood, giving the external surface of the bowel the appearance of being beaded with black glands. The caliber of the gut at this point was extremely narrow, and the canal was filled with liquid blood. The liver, kidneys, spleen, and bladder were all healthy in appearance.

This case is of interest because of the advanced age of the patient, and the fact that he had typical symptoms of gastric ulcer thirty years ago, three or four recurrent attacks, and during the intervals enjoyed good health. It would seem, therefore, that the ulcers healed after each attack. At eighty-four years of age he was unusually well-preserved, being vigorous, both mentally and physically. The case is also unusual, because death was caused directly by the gastric hemorrhage. Ewald ("Diseases of the Stomach") says that immediately fatal cases of gastric hemorrhage are comparatively rare. The absence of disease in any other organ and of complications is also interesting.

A CASE OF INFANTILE MALARIAL FEVER, WITH GRAVE ANEMIA.

By JOHN S. BILLINGS, JR., M.D.,
OF NEW YORK.

THE following case was observed in the wards of the Johns Hopkins Hospital, Baltimore: The patient, a female, aged ten months, of American parentage, was admitted to the hospital October 20, 1893. The family history was negative, with the exception that all but one member had had malarial fever, contracted at the same time and place—an exceedingly malarious district in Maryland. In all, five members of the family had developed the disease. Until the present illness the child (whose case is here reported) had always been strong and well. The mother stated that the patient had been having daily attacks of fever with slight sweating at night, but no chills. The febrile paroxysms came on late in the afternoon and lasted about one hour. The child lost flesh and strength steadily from the first. She had had a little diarrhea but no vomiting; appetite fairly good; slept well. At the beginning of the illness a general eruption of dark blue spots and patches (purpuric?) appeared, which became confluent and persisted until a week previous to admission after which they gradually faded.

The following is an abstract of the memoranda made at the bedside by Professor Osler: "Child appears wasted; skin very pale; lips and mucous membranes generally almost colorless. Head somewhat rachitic in appearance. The skin is loose all over the body and hangs in ridges and folds everywhere, except over the hands and feet. These are much swollen and pit deeply on pressure, the skin over them being tense and glazed. The skin over

the abdomen shows evidence of old ecchymoses. Splenic dulness not increased but the sharp border of this organ may be felt about half an inch below the costal margin."

An examination of the blood revealed the presence of two sets of malarial organisms of the tertian type, giving rise to the double tertian or quotidian variety of fever. The organisms of one set occupied only one-quarter of the red corpuscle, and contained a few grains of almost immobile, brownish pigment. Some of the organisms of this set were without pigment, and gave the appearance of oval or irregularly shaped clear spaces in the red corpuscle. They were ameboid, changing shape and position at will. The other set occupied almost the whole of the red corpuscle, and had the appearance of circular, highly refractive bodies filled with grains of brownish-black pigment in constant, dancing motion. Several full-grown organisms, *i.e.*, occupying the whole of a corpuscle, were observed, and one matured or segmenting form. In the latter the pigment was gathered into a dense mass at the center of the organism and had segmented, dividing into fourteen or sixteen small, round, highly refractive bodies. Upon the bursting of the matured organism, these small hyaline bodies find their way into the red corpuscles, there to begin their life cycle anew.

Medication consisted of the administration of sulphate of quinin in quarter-grain doses every four hours.

On October 31st, the temperature rose to 101° F. at 8 P.M., falling to normal by 4 A.M., the following day. It remained normal until the morning of November 3d, when there was a sudden rise to 104° F., again reaching normal by 2 A.M. on November 4th, the paroxysm continuing during twenty hours. November 4th, the dose of quinin was increased to one grain repeated every four hours. The succeeding day the temperature rose sharply to 103° F., and on November 7th, it reached 101° F., after which it remained normal. There was practically no sweating during these attacks.

Daily examination of the blood showed the presence of the organism described above at various stages of development according to the time of examination. Their number grew gradually less, however, and they were not found after November 8th.

The child did well for the first few days, but on November 4th, appeared very ill, and had an attack of vomiting, also curds appeared in the stools. The diet had previously consisted of two parts milk and one part lime-water. The proportions of milk and lime-water were made half and half, following which vomiting did not again occur, the curds disappeared from the stools, and the child continuing to steadily improve.

An analysis of the urine made during the illness showed it to be cloudy, but with no sediment; specific gravity, 1.003; very faint trace of albumen. Microscopic examination revealed the presence of leucocytes and squamous epithelium.

The quinin was discontinued November 19th, and Fowler's solution, 1 grain, three times daily, was substituted. The patient was discharged on December 4th. She was again seen on December 15th, when she appeared plump, strong, and healthy.

The first blood-count, October 22d, indicated the following condition: Red corpuscles, 1,381,000 per c.mm.; leucocytes, 18,500 per c.mm.; hemoglobin, twenty-five per cent. (v. Fleischl). The fresh specimen showed moderate variations from the normal in the shape and size of the red corpuscle, poikilo and schuzocytosis. Hardened and stained specimens evidenced the same changes in the red corpuscles. Quite a large number of nucleated red cells (twenty in one specimen) were observed. These were all, with one exception, normoblasts; *i.e.*, though the corpuscle is of normal size, it possesses a deeply staining nucleus, occupying only one-sixth to one-quarter of the area of the corpuscle. The exception noted was a megaloblast; a corpuscle twice the size of the normal red cell with a relatively large, palely staining nucleus. The hemoglobin of many of the red corpuscles, of about one-third of the normoblasts, and of the megaloblast was polychromatophilic; *i.e.*, instead of showing an affinity for acid stains, as is characteristic of normal hemoglobin, it takes a neutral stain best. No abnormal leucocytes were noted. A differential count of 1000 leucocytes showed a marked increase in the number of so-called polynuclear neutrophils (92.1 per cent.). This would be expected in such a well-marked leucocytosis as was present in this case. The condition of the blood steadily improved from the date of admission until November 9th. The number of red corpuscles increased, the number of nucleated red corpuscles grew constantly less, and poikilo and schuzocytosis became less marked. On the date mentioned the condition was not so good, but one week later the state of affairs was again much improved, leucocytosis having entirely disappeared. The increase in the number of red corpuscles and in the percentage of hemoglobin present progressed hand in hand with the improvement in the condition of the child, and upon the date of the last examination the blood was practically normal. red corpuscles, 4,870,000 per c.mm.; leucocytes, 5700; hemoglobin eighty-nine per cent.

The interesting point in the condition of the blood was the presence of nucleated red corpuscles in relatively large numbers. The occurrence of grave anemia during and following malarial fevers has, of course, been noted by many observers. It is rare, however, that the number of red corpuscles falls as low as it did in the present case. The presence of nucleated red cells and polychromatophiles was an evidence of an increased activity on the part of the blood-forming organs, with resultant new formation. Such an indication of regeneration warranted a favorable prognosis. In a case of purpura hemorrhagica reported by the writer in *The Johns Hopkins Hospital Bulletin*, vol. v, p. 65, the anemia was more marked than in the present case, yet there was a total absence of nucleated red corpuscles, showing a lack of regenerative effort, and warranting an unfavorable prognosis which was justified by a fatal termination. While the presence of nucleated red cells is indicative of a severe grade of anemia, their absence in cases where the red corpuscles are below 1,500,000 per c.mm., is of bad omen.

The occurrence of a typical megaloblast in a case of secondary anemia, such as this, sustains the view of sev-

eral authorities that these corpuscles are not pathognomonic of pernicious anemia. In fact, it is now generally recognized, that any secondary anemia, if severe enough, may show the same blood-changes that were formerly supposed to be characteristic of pernicious anemia.

The well-marked leucocytosis observed was probably due to anemia. Malarial fever without anemia is unaccompanied by an increase in the number of leucocytes; but the writer has elsewhere reported instances of marked leucocytosis occurring during post-malarial anemia.

MEDICAL PROGRESS.

New Mexico as a Health-Resort for Consumptives.—CAUTHORN (*Medical Sentinel*, August, 1897) directs attention to the advantages of New Mexico as an ideal locality for consumptives. The South Atlantic States and California show a relative humidity of the air and a rainfall—one or both—which is entirely too marked for patients suffering from this disease. The Adirondacks and Colorado are subject to intense cold, a harshness of climate, and a violence of weather changes at certain seasons which are certainly objectionable. On the other hand, between Santa Fé on the north, and Tucson and El Paso on the south, the desired conditions of altitude, dryness, and mildness suited to every consumptive who is not hopelessly affected, may be found during every month of the year. New Mexico will probably be chosen as the site for a sanatorium for tuberculous seamen of the Marine Hospital Service, if the plan to provide such an institution is carried out. There are at present more than 1100 of these patients in the various marine hospitals of the country and the bringing together of so large a number of consumptives, under such favorable conditions, will afford opportunity for the most valuable conclusions regarding the treatment of this disease.

The Fate of Microbes in Granulation Tissue.—AFANASJEW (*Centralbl. für Chir.*, August 14, 1897), in order to determine exactly the power of granulation tissue to protect the organism from bacterial infection, experimented upon quadrupeds with the bacillus of anthrax, and upon birds with the vibrio Metschnikowi. He found: (1) No general infection takes place through healthy granulations. (2) After withstanding this test animals are usually protected from an infection through a fresh wound. (3) The destruction of the bacteria was demonstrable microscopically; but in this process phagocytosis does not seem to play a chief part. (4) Pure cultures taken from the granulations twelve hours after inoculation seemed to be weakened.

Adenoids Removed with a Fatal Result.—SCHMIEGELOW (*Centralbl. für Chir.*, August 14, 1897) mentions an accident which happened in the practice of another surgeon, and one who has many times performed, without bad result, the simple operation which brought on a fatal hemorrhage in the instance mentioned. The patient, a boy aged twelve, had adenoids, and except that the lad was of scrofulous diathesis, the case was absolutely uncompli-

cated. No anesthetic was used. While the operator was scraping the right wall of the nasopharynx with a Gottstein's ring-knife, there was a sudden gush of blood which proved uncontrollable, and the patient died within a few minutes. At autopsy it was found that the internal carotid artery had been ruptured by the manipulations.

Anasin, a New Local Anesthetic.—VAMOSSY (*Centralbl. für Chir.*, August 14, 1897) describes a new local anesthetic to which he gives the name of Anasin, and for which he claims distinct advantages over cocain, in that it may be sterilized, does not change with age, and has absolutely no irritant properties, nor general toxic effects. This drug which is an acetone-chloroform, is used in a one-per-cent. watery solution, the effects of which are about equal to those of a two-per-cent. cocain solution. In a number of tests upon the lower animals and also upon man the writer was not disappointed.

Hernia into the Intersigmoid Fossa.—LAMBRET (*L'Echo Méd. du Nord.*, August 22, 1897) reports a case of hernia of the intersigmoid fossa, a variety of the greatest rarity. Herniæ have been mentioned as occurring in the foramen of Winslow, in the retroduodenal fossæ, and in the retrocecal fossæ, but as far as is known this is the third case of hernia into the intersigmoid fossa. This fossa which exists in more than eighty per cent. of all individuals and may therefore be considered normal, is concealed by the sigmoid meso-colon. In order that the intestinal coils may become engaged in it, it is necessary that the mesentery should be straightened, and this occurs only when the sigmoid is drawn upward into the abdomen. Under these conditions, which are the same as those brought about in order to expose the fossa, its entrance is open, and the small intestine may, therefore, become prolapsed into the cavity.

The Conditions Found More Than Two Years after Ligation of the Large Vessels of One Side of the Neck.—THOMAS (*British Med. Jour.*, August 21, 1897) reports the conditions found in the case of a man sixty-five years old, who two and one-quarter years previously had cut the internal, external, and anterior jugular veins, as well as the common carotid artery, in an attempt at suicide. (See THE MEDICAL NEWS, January 18, 1896, p. 76.) At the time hemorrhage was controlled by clamping and ligation, secondary hemorrhage occurring, it became necessary to ligate the internal and external carotids. The patient recovered and resumed his occupation as a house-painter. This he followed for nearly two years when he came under observation again on account of severe cough and pain in the right chest. The temperature was high and expectoration copious. Rapid failure took place and death ensued.

Upon *post-mortem* examination, the blood-vessels forming the circle of Willis appeared normal. The last half-inch of the internal carotid artery was hollow, while the portion in the cavernous groove was represented by a fibrous cord. Upon the left side, the sternomastoid muscle was entirely replaced by cicatricial tissue. The common carotid trunk was small and terminated abruptly five

inches from the arch of the aorta in a mass of scar-tissue, there mingling with the cut ends of the pneumogastric, sympathetic, and some cervical nerves. (The phrenic nerve was normal.) Above this fusion, nothing but the two nerves (vagus and sympathetic) and a small artery could be found. This artery, not so large as a normal facial, came down from above and gave off the small facial, lingual, and superior thyroid, and was the sole representative of the external carotid. No trace of the internal carotid or of the internal jugular as far as the base of the skull could be found. The inferior thyroid artery was smaller on this side, but the left vertebral was half as large again as its fellow. This, in fact, appeared to be the only special provision made for collateral circulation. The deep cervical artery was much smaller on this side. The left lung was normal, and therefore had not suffered from interference with the pneumogastric and sympathetic nerve. Upon the right side the common carotid artery seemed slightly larger than normal, but the superior thyroid, the lingual, the facial, and the inferior thyroid were apparently not enlarged. In the right lung some pathologic changes, with a collection of pus, had caused death.

The conditions present illustrate how little reliance can be placed upon the theoretic collateral circulation laid down in the text-books, based on ordinary anatomic anastomosis, for with the exception of the enlarged left vertebral artery and some little enlargement of the right common carotid, all the other arteries were not only no larger, but were actually smaller; even the deep cervical artery was considerably smaller than its fellow of the opposite side.

Perforating Ulcer of the Duodenum.—DARRAS (*Gaz. heb. de Méd. et de Chir.*, August 22, 1897) shows that the perforation of the duodenum as a result of simple ulceration—the commonest complication in this affection, and one which often gives rise to the first and last marked symptoms—occurs usually in the anterior wall. Consequently it is followed by a general peritonitis. It is necessary to differentiate between this peritonitis and that occurring as a result of gastric and appendic perforation. The points of distinction to be remembered are: The previous history of the patient, the circumstances under which perforation takes place, and the exact site of the first pain. Perforation of the duodenum is more frequent in men than in women, while the reverse is true of perforation of the stomach. The latter more often runs a latent course than the former. Vomiting is more constant in connection with perforation of the duodenum.

The only treatment is surgical, and to succeed this must be prompt and thorough. If possible the opening should be sutured. Failing in this, it is to be packed about with gauze. Post-operative treatment is important and should not be neglected.

THERAPEUTIC NOTES.

Sulfonal as an Antisudorific in Phthisis.—COMBEMALE and DESCHECMOCKER (*La Méd. Mod.*, September 11, 1897) have obtained very good results from the use of

sulfonal in the night-sweats of phthisis. In one patient the sweats disappeared after three doses, while in others they became limited to a portion of the body, usually the head, and in others, though remaining general, lost a severe character. In most of the patients to whom the remedy was administered there was a persistent action for a number of days after its use was interrupted. No serious symptom attended its employment. In one instance there was a mild intoxication following a two-weeks' exhibition of the drug, which disappeared when it was discontinued. The dose was generally from 15 to 30 grains at bedtime or a little before, and this was continued daily for two weeks.

Treatment of Melancholia.—In discussing the treatment of cases of melancholia, PRITCHARD, *New York Polyclinic*, says that if the domestic situation can be controlled by the family physician, the patient should most emphatically be treated at home. Nearly all such patients are appreciatively cognizant of their surroundings, and hence great harm is done by incarceration and association in an institution with others who are insane. In treating these patients at home, two conditions should be demanded by the attending physician, positively and imperatively: First, absolute control over the patient's personal and domestic life; and, second, the constant presence of an attendant, preferably one who has had special training. As a rule, the patient should be isolated from the rest of the family, leaving the personal influence and domination of the physician and nurse free from interference. The patient's room should be changed in both location and furnishings. In the debilitated cases partial enforced rest should be obtained by requiring the patient to lie abed until ten, eleven, or twelve o'clock in the morning. The diet should be nutritious and quite sufficient. If through delusions, or in an effort to commit suicide in this way, the patient refuses to eat, enforced feeding should be resorted to by rectum or mouth, or if resistance is excessive, by means of a catheter introduced through the nose.

The drug treatment resolves itself into three indications: (1) The relief of insomnia; (2) the correction of visceral derangement and disturbed secretions; and (3) the relief of psychic pain. For insomnia the author prefers trional above all other drugs, and says that it is free from injurious or disagreeable effects, and is more certainly reliable than any other. The dose should be from 10 to 20 grains, in water, shortly before retiring. It may be combined with an equal quantity of sodium or potassium bromid. It does not seem to lose its hypnotic action even after prolonged continuance, nor does it tend to establish any drug habit. Occasionally the sleep induced from a full dose is alarmingly prolonged, but this is a rare idiosyncrasy of no harmful significance. He calls attention to the importance of removing auto-infection of the gastro-intestinal tract by the administration of laxatives (cascara sagrada, decimal doses of calomel, etc.) and intestinal antiseptics (bismuth subgallate, salol, etc.), and of relieving psychic pain by opium, in the form of the aqueous extract, in doses of $\frac{1}{8}$ to $\frac{1}{2}$ of a grain three or four times daily.

THE YELLOW-FEVER EPIDEMIC.

IN regard to the origin of the present epidemic of yellow fever in the South, sanitary authorities are divided in their opinions. One theory, which is strongly advocated, is that it has been brought to this country from external sources, and is ascribed to Cuban refugees who evaded quarantine at Ocean Springs. None of those refugees, however, so far as known, has died of the disease or even been attacked by it. Certain it is that the first case which was clearly recognized as yellow fever was that of a gentleman from Louisville, Ky., who had been staying at a boarding-house in Ocean Springs, kept by a family in sympathy with the Cubans to such an extent that refugees found welcome and hospitality, and were permitted to hold clandestine meetings there.

In opposition to this theory is the position taken by the *Sanitarian*, which maintains that the yellow-fever germ is a denizen of the Gulf States; that it thrives there in greater or less luxuriance in accordance with the varying climatic changes from season to season; that a prolonged siege of hot weather during which there is a prevailing temperature of about 80° F., especially when accompanied by great humidity,

develops this germ in a virulent form and gives it wide distribution. Such was the climatic condition which preceded the present epidemic. Moreover, it was preceded, as have been previous similar epidemics, by an invasion of dengue or malarial fever, showing that the atmospheric conditions were such as to favor the development of noxious germs. Furthermore, this authority points out that in addition to this atmospheric condition, favorable soil for its widespread development was afforded these germs by an indifference on the part of the inhabitants to sanitary precautions due to the prevailing confidence in quarantine regulations.

Whatever may have been the origin of the disease, it is an accepted fact that its propagation is favored by unsanitary conditions, and the logical steps to be taken in the present emergency are to place the towns and villages within the influence of this *contagium* in a sanitary condition with the utmost despatch. Frosts and freezing weather cannot be had for the asking, nor can they be bought for a price. But the thorough cleansing of houses and streets, is a rational means of relief which may be undertaken at once. Mob violence and shotgun quarantine are disgraceful. The wheels of industry and the channels of trade are blocked. This is the opportunity to teach the gospel of cleanliness, and practically demonstrate its truth long before the uncertain frost can come.

MEDICAL TEACHING.

SINCE writing the article upon this subject, which recently appeared in these columns, our attention has been called to one written by Dr. Montgomery A. Crockett in the *Educational Review* for September. This author develops the subject along lines similar to those followed by us, but his article is more elaborate in detail and is so full of suggestion that it is worthy the careful attention of those interested in medical teaching.

He insists that the methods now employed in the best secular schools are also applicable to medical pedagogy, and advances the suggestion that the future medical student is now receiving his preparatory education along modern lines; that upon reaching the professional school he will not be content to be subjected to methods of teaching long deemed obsolete. "The object of medical education is the development of power in a special field,

and this object is not accomplished merely by the presentation of a large number of facts. Reform in medical teaching does not mean that medicine will be made easy; it means the adoption of methods by which every particle of mental energy expended is realized by the student in the shape of increased power." The author arraigns the medical curriculum of to-day as subvertant of the order in which the mind most easily acquires knowledge. "Instead of stimulating mental activity at the outset by beginning at the point of greatest interest, it wearies the mind and interposes the resistance of the least attractive subjects. Instead of aiming to give the student an impetus which will carry him over the dry details, it applies friction when it should be getting up speed; it adds a handicap just as the student steps upon the race-course of medical education."

From the standpoint of the subject-matter alone, the medical curriculum is sufficiently logical; but from the standpoint of the man who hopes to acquire an efficient education, the arrangement of subjects is presented in an inverse order. The two great principles upon which modern education rests are the necessity of arousing interest in the mind of the student and the correlation by the instructor of the facts which he desires to impart. In accordance with this theory the development of mental power is kept in mind as well as the capacity of acquiring an endless number and variety of facts; and at the same time the method of presentation makes easy the assimilation of these facts, and their retention in the memory. In outlining the application of the new curriculum, the author insists that the first-year student shall take up the work at the point of greatest interest, *i.e.*, the clinic; and that when interest has been aroused by the clinical picture of disease the mind is in a condition to absorb easily, logically, and permanently, the facts of anatomy, physiology, pathology, and therapeutics, which naturally group themselves around the disease under discussion. This assumes that the professor or instructor is intimately conversant not only with the group of phenomena presented clinically in the case but also with the underlying facts.

At the present time clinical teaching is reserved for the senior year, and in many colleges the first-year students are debarred even the privilege of being present, so that the suggestion that the first-year

student shall begin his education with the clinic will strike those who have been giving didactic lectures for the last fifteen or twenty years as quite preposterous. But it must be borne in mind that the presence of the patient in the clinic is for the purpose of arousing interest, and, as Dr. Crockett suggests, this is a legitimate end, as the first step in the process of education. To be more specific, let us suppose that a class of first-year students is to be instructed in the physiology and anatomy of the lungs. Nothing can certainly arouse the students' interest in this subject so thoroughly, and at the same time so appropriately, as the clinical picture presented, let us say, by a case of pneumonia. The history of the case is given; the signs and symptoms of the disease are presented, and the question arises: What is the cause of these symptoms and signs? The answer involves an explanation of the physiology and the anatomy of the lungs, and leads up to an elaboration of all the processes of health and disease in these organs. In this illustration the application of the great principles involved in the acquisition of knowledge have been presented; first, the arousal and stimulation of interest, and, second, the proper correlation of the facts necessary to an understanding of the case. The hour is spent in a great object lesson, replete with interest and fruitful of results. If the allotted time is not sufficient the subject may be continued at a following lecture. The probabilities are, however, that interest will be so thoroughly aroused that the student will not wait for the following lecture, but will gratify his curiosity and interest by consulting whatever authorities may be accessible.

The presentation of the less interesting facts of anatomy may be elaborated in an equally attractive manner, the details of which will suggest themselves to the thoughtful mind. No accessory of teaching is of greater importance than freehand blackboard drawing. Colored charts and illustrations have a place, but for holding the attention of the student, can never be compared to freehand drawing on the blackboard, which keeps pace with the development of the subject. Another means of whipping up mental activity is by a series of direct questions, calling indiscriminately for responses to questions, reviewing the points already explained, and going from one to another until the correct answer is obtained. This brings before the students facts already

presented and places the mind in an attitude of receptivity for what may follow, at the same time it informs the instructor whether he has been successful in presenting the subject. In this way each lecture may be made a mental gymnastic in which every one present participates, not through fear of the mark he will receive, nor through dread of the final examination, but because of the interest aroused. The successful instructor thus develops the faculty of putting the class on its mettle, so to speak, making the mind work throughout the hour up to the limit of its power. Thus not only are facts permanently lodged in the mind, but mental power is developed and facts in anticipation of those already explained may be elicited by nicely adjusted questions correlated to what has already been explained.

Dr. Crockett makes a strong plea for the special training of men for the work of medical education. The objection so frequently made that the physician cannot afford to give so much time to educational work is tersely answered by the author when he says: "This objection constitutes the reproach of medical teaching, for it means that a man is willing to accept a place in the medical school and then knowingly give the student a poor article for his money. Such a man has no business to be a teacher, and the medical school would be better off without him; he probably is keeping out a better man, and, while posing as a martyr, is sacrificing educational interests for the sake of personal prestige. Anyone who knows more than his hearers can fill a lecturer's place, but the proper conduct of a recitation requires ability, application, and skill; the modern recitation offers a field worthy of the best intellects."

ECHOES AND NEWS.

New Instrument for Making Brain Sections.—A microtome for making sections of the entire human brain is being constructed by Messrs. Bausch and Lomb. It is expected that this instrument will make large sections of great thinness and accuracy.

Professor von Esmarch.—Professor von Esmarch of Kiel, recently celebrated his silver wedding with his second wife. He is seventy-four years of age, and his wife was one of his patients, Princess Henrietta of Schleswig-Holstein, aunt of the German Empress.

Dr. Newborn Resigns.—Dr. A. D. Newborn, of the United States Marine Hospital Service, who for seven years has been detailed as Medical Examiner of Immi-

grants at the port of New York, has resigned his position in order to continue his studies at London, Paris, and Heidelberg.

Antiseptic Road-Watering.—The necessity for antiseptic street-sprinkling is being agitated in England. Perman-ganate of potash has been used for this purpose but in solutions so weak as to be ineffectual. It is suggested that a powerful germicide such as corrosive sublimate be employed.

School Commissioners Oppose Vaccination.—It is reported that the Catholic Board of School Commissioners of Montreal, Quebec, has refused to comply with the order of the provincial board of health requiring it to refuse admittance to its schools to children without vaccination certificates. The city, however, will station officers at all Catholic schools to vaccinate the children.

New Order for Midwives.—Steps are being taken in Vienna to ensure the better instruction of midwives. An order for examination has been issued by the Minister of Education which is to take effect at once. All midwives who have already passed the examination of 1881 are allowed a year's grace for preparation before presenting themselves for re-examination.

Prevention of the Spread of Phthisis.—A society with the above object has been formed in Hanover, Germany. It is to be hoped that it will meet with the success it deserves. The society will endeavor to attain its object by the dissemination of information by word and writing, and for this purpose has issued a brochure with the following inspiring name: "Up to the Fight against Consumption!"

A Diphtheritic Cat.—The health authorities of the Oranges, New Jersey, are in pursuit of a cat said to be suffering from diphtheria. The sick animal strayed into a home where two pet cats were kept. These soon after showed signs of illness which was pronounced by the health officer to be diphtheria, and they were at once killed. Meanwhile the cat which caused all the trouble has disappeared.

Home for the Chicago Medical Society.—After an existence of forty-five years, the Chicago Medical Society has established a permanent home in the Stewart Building, where sufficient space has been rented to provide for a meeting-hall, reading-room and library, committee-rooms, and cloak-rooms. The society has a membership of nearly eight hundred and is the largest local medical society in the United States.

Army Examining Boards.—A board of officers has been appointed to meet at Headquarters, Department of Colorado, Denver, Col., on Monday, October 18, 1897, for examination for promotion of officers of the Medical Department. On the same day a similar examining board will meet at Headquarters, Department of Dakota, St. Paul, Minn., and on Monday, October 25, 1897, at Headquarters, Department of California, San Francisco, Cal.

Heart Failure from Over-Training.—A medical student of the New York University is in a serious condition at Fordham Hospital as a result of over-training. The young man, who is twenty-four years of age and has a record as a runner and pole-vaulter, has been training very hard for the fall games. The other day he lost consciousness in the street and was sent to the hospital, where he now lies completely prostrated.

Entertainment for Charity.—The concert and theatrical performance which are to be given at the opening of the Hotel Astoria, at New York, on November 1st, will benefit several hospitals and charitable institutions. The receipts will be divided among the Saturday and Sunday Woman's Auxillary Hospital, Loomis Sanitarium for Consumptives, Mothers' and Babies' Hospital, Babies' ward of the Post-Graduate Hospital, and two day nurseries.

Health Reports.—The following statistics, concerning smallpox, yellow fever, cholera, and plague, have been received in the office of the Supervising Surgeon-General of the United States Marine Hospital Service during the week ending October 9, 1897:

Dr. Wiseman Probably Insane.—Dr. William Wiseman, a graduate of Heidelberg University and for a long time a practising physician in Pennsylvania, was recently adjudged insane by a lunacy commission at Binghamton, N. Y. He has shown signs of insanity for the last eighteen months, and recently disappeared from his home. He was found hidden in a hovel, five feet by seven, in the little settlement of Liberty, Tioga County. He will probably be committed to the State Hospital.

Yellow-Fever Notes.—It is not generally known that Sanarelli has himself suffered from yellow fever. During the summer of 1896, while studying the disease on the Island of Flores, where it was very prevalent and where he made numerous autopsies, he was smitten with the fever, from which he recovered in due time.

It is reported that the local physicians of Nitta Yuma, Louisiana, have refused to treat yellow-fever cases.

According to the daily papers, an attempt was made by the panic-stricken inhabitants of McHenry, Mississippi, to lynch a man whom they accused of evading quarantine.

The New Orleans members of the Louisiana Legislature have been asked to pledge themselves to ratify any act introduced at the next session appropriating the amount of money which will have to be raised now to continue the fight against yellow fever. The funds of the Board of Health are exhausted and relief must come from the State, as it is useless to look to the city for assistance because its funds are completely tied up by suits now pending.

Passed Assistant-Surgeon Bratton, of the United States Marine Hospital Service, who has been on duty at Sabine Pass, Texas, fell through the hatch of a vessel he was inspecting and was so badly injured that he died on the following day. He was a son of General J. D. Bratton of South Carolina. At the outbreak of yellow fever in the South, he volunteered for service in the infected districts.

The first case of yellow fever of the present epidemic occurred at Ocean Springs, Mississippi, in a boarding-house where the meetings of several Cuban refugees took place. It is said that these Cuban refugees, eluding the quarantine officers, escaped from ships lying in the harbor and reached Ocean Springs by means of cat-boats.

The Medical Department of the Tulane University of Louisiana has given notice that in consequence of yellow fever and resulting quarantines, the opening of its winter session is postponed from October 14th to November 11th. Students entering after cessation of danger from infection, will be credited with a full course.

Thirty-eight new cases of yellow fever were reported in New Orleans on the 6th inst. This is the largest number of new cases reported in one day, and is probably due to the warm weather which has prevailed.

The Mayor of New York has received a telegram from the Acting Mayor of Edwards, Mississippi, saying that financial aid is badly needed for fever sufferers.

Dr. Brunner, United States Sanitary Inspector at Havana, in his last report to the Surgeon-General of the Marine Hospital Service, dwells upon the danger of yellow-fever infection being carried by cattle steamers plying between Cuba and the United States.

CORRESPONDENCE.

OXYTUBERCULIN AND PULMONARY TUBERCULOSIS.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: I wish to communicate the result of the employment of oxytuberculin (Hirshfelder) in the treatment of a patient with pulmonary tuberculosis: Mrs. S., aged 33 years, had been ill with phthisis for two years. Paroxysms of nocturnal asthma were a frequent and troublesome complication. One sister died of pulmonary tuberculosis and another sister has the disease. The patient rapidly lost weight as follows: February, 1896, weight, 109 pounds; August, 6th, 103 pounds; November 10th, 100 pounds; November 20th, 90 pounds. Physical examination revealed the presence of consolidation of both apices down to the fourth ribs; there were abundant râles, and numerous bacilli were found in the sputum. During November a severe attack of tuberculous pleurisy occurred, and the physical signs indicated disseminated tuberculous foci throughout the lungs. During the previous four months the temperature ranged from 99.5° F. in the morning to 102.5° F. in the evening; pulse from 90 to 110. The administration of oxytuberculin was commenced on November 25th: December 10th, fever absent; cough diminished; expectoration lessened and the general condition improved.

On January 10, 1897, the condition was as follows: fever absent; cough still less; expectoration greatly diminished; appetite good. On February 10th, the patient was so much improved that she resumed house-work. In the meantime the weight had increased to 110 pounds and the asthma had entirely disappeared. By May 10th, the weight had increased to 122 pounds; cough and expectoration had ceased. Physical examination showed that consolidation had disappeared; bronchial breathing over a small portion of one lung. Microscopic examination revealed one or two bacilli to the cover-glass. The improvement continued until at the present time the patient appears to be perfectly well. No examination of the sputum has been made for some months.

The treatment previous to the employment of oxytuberculin had consisted in the administration of the carbonate of creosote, protonuclein, cod-liver oil, and various other remedies, all of which proved of no avail. At the beginning of the treatment the patient was not expected to live a week. One point worth notice is the effect of the remedy in promptly relieving the attacks of asthma, which practically disappeared after one or two doses of oxytuberculin. In conclusion, I wish to add that the progress and termination of the illness has been carefully observed by four physicians.

D. A. BEATTIE, M.D.

SANTA CLARA, CAL., October 2, 1897.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

BACTERIOLOGIC EXAMINATION OF THE MILK-SUPPLY BY THE CITY LABORATORY—EXTENSIVE IMPROVEMENTS AT THE JEFFERSON MEDICAL COLLEGE—MEDICO-CHIRURGICAL COLLEGE'S OPENING—CHANGES AT THE UNIVERSITY MEDICAL SCHOOL—THE PUBLIC CLINICS AT THE TEACHING HOSPITALS—YELLOW FEVER ABOARD A VESSEL AT THIS PORT—ENLARGEMENT OF THE BLOCKLEY INSANE DEPARTMENT—PERSONAL—MEDICAL SOCIETY MEETINGS OF THE WEEK—VITAL STATISTICS FOR THE WEEK ENDING OCTOBER 9TH.

PHILADELPHIA, October 9, 1897.

MANY and urgent demands have been made from time to time by the physicians of this city for more careful attention on the part of the health authorities to the question of milk adulteration and contamination. In compliance with these petitions the Board of Health is about to adopt a new regulation which provides for the systematic bacteriologic examination of the milk-supply at the city's bacteriologic laboratory. Inasmuch as the real danger to the community lies not so much in the adulteration of the milk-supply as in its contamination by being sold in unsanitary and filthy shops, the proposed innovation should prove a distinct advance in the municipal control of this very important article of food. Guided largely by the result of bacteriologic findings, it will be a comparatively easy matter to treat the question of milk contamination efficaciously, and to proceed against unsanitary dairies and milk-shops in a manner which will give the best results.

The seventy-third annual term of the Jefferson Medical College was inaugurated on October 4th by the delivery of the opening address by Dr. G. E. De Schweinitz, Professor of Ophthalmology to this institution. Introductory remarks were also made by the President of the Board of Trustees, the Hon. William Potter, and an official announcement of much importance concerning the future of Jefferson was made by Dr. J. W. Holland, the Dean of the Faculty. It related to the immediate steps which are to be taken in the reconstruction of the college and hospital buildings, and contained the information that, as the leases of the adjoining properties purchased by the trustees of the college as sites for a new hospital and a new college will expire in March, 1898, work will be begun at once on the erection of a handsome and altogether modern hospital building. When this structure is completed, a college, to conform architecturally with the new hospital, will replace the present building. This extensive improvement, which has been planned for a number of years, will entirely reconstruct the institution, and is an advance viewed with liveliest satisfaction by the alumni and friends of the college. Speaking of "Jefferson," it is worthy of note that, since the inauguration of the four-years' course and additional requirements for admission, the character of the student body has materially improved, and, further, that, contrary to general expectations, the number of matriculants has, instead of decreasing, markedly increased, for the registration up to the present time is over fifty more than last year.

Health and Late Hours.—A German doctor, who has been collecting information about the habits of long-lived persons, says that the majority of those who have attained old age indulged in late hours. That is they retired after midnight and remained in bed late in the morning.

The opening lecture in the winter session of the Medico-Chirurgical College was delivered on October 4th by Dr. William L. Rodman, the newly elected professor of surgery. In company with the other medical schools of Philadelphia, the class at this college is a large one—in fact, the largest in its history, and having all the characteristics of a body of men from which is exacted for matriculation a high standard of qualification in the English branches.

A recent change in the teaching staff of the Medical School of the University of Pennsylvania is the appointment of Dr. J. P. Arnold as demonstrator of physiology, to succeed Dr. W. S. Carter, who recently resigned to accept a professorship in this branch in the University of Texas. Drs. A. Ferree Witmer and E. R. Shreiner were appointed assistant demonstrators of physiology and Dr. L. A. Ryan assistant demonstrator of chemistry. Owing to the ill-health of Professor Penrose, which enforces his absence from the city for the present, the didactic lectures on gynecology will be delivered by his assistant, Dr. H. D. Beyea, while Professor Hirst will conduct the gynecologic clinics during Professor Penrose's absence.

With the openings of the various medical schools, the public clinics at the several teaching hospitals have been resumed for the winter. There have been clinics at the Philadelphia Hospital for the last two weeks; those at the Pennsylvania and German Hospital began a week ago, while the clinics at the Children's Hospital are about to resume in a few days.

The arrival in the Delaware River a few days ago of a vessel with yellow fever aboard from an infected port in South America, has caused the sanitary officials of this city no apprehension, thanks to the efficient quarantine regulations by which Philadelphia is protected. The extent of these precautionary measures for the health of the community is not generally known. Before a vessel may enter this port she must pass the scrutiny of three distinct quarantine stations, the first two being Government quarantines, one situated one hundred miles down the Delaware, the second fifty miles further up, and the third the State quarantine station, thirty miles below the city. It is thus apparent that, with these inspections to pass, it is practically impossible for an infected ship to reach the city wharves.

A sum of \$60,000 is to be spent in additions and improvements to the Insane Department of the Philadelphia Hospital (Blockley), and this much-needed work is to be immediately begun, in view of the overcrowded condition of the insane wards of the hospital. There are 1300 patients in the insane department, notwithstanding the fact that the present accommodations are intended for but 1000 persons.

Among the recent arrivals from Europe of Philadelphia medical men may be mentioned Drs. G. E. de Schweinitz, Judson Deland, J. William White, Alfred Stengel, Horatio C. Wood, Joseph P. Tunis, P. S. Donnellan, D. D. Stewart, W. Eastery Ashton, Charles B. Noble, John B. Deaver, and John H. Packard.

Among the distinguished visitors to Philadelphia during

the past week have been Mr. Christopher Heath and Mr. Watson Cheyne, the British surgeons, who were entertained by Dr. W. W. Keen during their stay, and Lord Kelvin, the famous English scientist, who is at present a guest in the city.

A stated meeting of the College of Physicians of Philadelphia was held on October 6th, at which an interesting paper was read by Dr. A. A. Eshner, entitled "A Case of Obscure Diagnosis Exhibiting Hysterical Symptoms." At the election for Fellowship held after the close of the scientific business of the evening, the following were elected members of the College: Drs. William G. Spiller, John H. Girvin, W. A. N. Dorland, and Alfred Hand, Jr.

At a stated meeting of the Section on General Surgery of the College of Physicians, held on October 8th, Dr. John B. Roberts exhibited a patient upon whom he had performed a successful excision of the subclavian vein for a secondary malignant growth. The tumor was a scirrhous carcinoma of the mammary gland, with secondary nodules about the subclavian vein. These were excised without, it is interesting to note, any edema of the hand of the affected side as a sequence of the operation, and with recovery of the patient. Dr. Roberts also presented a note on a novel method of hastening consolidation in delayed union of fractures, which consisted in applying to the injured member a tight bandage, with the hope that the resulting increased local congestion of the part would hasten and augment the formation of callous. The treatment mentioned has given favorable results.

Dr. J. Chalmers Da Costa showed a case of gunshot wound of the lung. Eleven days after the injury there was a secondary intrapleural hemorrhage which almost proved fatal. Rib resection was performed, and $4\frac{1}{4}$ quarts of blood was evacuated. The lower lobe of the lung was badly lacerated and sloughing, and neither ligatures nor forceps would hold; so that the entire pleural cavity had to be filled with gauze about the lung in order to give a base of support before packing could be applied to the bleeding surface by which the hemorrhage was finally controlled. The patient recovered, and was exhibited at the College, along with a skiagraph which clearly showed the bullet lodged in the anterior mediastinum.

Dr. W. W. Keen described the sterilization of catgut by the Jefferson method, which consists of the use of ether, alcohol, mercuric chlorid, and palladic chlorid. Gut prepared by this method was found to retain its toughness for an indefinite period.

At a stated meeting of the Philadelphia Obstetrical Society, held on October 7th, Dr. Anna M. Fullerton read an interesting paper dealing with two unique cases of abdominal section. The first case was one of double ureter of the right side, which extended from the kidney to the bladder, and which was accidentally injured during a celiotomy. Implantation of the ureter into the bladder was effected, with recovery of the patient. The second case was one of wandering spleen simulating ectopic gestation. The organ was removed without bad effect upon the patient.

The deaths occurring in this city during the week end-

ing October 9th numbered 345, of which 99 were in children under five years of age. The total number showed an increase of 3 from the preceding week, and a decrease of 12 from the corresponding week of last year. Contagious diseases were responsible for 31 deaths—2 less than last week. Diphtheria cases numbered 116, with 26 deaths; scarlet fever 46, with 1 death, and enteric fever 44, with 4 deaths.

OUR BERLIN LETTER.

[From our Special Correspondent.]

THE INCREASE OF RED BLOOD-CELLS AT HIGH ALTITUDES QUESTIONED—THE BERLIN POLICE AND CERTAIN FORMS OF QUACKERY—FOOT AND MOUTH DISEASE AND THE GOVERNMENT COMMISSION'S REPORT AS TO VACCINATION FOR IT—A DISCUSSION AS TO THE MERITS OF CATHETERIZATION OF THE URETERS—DANGERS OF URETHRAL INJECTIONS.

DURING recent years much theory has been evolved in an effort to explain the physiologic causes of the increase in the number of red blood-cells in high altitudes. The whole subject of the *rationale* of mountain climates in the treatment of tuberculosis has been revolutionized by the series of observations on this subject begun about 1890. It has come to be generally accepted that the call on the organism for more oxygen carriers in the rarefied atmosphere of high altitudes leads to a reflex excitation of the blood-making organs, and to a consequent increase in the number of red cells. Nothing was more striking in the debate on the therapeutics of tuberculosis at the International Congress at Moscow than the perfect complacency with which this theory was referred to as though it were beyond doubt or cavil. Now comes a daring skeptic with the suggestion that the phenomena observed are the result of physical conditions acting upon the instruments employed in making the determination of the number of red cells—that the increase is only apparent and does not occur in the circulation, but is due to faulty, though supposedly exact, apparatus. Dr. Gottstein (*Allgemeine Med. Cent. Zeit.*, No. 64) reports a series of observations made with the Thoma-Zeiss blood-counting apparatus and artificial serums prepared to imitate blood. With these he claims to have found under varying atmospheric pressure variations in the number of objects, about the size of blood-corpuscles in the solutions usually employed, such as are commonly described as occurring in the circulation at high altitudes. His claim is that the varying pressure of the air on the cover-glass is enough to cause sufficient difference in the volume of the space beneath it to account for the variations in the number of red blood-corpuscles. The large factors employed in obtaining the number of cells in a cubic millimeter multiply the slightest inaccuracy, and thus explain the errors in question.

The fact that the increase in the number of red blood-cells immediately follows the ascent of the mountains and does not persist after the descent, and also that it is strictly proportionate to the altitude at which the observa-

tion is made, are circumstances that would seem to substantiate Dr. Gottstein's theory.

In this city there has recently been a good deal of advertising of another electric current-developer. Like the electric rings, the electric belts, and dry batteries of all varieties, which develop electric currents with untold healing powers when worn in contact with the skin, the new electrical remedy, the *voltakrenz*, is warranted to cure all the ills to which flesh is heir. The apothecaries took it up very generally, for the public was beginning to inquire for it, and the inducements offered by the manufacturers to retailers were even more generous than usual. There is some limit, however, to the extent to which Quackery is permitted to go in Berlin, and this latest addition overstepped the limit. There are regulations to prevent "*Curfuscheri*," which is the expressive word they have here for Quackery, and so the Commissioners of Police took a hand. A notice to the effect that the *voltakrenz* is an evident humbug, meant only to deceive the public, and that its sale, or the keeping of it for sale, is unworthy of the public service due from an apothecary and contrary to the legal regulations relating to their business was served on the apothecaries. As the notice closed with the very practical words, that the sale of the article in question would be punished by a fine of three hundred marks, it is probable that the last has been heard of the *voltakrenz*.

There remains, of course, any amount of Quackery in Berlin which cannot be reached so effectively by public regulation, but it is encouraging to find that even this much may be accomplished by means so simple. Surely some of our American cities could well imitate Berlin in this matter, as in many others, and do something to stop the palpable medical swindles which are every day displaying more effrontery and shamelessness.

The commission appointed by the German Government sometime ago for the investigation of foot and mouth disease has just made a preliminary report. The results of its observations at the Institute for Infectious Diseases in Berlin is that so far no microbe can be demonstrated to be the cause of the disease. Lymph from affected animals which seems to be sterile as regards bacteria conveys the disease when intravenously injected into susceptible animals.

As various tissue particles and other organic matter is present in the lymph, it is suspected that the cause of the disease is a protozoon, but this is merely a suspicion. Lymph from the vesicles of the disease, intravenously injected, produced the disease in from one to three days, the first symptoms occurring in the mouth, followed after a day or two in cattle by vesicles on the udders and feet. After the appearance of the local manifestations the virus no longer exists in the blood, so that the vesicles are really Nature's method of eliminating the poison. Cattle and swine may be artificially immunized. If virulent lymph be mixed with the blood of an animal that has had the disease it may be injected into susceptible animals without producing the affection, but with the production of immunity. Lymph which has been heated to a certain degree produces the same effect and without noticeably affecting the

health of the animals into which it is injected. The members of the commission consider that the progress of the disease may be hastened to a cure by the use of the serum of immunized animals—that epidemics of the affection may be prevented by protective inoculations with a modified lymph. As to the methods of protective and therapeutic inoculations their observations have not as yet been sufficiently extended to enable them to state definitely the conditions of preparation, and the *mode* of employment best calculated to secure certain results. The whole subject is of more interest in Berlin than almost anywhere else, as it is from this city and its immediate environs that most of the epidemics among human beings have occurred.

As it is in Berlin that the methods and instruments for the catheterization of the male ureter have been brought to such a state of perfection as to make the procedure practical, one is a little surprised to find a discussion as to the diagnostic and therapeutic value of ureteral catheterization occupying a good deal of attention. Sometime ago Dr. Holländer, in an article in the *Berliner klinische Wochenschrift*, called the utility of the procedure into question, and pointed out that the admitted dangers are too great to justify its employment in view of the very problematic results. In fifty per cent. of the cases it causes some hemorrhage from the mucous membrane either of the ureters or of the ureteral papillæ. In about one-half of these cases, it is true, this is supposed to be not more than a diapedesis of red corpuscles owing to irritation of the mucous membrane. This furnishes, however, in either case an extremely favorable lodging-place for pathogenic bacilli. The most careful antiseptic douching of the bladder is recommended before catheterization of the ureters is attempted, but it is needless to say that antiseptics strong enough to give the remotest prospect of making the interior of the bladder sterile are utterly out of the question. When an ascending pyelitis does not exist, a very favorable opportunity for its inception is furnished by the procedure even in the most skilful hands. That this danger is not imaginary the observation after catheterization of some cases of infectious lesions, notably tuberculosis of the ureteral papillæ, serves to show. As to the advantage usually claimed for it—that it enables the surgeon to judge of the possibility of the other kidney being healthy enough to carry on the eliminative functions after nephrectomy of a diseased organ, it is not always so unquestionable. In any case where there is a purulent or other infectious disease of one kidney there will be found, owing to the elimination of toxins going on in the other, more or less albumin and casts in the urine derived from it, which will cause the surgeon to hesitate in giving an opinion as to the advisability of doing a nephrectomy. That catheterization of the ureter cannot always be depended upon even where the other kidney is extensively diseased, a case reported at the Moscow Congress very strikingly shows. Almost normal urine was obtained from the ureter of a supposedly healthy kidney. Nephrectomy of the other kidney was followed by complete anuria, and the autopsy showed a pyelonephritis of the remaining organ, but with one unaffected pyramid from which the normal urine had been excreted.

Dr. Casper in reply to Dr. Holländer in the last number of the *Wochenschrift* points out how much has been done for the diagnosis of kidney conditions by catheterization of the ureters, and how much light it has thrown on one of the darkest pages of surgery—the diagnosis of nephritic conditions. As to tuberculosis it gives undoubted proof of the one-sidedness of the affection, and so makes surgical interference possible in an otherwise fatal disease. As to the presence of calculi in the lower part of the ureter, soundings form an excellent guide as to their position. In regard to the dangers, he does not seek to minimize them, but states that experience and the minutest antiseptic precautions are required; further, that the procedure should only be employed in cases where the seriousness of the affection is such as to justify the risk involved. He concludes by pointing out that in certain cases of pyelonephritis, in his own and other's hands, cure has followed the frequent flushing of the renal pelvis through the ureteral catheter.

A curious comment on this last statement is furnished by a report from Professors Goldscheider and Lewis in the last number of the *Deutsche Med. Wochenschrift*. They found in dogs that but very little pressure of liquid in the ureter and renal pelvis is sufficient to force the renal filter and lead to the entrance into the circulation of liquids or gases. They saw animals die very rapidly as a consequence of the entrance of air into the renal veins and the vena cava, whence it was carried to the heart. They observed the air-bubbles in the veins during life and found them, *post-mortem*, in the cardiac ventricles. They quote Poirier, the French anatomist, who reported some time ago that he had seen solutions, injected under very slight pressure into the ureter, appear in the renal veins. Evidently the subject of ureteral catheterization is in an experimental stage, but it is to be hoped that the enthusiasm of the young votaries who have taken it up because it requires knack and practice will not be carried on into fatal experiments upon human beings. It is just such fads which are the righteous occasion of the most serious condemnation of the profession. Such is, as it were, the index of an overzealous longing for personal distinction in a new field which completely oversteps the bounds of well-ordered conservatism.

SOCIETY PROCEEDINGS.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held Monday, September 27, 1897.

The President, LANDON CARTER GRAY, M.D., in the Chair.

CERTAIN SOURCES OF NEUROSES IN WOMEN

was the title of a paper read by DR. EGBERT H. GRANDIN. (See page 494.)

DISCUSSION.

DR. ROBERT A. MURRAY agreed with the author that in most instances the trouble is not a neurosis, but a bad diagnosis. The cause of pain and objective symptoms

must be sought for, the whole body being examined if necessary and the attention not confined to any one set of organs. He also urged that more care be taken in obtaining the history. He then cited the case of an unmarried woman, forty-four years of age, who at intervals had been flooding for years. Her physician attributed this to "the change of life," and did not make a vaginal examination because she was a single woman. When seen by the speaker it was found that the cervix was almost entirely destroyed by malignant disease, and the case was, of course, hopeless.

DR. H. N. VINEBERG asked the author how he had been led to examine the neck of the bladder in the first case mentioned. When no bladder symptoms are present he hardly considered such an examination justifiable. In regard to adhesions of the clitoris being the cause of reflex symptoms, he had never seen such a case, possibly because he had not much faith in the theory and had not looked for the condition. He was of the opinion that altogether too much importance is placed upon insignificant adhesions of the clitoris. He had seen cases in which reflex symptoms were due to injury of the coccyx, but in such cases his attention had been directed to the part by pain in its neighborhood, and the diagnosis was easily made. He was glad to hear the author sound a note of caution against removal of the tubes and ovaries in the hope of relieving nervous symptoms. In the majority of cases in which this is done the patient is made worse by the operation, and it is generally accepted that it is not justifiable to remove the appendages unless there is actual disease present, no matter what the nervous symptoms may be. The speaker then said that, in his opinion, incomplete sexual congress is a frequent cause of neuroses in women, and very often overlooked. Dr. Bangs of this city has pointed out the injurious effect which this has upon men, and it should not be forgotten that the effect upon women is just as serious.

DR. C. A. VON RAHMDOHR called attention to one cause of general neuroses and hystero-epilepsy in women which the author had not mentioned, *viz.*, laceration of the cervix. He said he had seen a case in which simple closure of an everted cervical laceration resulted in curing a condition which had been diagnosed as hystero-epilepsy. He also referred to neuroses occurring during labor and caused by fissure of the anus or of the neck of the bladder.

DR. L. F. BISHOP said that as epilepsy is a disease of the cells of the brain, it cannot be cured by attacking other organs of the body or by any operation. Therefore, it is a mistake to remove the tubes and ovaries in the hope of relieving epilepsy. He mentioned "post-operative neurasthenia" as another neurosis which frequently develops in women after surgical operations.

DR. CARTER believed with the author that fissure of the neck of the bladder is a frequent cause of reflex symptoms in women. He mentioned three cases in which neuroses were due to this condition, although no bladder symptoms were present. In speaking of the relation of the clitoris to neuroses, he remarked that the Chicago practitioner who wrote about "clitoroid women" and Baker Brown, who believed that every woman should be

deprived of her clitoris, undoubtedly are extremists, but, nevertheless, ninety-nine women out of a hundred have adhesions of the clitoris, and that not one of the ninety-nine is free from neurotic symptoms.

DR. O'BRIEN spoke of a case in which neurotic symptoms were due to middle-ear disease, and to another in which asthma was relieved by removal of the middle turbinate.

DR. W. M. LESZYNSKY said he wished to enter his protest against the removal of healthy ovaries for the relief of epilepsy or insanity. Such operations he considers not only unjustifiable, but criminal.

THE PRESIDENT agreed with the author in believing that a neurosis is a very indefinite condition. Epilepsy has a certain group of symptoms which mark it as something apart, although but little is known of so-called "idiopathic" epilepsy. He does not think that all the nervous symptoms which occur in women as a result of visceral disease can be called "neuroses" in the true meaning of the word. True epilepsy, with absolute loss of consciousness and with tonic or clonic convulsions can never be caused by disease of the pelvic viscera. There are, however, many forms of neurotic phenomena, as neurasthenia; neuralgia, and those symptoms which cannot be grouped unless they are called "hysteria," which are due to some disturbance of the pelvic viscera. In such cases it is well to examine the whole economy, and if any pelvic trouble exists this should be remedied. He has, however, never observed anything but temporary benefit follow the removal of healthy tubes and ovaries in a hysterical case.

DR. GRANDIN, in closing, said, in reply to Dr. Vineberg's question, that there were probably some bladder symptoms present in his first case, but that such were masked by more prominent symptoms. However, as nothing was done to cure the woman except to dilate the vesical sphincter and apply phenic acid to the fissure, he did not think there could be any doubt in regard to the cause of her symptoms. He disagreed with those who said that too much attention is being directed to the clitoris, for he is thoroughly convinced that adhesions of this organ to its prepuce are responsible for many nervous manifestations in women, and may even simulate pelvic disease. He, furthermore, expressed the opinion that the clitoris should be carefully examined at birth, and if adhesions exist they should be severed.

NEW YORK ACADEMY OF MEDICINE.—SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held October 7, 1897.

DR. E. G. JANEWAY, President, in the Chair.

DR. C. J. JEWETT of Brooklyn read the first paper of the evening, entitled

MEDICAL TREATMENT OF PUERPERAL SEPTIC DISEASES.

He gave a brief outline of the general plan of treatment, beginning with the statement that if sepsis develops in a puerperal woman the physician is to blame. Sepsis is a preventable disease, and what is wanted is prophylaxis.

It is not only necessary to be aseptic at the time of labor, but the asepsis should begin weeks before. Conditions such as anemia, albuminuria, syphilis, etc., should be treated, and the state of the digestive tract and alimentary canal looked after to guard against auto- and fecal intoxication. Sepsis does not occur in people whose kidneys are in good working order. Attention must be given to the birth canal, in which microbes may be present, and pre-existing disorders of the bladder should be investigated. Gonorrhea is a frequent cause of puerperal sepsis. If present the vagina should be douched twice daily with a solution of bichlorid of mercury for two or three weeks previous to labor, or the vaginal canal may be dusted with subnitrate of bismuth. The importance of asepsis culminates in the labor. Obstetricians of special training have practically no death-rate in their practice, and there should be none. Douching during labor is not only useless but positively harmful, for it washes away and interrupts for hours the flow of the natural acid secretion of the vagina which is its own protective agent against disease-producing germs.

Infection is most liable to occur during the first few hours after the birth of the child. The resistance of the tissues, especially those of the vagina, is at a minimum and for this reason manipulation of the lower passages is dangerous. Introduction of the hand is dangerous. Retained remnants of the placenta or of the secundines had best be left to be cast off spontaneously. The advantages of immediate suture of lacerations of the cervix are doubtful, unless they cause hemorrhage.

As soon as infection is suspected, an examination should be made. Septic vaginal wounds should be cleansed twice daily, touched with iodine or chlorid of zinc, and a strip of gauze inserted in the vagina. If douches are required, peroxid of hydrogen or Labarague's solution may be employed. The treatment of the uterine cavity requires much tact and judgment. The risk of carrying infectious material with the hand from the vagina to the uterus must be borne in mind, and for this reason the dull curette is best employed to ascertain if there is necrotic material in the uterus, should this be suspected; but the curette should not be used as a routine measure. The presence of sepsis in the uterine cavity can be determined by the odor of the material which clings to the curette, and which should be subjected to a bacteriologic examination. Decomposed blood-clots and all other *débris* should be removed with the curette which is cleaner than the finger. Intra-uterine irrigation with a non-toxic disinfecting fluid should then be practised to wash away all putrescent matter. The entire cavity of the uterus may then be painted with iodine, a solution of carbolic acid (1-40), or with phenique. A loose packing of gauze should then be introduced and allowed to remain for twenty-four hours; or pencils of iodoform may be inserted. It is well to irrigate first with salt solution or a mild antiseptic. In the absence of *débris* in the uterus, the curette is contraindicated.

In violent forms of infection local measures will do no good. Intra-uterine irrigation is of but little use except to wash away *débris*. Some advocate the introduction of

a soft drainage-tube, and the washing out of the uterus with absolute alcohol. Iodine water has also been recommended for this purpose, and in Germany intra-uterine injections of steam have been practised. The uterus is first curetted and the steam at a temperature of 100° C. (212° F.) is injected through a perforated metal tube for two minutes; the temperature of the steam is then raised to 112° C. (233.6° F.) and the injection continued for fifteen seconds. It is said that no pain or discomfort follows this treatment, the metal tube being so encased that it does not burn the parts with which it comes in contact.

The systemic treatment should be such as will control the local septic process as well as keep up the patient's strength. Alimentation and elimination are important. Alcohol should be administered to the point of intoxication, but this unfortunately is not well born by the stomach. Strychnia and quinin should be given, especially the former. The latter is of value in small doses; in large doses it does harm by hindering oxygenation. Spartein and other cardiac stimulants are of value in heart depression. Feeding should be limited to liquid foods, predigested if necessary. An abundance of fresh air is imperative. All measures tending to elimination should be employed, and plenty of water administered. Experiments show that three times as much poison is required to affect animals which drink water as is needed to affect those who do not. The administration of saline purgatives is also important, and ergot is recommended to limit diffusion of the septic poison. Intravenous injection of mercuric chlorid has also been practised, but this is hardly to be recommended in general practice. The subcutaneous injection of turpentine has also been suggested. The coal-tar antipyretics are not only heart-depressors, but they hinder oxygenation. Cold bathing on the other hand, has the effect of a nerve tonic, and also favors elimination. Cold sponging is indicated when the temperature is above 100° F. The treatment of puerperal sepsis by antistreptococcic serum is still under trial, and as yet no definite standard of strength has been decided upon. The author's experience is limited to six cases, and in only one was any improvement noticed. Care should be taken to procure a reliable preparation, and it should be fresh. Nuclein, which acts upon the leucocytes, has recently been recommended. It is to be regretted that, while much has been suggested, little has proved of value in the treatment of local septic disease.

DR. E. H. GRANDIN then read a paper on the

SURGICAL TREATMENT OF PUERPERAL SEPTIC DISEASES.

The author said that inasmuch as puerperal infection is simply wound-infection, surgical principles such as are applied to sepsis in other parts of the body, should be employed in its treatment. He treated the subject under two headings, *viz.*, putrid infection, so-called sapremia caused by toxins, and septicemia due to pathogenic germs. Sapremia, treated early and properly, may be ordinarily controlled, because the elements of putrefaction tend to remain localized at the site of their origin. In septicemia, on the other hand, we have to deal with a condition de-

pendent upon the growth of pathogenic microbes, the streptococcus, and the staphylococcus, which through rapid multiplication and dissemination through the venous and lymphatic channels, make the infection systemic as well as local. A neglected sapremia may become a septicemia.

Before deciding upon the treatment, it is essential to determine whether the condition is one of sapremia or of septicemia. The most frequent form of puerperal infection is sapremia, and the uterus is generally its location. The present method of treatment is curettage, which, however, is often resorted to unnecessarily, to the detriment of the patient. At the present time the impulse is to curette in every case, just as formerly it was the habit to employ the intra-uterine douche. The curette is indicated in sapremic infection; but in endometritis curetting will cause dissemination of the pathogenic microbes throughout the body. Research has shown that in putrid endometritis Nature throws out a barrier of leucocytes under the putrescent mass in the uterine cavity, to prevent the passage of microbes into the lymphatics and veins. Local infection will become general infection if this barrier is broken down by curetting. The chances of recovery are good in proportion as the infection remains localized. Therefore, our treatment of puerperal sepsis should favor localization, and if surgical measures are employed they should be undertaken before systemic infection is marked. As a rule, putrid endometritis becomes septic endometritis only when there has been infection from without at the time of delivery or during the puerperium, although it is possible for the two to co-exist. The differentiation should be made under perfect asepsis by exploring the cavity of the uterus with the fingers, the patient being anesthetized. This should be done before the curette is used. The curette is contra-indicated unless the examination shows putrid retained *débris*. If such be the case, the putrid masses and softened necrotic tissue down to the granulation layer only should be removed. The uterine cavity should then be irrigated and packed with sterile gauze. If no improvement takes place within thirty hours, the case is probably one of septic endometritis, and the less active the treatment the better. Such local measures as will kill the germs at work on the surface of the uterus should be undertaken in the hope of preventing further dissemination. Iodoform gauze should not be used, because the symptoms of iodoform toxemia, which may set in, resemble those of septicemia.

In septic endometritis, no putrid remnants will be found in the uterine cavity unless there is a combination of both varieties. This form of endometritis leads to septic metritis, salpingitis, and peritonitis. Frequent irrigation with bichlorid may be effective.

When infection has ceased to be local and involves uterus, tubes, ovaries, and peritoneum, the main point is not *how* to operate, but *when*. The indications and technic are the same as in similar conditions in the non-puerperal state. The only difference lies in the prognosis. The point is to act before systemic infection is complete. Operation avails but little when veins are clogged with septic thrombi, and liver, spleen, kidneys, heart and brain have been invaded by septic germs.

Local peritonitis and so-called cellulitis are, as a rule, benign as regards life if they remain localized, and these exudates often disappear without surgical treatment. They may, however, become purulent, and general systemic infection result. When the symptoms remain acute for days, an examination under narcosis should be made to locate the purulent foci which should at once be incised and drained at the most accessible point. Local peritonitis, however, is in reality extra-peritoneal and does not require surgical treatment unless the general peritoneal cavity has become affected secondarily.

If local peritonitis is associated with metritis and salpingo-öophoritis, early diagnosis and prompt, radical surgery is necessary to save life. It may become a question of vaginal hysterectomy in order to afford thorough drainage of the pelvis. In such cases, however, systemic infection is so intense that death generally results in spite of operation. The all-important problem of the hour is how to determine at an early stage whether surgery will be efficient. A high grade of metritis calls for hysterectomy, and in cases of septic endometritis the doctrine is now that the uterus should be removed if the infection is localized in the endometrium—something which no man can determine. Our policy, therefore, must be to treat surgically each complicating factor as it arises, and hope for the best.

In regard to the use of the antistreptococcic serum, cases of general septic peritonitis uncomplicated by the puerperal state have been reported in which cure has followed the antitoxic serum treatment associated with prompt and radical surgery, but no well authenticated case has been reported where this result was obtained in the puerperal state.

Other varieties of peritonitis, in which the prognosis is more favorable may complicate the puerperium. The peritoneal cavity may become infected by the rupture of an abscess of the vermiform appendix or of a pre-existing ovarian abscess or pyosalpinx. In either event the case should be treated as usual in that condition.

DISCUSSION.

DR. CHARLES P. NOBLE of Philadelphia said the results of the serum treatment of these cases had not been satisfactory in Philadelphia. Twelve cases with six deaths and six recoveries have been reported there by various men, and the general opinion is that the serum is harmful. It is but fair to admit that the cases in which it was employed were of more than average severity. Personally, he did not feel inclined to use the serum treatment unless bacteriologic examination showed the presence of streptococci in the system at large. He emphasized the importance of making a careful diagnosis and agreed with Dr. Grandin that an examination of the uterine cavity should be made under anesthesia. He would also investigate the condition of the vagina, as infection from lesions of that canal and perineal lacerations are common. If these be discovered early, the septic process can be cut short by touching them with carbolic acid or nitrate of silver. In cases seen late, a thorough examination is of value in showing the source of infection

and in determining whether or not pelvic exudate is present. In regard to the employment of radical surgical measures in cases of puerperal infection, he referred to the frequency with which these patients recover with intact organs and advised against extirpatory operations. He cited a case in which he had attempted to do an abdominal section, but was forced to desist because the patient could not be anesthetized, and he was finally obliged to drain *per vaginam* without narcosis. The woman made a good recovery, and much to his surprise has since had another baby. When employed early, surgical drainage results in recovery in many cases, and, therefore, great conservatism should be practised. When suppuration has not occurred, medical treatment will result in cure. In the matter of intra-uterine injections, he is of the opinion that the length of time during which they are employed should be limited, as he sees no advantage to be obtained from prolonged irrigation—if used longer than one or two days, it is more apt to do harm than good. His experience with the intravenous use of salt solution leads him to believe that it is an agent of great service in drawing off ptomains and in keeping up the strength of the heart.

DR. PAUL F. MUNDE expressed himself as being gratified by the conservative stand taken by the authors in regard to surgical interference. Some years ago he saw in consultation many cases of puerperal septicemia, and he had always felt that there was nothing to do but to keep the patient alive while the disease ran its course. If this were possible, she recovered; if not, then she died. He believes that much is to be expected of the new antitoxin treatment, which he has used in two cases with the most satisfactory results. The speaker was glad to hear the use of the curette advocated only in cases where placental tissue and *débris* are retained in the uterine cavity. Removal of the uterus in puerperal infection is not, as a rule, a good operation and generally results fatally. Cases of septic purulent peritonitis, whether puerperal or not, should be opened and drained.

DR. HENRY C. COE remarked that the treatment of puerperal endometritis, at first very conservative, then very heroic, and again very conservative, never seems to reach a middle ground. In looking back to the time when it was the custom to wash out the uterus every two or three hours day and night, he is impressed with the remarkable power of resistance which the patients must have had to be able to stand the nervous shock and physical fatigue of the often repeated intra-uterine irrigation. After that, when the curette came in vogue, all cases were curetted and much harm resulted. He agreed with Dr. Grandin that the differential diagnosis in puerperal fever could only be made by exploring the uterus with the fingers under narcosis, but added that this is not always possible in cases where the uterus is so large that it reaches the umbilicus. The author did not mention one important point, *i.e.*, that immediately after delivery the uterus is in a state of antelexion which prevents drainage, and that this often causes septic infection. In some cases the only treatment necessary is the opening of the canal. In regard to the treatment applied to the uterine

cavity, he has seen good results follow the use of peroxid of hydrogen in a desperate case, but keeping the uterus packed with gauze saturated with alcohol is probably the best method now in use. He has never seen a case suitable for hysterectomy. The intravenous injection of salt solution has proved very useful in his hands, the patients showing improvement at once. He has also employed oxygen inhalation with so much benefit that it seems to have an almost specific effect.

DR. C. A. VON RAMDOHR called attention to the following points: The proper treatment of puerperal sepsis is prevention, and it is possible to prevent it. When infection takes place, the obstetrician is the infector. Auto-intoxication does not exist. The differential diagnosis between sapremia and septicemia must be made early. *Never* use bichlorid. It has been proved that when applied to the parturient canal, under certain conditions, it will give rise to acute nephritis. Whenever sapremia is present, as indicated by fever, leucorrhea, and the presence of retained *débris*, the latter should be removed by the curette and *one* intra-uterine douche given. Whenever there is a pus-collection in the pelvis, it should be treated like any other abscess. When such a collection exists and the uterus proves an obstacle to thorough drainage, the organ should be removed, for it will always be a nidus for future disease and never a useful organ. Give alcohol in large doses—one pint of brandy in twenty-four hours. Serum-therapy will be welcome if it can give us hope. The use of the coal-tar preparations is a step backward, for they weaken the muscle of the heart. Where systemic infection has taken place, local treatment is worse than useless.

DR. H. VINEBERG narrated the history of a case of puerperal endometritis in which the patient had done well for a week when she suddenly had a chill and a rise of temperature, the chill being repeated on the following day. Abdominal pain soon developed. Upon examination, the vagina and cervix appeared intact, and the only thing which attracted attention was the large size of the uterus. Investigation showed that a portion of the placenta was retained, and the patient recovered after curettage and irrigation.

DR. ROBERT A. MURRAY expressed the opinion that sepsis in many cases is due to neglect of the old rule to give ergot in the third stage of labor in order to secure firm contraction of the uterus. In a large hospital and out-door obstetric practice, he had followed this rule with the result that he seldom had a case of sepsis, and this in spite of the fact that many of the women were delivered amid the most unfavorable surroundings. A second dose of ergot was given if there was much bleeding. If the uterus is kept well contracted, blood-clots will not lodge there, decompose, and cause sepsis. If there was a slight rise of temperature, the finger was passed over the entire surface of the uterine cavity, and if any foul odor clung to the examining finger, the uterus was curetted, treated like an abscess cavity, and swabbed with alcohol, carbolic acid or tincture of iodine to prevent further absorption of septic germs. He was glad to hear Dr. Coe mention inhalation of oxygen, which the speaker knew to be very

beneficial. Alcohol should be given and also veratrum viride, which acts upon the heart when given in small doses. In general septic peritonitis he considered it useless to operate. When seen early, incision and drainage may be employed.

DR. J. RIDDLE GOFFE said that the treatment he employs in these cases is similar to that outlined by Dr. Grandin, differing only in that he always explores the cavity of the uterus with a curette rather than with the finger, not because he fears that infection may be carried by his own hand, but for the reason that he has seen so many cases in which sepsis has been conveyed in this way; that he has made it a rule to advocate the use of the curette for diagnostic purposes, because it can be made *absolutely* aseptic by boiling.

DR. SIMON MARX thought it would be difficult to follow Dr. Grandin's advice, to curette down to the granulation layer only, in cases of putrid endometritis. In regard to the antistreptococcic treatment not being successful in cases of puerperal sepsis, although of so much benefit in surgical cases, the speaker attributed this either to the fact that in the former the infection is often a mixed one, or to some influence which the puerperal state has in intensifying the poison. His experience with the serum has been most unsatisfactory and in some cases has seemed to hasten death, and he is of the opinion that the cases reported as cured by it in France and Germany were cases of sapremia and not of septicemia.

DR. J. M. MABBOTT called attention to the frequent occurrence of malarial fever during the puerperal state. Several such cases have been noted at the infant asylum, and in all the plasmodium malariae was found in the blood. The temperature fell after large doses of quinin. It was his opinion, therefore, that quinin should be given when a rise of temperature takes place in the puerperal woman, rather than resort should be made to the antitoxic treatment which, it is acknowledged, may be harmful.

DR. W. EVELYN PORTER expressed himself in favor of intra-uterine irrigation, but said that much discomfort and pain is caused by it and much damage done if it is not properly performed. These disadvantages will be obviated if a flexible rubber tube is inserted into the uterus well up to the fundus. Frequent irrigation is followed by good results. Where portions of the placenta and membranes are retained, they are more easily removed with forceps specially constructed for this purpose, than with the curette.

DR. A. MONAE LESSER also referred to the frequent occurrence of malarial fever in puerpera, and recommended the administration of large doses of quinin and a liquid diet.

DR. JEWETT referred to Dr. Grandin's division of septic infection and said he would make three, *viz.*, *sapremic*, *mildly septic*, and *highly septic*. He emphasized the fact that the curette is permissible only when there are blood-clots and shreds of membrane in the uterine cavity, and that it is contra-indicated in purely septic cases. He was glad to learn from Dr. Noble of the beneficial effect which follows the intravenous injection of salt solution.

DR. GRANDIN took exception to the statement that it

is safer to examine the uterine cavity with the curette than with the hand because the former is cleaner, and said that the man whose hands are not clean enough to examine the uterus, is out of place at the obstetric bedside.

REVIEWS.

A SYSTEM OF PRACTICAL MEDICINE. By American authors. Edited by ALFRED LEE LOOMIS, M.D., late Professor of Pathology and Practical Medicine in the New York University, and WILLIAM GILMAN THOMPSON, M.D., Professor of Materia Medica, Therapeutics, and Clinical Medicine in the New York University. Vol. II., Diseases of the Respiratory and Circulatory Systems, and of the Blood, Kidneys, and Genito-Urinary Organs. For sale by subscription. Philadelphia and New York: Lea Brothers & Co., Publishers, 1897.

IT was no idle assumption to infer, after a careful reading of the first volume of this system, that each succeeding volume would be up to the high standard set by its predecessor. That this is true of the present book, the merest casual perusal will prove. A conscientious inspection of the work, however, brings out so many points of notable interest and value that we predict that its contents will long remain, in many parts at least, classic in American medical literature.

Almost the last, if not the last, article which the senior editor of the work wrote prior to his death is the one on "Endocarditis" contained in this volume. Here one reads experience, observation, practice, symptoms, and pathology, penned by the hand of a master. The style is so flowing and clear, the text so free from verbiage and diffuseness, the logic so convincing, that it is safe to assert that the subject has never been treated in a more perfect manner. Dr. Loomis need not have conceived this monograph to have produced a lasting monument to himself among medical readers; but if all his other works were swept away, this complete treatise on valvular disease of the heart would remain as a perpetual reminder of his greatness.

What is true of Dr. Loomis' article may be said of the others. Here and there are to be noted omissions and slight inaccuracies, but they do not mar the excellence of the entire work. The diseases of the respiratory and circulatory systems and mediastinum appear in the form of monographs, and bear many evidences of close editorial supervision, with an unusual result of harmony in the various articles. The diseases of the blood are assigned two chapters, those of the kidney four. The volume is concluded by three chapters which are devoted to the diseases of the bladder and prostate gland.

It may be of interest to point out that no mention is made in the article on pulmonary embolism of the frequency of an embolus from the crural vein as the cause of sudden death in elderly people, a pathologic fact to which Kolisko of Vienna has called attention. In the discussion of new growths of the lung the microscopic examination of pleural exudates for typical cells is not spoken of. These trifling inaccuracies are mentioned not in the spirit of

criticism, but to show how practically perfect the work is, since only such omissions have crept into it.

There can be no doubt that the "American System of Practical Medicine" will rapidly take its place among the best works on internal medicine ever published in this country. It is so thorough, so complete, so well-conceived, and so well-written, it represents so perfectly American medical thought and teaching that it is bound to occupy for many years an exalted station. The volume is beautifully illustrated and handsomely printed.

EYE-STRAIN IN HEALTH AND DISEASE. By AMBROSE L. RANNEY, A.M., M.D. New York: The L. A. Davis Co., 1897.

THIS volume is very appropriately named, for in the space of 316 pages the author treats only of the effect of eye-strain upon health and in causing functional disease. A very advanced position is taken as to the importance of eye-strain in producing chorea, epilepsy, and insanity, as well as such comparatively slighter affections as headache, neuralgia, insomnia, and neurasthenia.

The importance of errors of refraction and of heterophoria in causing the graver of these diseases was ascribed a high place and bravely supported by the author as far back as 1888 in his work upon "Nervous Diseases." While American oculists in particular have recognized the necessity of the most thorough test and correction of these defects, and have ascribed and proved them to be the sole cause of many forms of headache, neuralgia, and various forms of morbid eye-conditions, as styes, conjunctivitis, ulcers, etc., but few of them have supported the author in the stand he takes in epilepsy, chorea, and insanity. The volume contains a large number of very full and complete histories of cases well verified by consulting physicians, tabulated and arranged in a most convincing manner.

However they may disagree with the author on certain points, a great benefit would accrue to oculists and neurologists, and thus to their patients, by a careful reading of his book. It would be rare, indeed, to find one of either specialty who would in this day deny to the eye its influence in causing reflexes, and who would not wish to eliminate that possibility as a cause, or, at least, as having an influence, in cases like the above.

In Chapter II. are given the methods of making all the modern tests of vision and ocular muscles. One of the best features of the book is that every test is fully, but briefly, described, and the difficulties to be encountered pointed out.

Dr. Ranney's work deserves careful reading, even if some of his conclusions cannot be accepted.

TRANSACTIONS OF THE ASSOCIATION OF AMERICAN PHYSICIANS. Twelfth session, Philadelphia, 1897.

THE high standard set by this Association has been carried out in its meeting of 1897. The address of President Da Costa, on "Tendencies in Medicine," is a thoughtful and scholarly paper. Among the more striking contributions may be mentioned "Cancer of the Stomach in Early Life, and the Value of Cells in Effusions in the Diagnosis of Cancer of the Serous Membranes," by Dr. George

Dock; "Hepatic Complications of Typhoid Fever," by Dr. William Osler, and the report of a case of "Jacksonian Epilepsy; Adenoma of the Liver; Acute Ascites with Tubercle Bacilli," by Dr. A. Jacobi. It is most unfair to discriminate, since all the papers are marked by original thought and original research. The volume, as usual, is beautifully printed.

DIGEST OF CRITICISMS ON THE UNITED STATES PHARMACOPŒIA. Part I. Comprising Abstracts of Papers up to July 1, 1896. New York: 1897.

THIS is a review by the committee on revision and publication of the new Pharmacopœia of the United States. The committee has made abstracts of papers relating to its work, and they will be found of interest not only to those engaged in pharmaceutical work, but to every practising physician. We note particularly the desire expressed for a more scientific accuracy in the nomenclature of chemical compounds, and the plea that there is no apparent reason why the oil from American cods should not replace that from the Norwegian fish. The Digest shows that there is great activity in the profession toward the securing of accurate compounds and simplicity of nomenclature.

THERAPEUTIC HINTS.

For Frost-bite, when the skin remains unbroken, the following combination has been highly recommended:

℞ Camphoræ	3 i
Olei cajuputi	3 ii
Ætheris	3 i.

M. Ft., linimentum. Sig. Apply locally.

For Pyrosis.—Tincture of nux vomica is recommended by Ringer as an excellent remedy for gastric hyperacidity. It should be given in 5-drop doses in a small quantity of water a quarter of an hour before eating. For the same purpose Alonzo Clark recommended simple bicarbonate of soda in 15-grain doses to be taken in water immediately after meals.

For Acute Alcoholism.—The following combinations are recommended:

℞ Spts. ammon. aromat.	3 ii
Tinct. camphoræ	3 iss
Tinct. hyoscyami	3 iiss
Spts. lavandulæ co., ...	q. s. ad. 3 ii.

M. Sig. One teaspoonful every hour.

When the acute symptoms have been relieved the following may be substituted:

℞ Pulv. capsici	gr. xxiv
Quininæ sulph.	gr. xxxvi.

M. Ft. cap. No. xii. Sig. One capsule before each meal and continued for several days.

Should insomnia be an element administer the following:

℞ Sodii bromidi	3 ss
Chloral. hydrat.	3 iiss
Syr. aurantii cort.	3 ss
Aquæ, ...	ad. 3 iv.

M. Sig. A teaspoonful at bed-time and repeated during the night if necessary.

No. 17.

ORIGINAL ARTICLES.

WHAT CONDITIONS INFLUENCE THE COURSE OF SYPHILIS?¹

BY ROBERT W. TAYLOR, M.D.,
OF NEW YORK;

CLINICAL PROFESSOR OF VENEREAL DISEASES IN THE COLLEGE
OF PHYSICIANS AND SURGEONS; VISITING SURGEON
TO BELLEVUE HOSPITAL.

IN approaching this subject the first question which confronts us is, What is the syphilitic virus? Unfortunately we are not able at this time to answer this question in an absolutely scientific manner. Though our knowledge is very precise as to the *materies morbi* of diphtheria, tuberculosis, leprosy, and many other infectious diseases, we are as yet grouping in the dark as to the essential nature of the syphilitic poison. Coincidentally with the amplification and greater precision of our knowledge of acute and chronic infectious diseases, much light has been thrown upon the pathology of syphilis, but the knowledge comes to us indirectly by means of the study of the analogic evidence presented by acute and chronic infective processes. Thus, in diphtheria there is a demonstrable micro-organism which attacks the system in one spot, most commonly the throat, and produces fever, headache, malaise, neuralgia, paralysis, albuminuria, and general toxemia. The analogy between syphilis and diphtheria is very striking, but it lacks many features which are approximately supplied by such chronic infective processes as tuberculosis, which begins as a local infection, and produces marked cell changes resembling in a measure, those produced by syphilis and leprosy, the initial lesions of which we know nothing. Leprosy, in its chronic proliferative course, strikingly resembles syphilis. This analogic evidence—and much more could be offered—points strongly in the direction of syphilis being a disease originated by a virulent bacterium, and it seems singular that, when the initial lesion is so readily procurable for microscopic study, we have not yet the necessary knowledge or means of demonstrating the morbid element. However, I think it warrantable to assume that syphilis is a chronic infectious disease due to an as yet unrecognized microbic cause.

Though we know nothing of the syphilitic bacte-

rium, we fortunately are in possession of minute knowledge of the morbid anatomy of the initial lesion, and this teaches us much more than we formerly knew of the intimate processes of syphilitic infection. I will here briefly summarize the results of my studies,¹ in which I was aided by my friend Dr. Ira Van Gieson, and which I think are entirely trustworthy.

The initial lesion, from which the following facts were derived, was excised by me four days after its first appearance and eighteen days after the infecting coitus, consequently it presented the very earliest appearances of syphilitic infection which can be studied by means of the microscope. The chancre appeared as a minute red erosion, and consisted of a circumscribed mass of tissue resembling in structure ordinary granulation tissue, but under and beyond it, when examined microscopically, there was a very marked change in the condition of the blood-vessels. This change consisted in the distention of the perivascular spaces with small round cells. Nearly every vessel examined, both arteries and veins, was in this way enveloped by masses of small round cells, forming a sheath like a coat-sleeve around the arm. Besides this condition of the perivascular spaces there was a change in the endothelial cells lining the arteries and veins, which were swollen and seemed to be proliferating. In two or three places the process had gone on to such an extent as to produce thrombi of the medium-sized veins. Careful study showed that it was very probable that these perivascular cell-clusters were produced by the proliferation of the connective-tissue cells of the adventitia of the vessels or by the proliferation of the same cells, just exterior to the adventitia. The point deserving of attention, and it has been further demonstrated in the examination of chancres from other patients, is the extremely early and far-extending involvement of the blood-vessels. Although the primary sore was but of a few days' duration, very small, and under the microscope was of such limited and circumscribed extent, the blood-vessels were very extensively surrounded by cell investments at a considerable distance—fully an inch—from the ulcer. The microscope also showed how deep-rooted syphilis is at the very beginning of the sore, having extended along the perivascular lymph-spaces, and how futile it is,

¹ An address read at the Twenty-first Annual Meeting of the American Dermatological Association, Washington, D. C., May 6, 1897.

¹ *Medical Record*, July 4, 1891, and "The Pathology and Treatment of Venereal Diseases," pp. 528, *et seq.*, 1895.

as experience has already shown, to attempt to abort it by excising the primary sore. Apparently, judging from the appearance of the vessels in this case, their involvement begins before the appearance of the sore. The microscopic analysis of this and other cases also shows how it is that the infection of syphilis travels from the primary sore and infects the body. The perivascular spaces are lymph-spaces which communicate ultimately with the inguinal glands, and the enlargement of these glands is undoubtedly due to the advancement of this cell proliferation along the perivascular spaces until it reaches them. The same process extends from the inguinal to other sets of glands or lymphatics.

The process of syphilitic infection, therefore, is one of constant growth and diffusion from the beginning. In the very first days of the existence of the chancre the poison is deeply rooted in the subcutaneous tissue; it is in a most active state and progresses along the course of the vessels until it reaches the body, and then infects the whole economy. In consequence it is very certain that excision of the chancre will not cause the abortion of the disease. Reasoning by analogy, we are warranted in assuming that this new, highly infectious, and rapidly growing tissue gives off, probably by means of its microbes, a poison which diffuses itself through the system. We have then in syphilitic infection two orders of morbid changes: (1) the heterologous new cells; (2) the diffusible poison.

In many diseases of microbic origin the severity of the attack depends upon the activity and the quantity of the virus inoculated or received. When the microbes are derived from active and exuberant lesions they usually produce an intense disease in vulnerable subjects, but when the virus is attenuated or when the microbes are in a weakly state (involution forms), then the resulting invasion is less severe. To these features offered by other infectious processes syphilis does not seem to present points of resemblance. In other words, we know nothing of the mildness or malignancy of the syphilitic virus, and extended clinical observations made by many authorities go to show that a virus which produces severe syphilis in one individual may only produce a mild form of the disease in another. Therefore, in syphilis it may be said without fear of contradiction that the potentiality of the poisonous dose is about the same whether it be derived from a severe case of syphilis, or from a mild one. I could offer the histories of many scores of cases in support of this statement, but will content myself with briefly narrating one. Many years ago I had under my care a very strong young man who had a small and insignificant chancrous erosion on the penis. This young man,

in whom the secondary stage was very mild, contaminated a rather anemic young woman who developed a well-defined vulvar chancre in which there was a slight tendency to sloughing. This patient was attacked by the malignant form of syphilis which resisted intelligent treatment and careful nursing, and she died six months after infection. While she was in a very debilitated state, just before the onset of the malignancy which terminated her life, she had connection with four young men and infected them all with syphilis. Three of these individuals had mild secondary syphilis, and in only one was the disease somewhat severe. In all four cases the initial lesion was small and not much indurated. My belief on this question is in accord with the opinions of many authorities. Clinical observation has also proved that the potency of the virus is about the same whether it be derived from the initial lesion, a secondary lesion, or the blood.

From the foregoing statement of facts it seems warrantable to conclude that there is a well-marked uniformity in the infectious quality of the virus no matter from whom it may be derived, and that this poison may produce in some subjects a mild and in others a severe form of syphilis. It, therefore, logically follows from what has been stated that the benignity or severity of syphilis is determined by the condition of the individual.

Clinical observation clearly shows that in some patients, owing to partial immunity, the syphilitic poison meets with such resistance on the part of the tissues that it makes but a slight impression, while in others a marked susceptibility to its action exists, and a more or less severe form of the disease is produced. It has been claimed that, from certain features observed in the chancre and during its course, we may draw prognostic points as to the mildness or severity of the subsequent course of the disease. It has been said that a small, slightly indurated chancre is usually followed by a mild attack of syphilis. This statement may apply to some cases but certainly not to the majority. It is not uncommon to see all grades of severe syphilis follow an insignificant initial lesion which might have undergone involution in ten days or two weeks, and have left little if any trace upon the part attacked. How common it is to see severe and extensive syphilitic lesions in persons who never knew they had a chancre, and in whom it must have been very small! The truth is that both mild and severe grades of syphilis may follow small initial lesions. It has also been claimed that large and deep primary lesions invariably lead to severe forms of infection, but this statement is only partially true. I have seen many cases of mild syphilis follow a very extensive chancre, and

have also seen instances in which two or three parts of the body were the seat of chancres (penis, lip, and finger, or penis and lip, or other part), and yet the course of the disease was not at all severe. Indurating edema may complicate a chancre (presumably as a barrier thrown out by Nature against the threatened invasion), and involve the whole penis and even the scrotum, or one or both labia, and then this great swelling may be regarded as indicative of severe syphilis. Such an assumption is a mistake, as I have had the opportunity of seeing in very many cases.

Ulceration, phagedena, and gangrene, attacking the initial lesion, have been claimed to be ominous signs of a severe attack of syphilis. Extended clinical observation shows that this assumption is not fully warranted. Destructive ulceration of any form or gangrene attacking the initial lesion is always the result of contamination with pyogenic microbes, usually caused by carelessness and uncleanness and also by intemperate cauterization, and they are to be regarded as disquieting accidents and not as indices of the malignancy of the initial lesion or as forecasting a severe attack of syphilis. In some cases of phagedena and ulceration of the initial lesion a temporary condition of ill health is produced, but careful treatment will soon remove this accidental complication. It is also claimed by some authors that extragenital chancres are the forerunners of severe syphilis. This view is certainly based on the observation of a few exceptional cases, and is not borne out by extended investigation. I have reached the conclusion (and it is in accord with that of Fournier, Feibes, Haslund, and others), from the statistics offered in seventy cases observed and recorded by me, that the course of syphilis averages about the same in cases beginning in genital or extragenital lesions. It not infrequently happens that the nature of an extragenital chancre is not recognized or that it runs its course unobserved by the patient. In such cases the resulting syphilis may not be treated, or it may be improperly treated, and then a degree of severity may result. This view of the malignancy of extragenital chancres is in some instances, of which I have seen many, due to the hue and cry raised by infected medical men and nurses who, having innocently contracted the disease, take kindly to the mild form of martyrdom with its resulting sympathy from friends and acquaintances. They usually exaggerate their symptoms and give the impression that they are suffering from a severe form of syphilis.

Fortunately for the human race, syphilis in the great majority of cases is contracted by young men between twenty and forty years of age in whom the vital processes are active and whose health as a rule is good. Such patients are naturally capable of

withstanding attacks of various diseases, but some are more resistant than others. According to my observations it may be said that syphilis is much less severe to-day than it was thirty years ago. We no longer, not even in large syphilitic clinics, see so many cases of malignant, of severe, and of malignant precocious syphilis, nor do we meet with the more profound and grave tertiary lesions by any means as frequently as we did a quarter of a century ago. This diminution in the severity of the disease is largely due to our improved methods of treatment, to better sanitary and nutritive conditions, and to the greater attention which is paid to cleanliness and antisepsis. But further than this, there undoubtedly exists to-day in the tissues of many individuals a greater resistance to syphilitic infection than was possessed years ago. In other words, in many people a moderate condition of immunity against syphilis exists, which is due to the changes in the tissues and perhaps in the blood induced by syphilis in their more or less remote ancestors.

We are now in the position to study the course of syphilis in healthy subjects and to consider the influence of other diseases and of unsanitary conditions upon it. In a general way it may be stated that the larger number of persons who contract syphilis are those who are in average good health and have not grown old. In a smaller number the standard of health is less high, and in many patients certain morbid conditions exist which are due either to disease or bad habits, and which lower their power of resistance. Extended clinical observation shows very clearly that syphilis when untreated by mercurials runs a somewhat uniform course. Following the chancre, in due time the secondary cutaneous and mucous-membrane manifestations appear, and remain for a short or long period, and then they seemingly undergo resolution. Next a more advanced form of lesions, such as large papules or papulotubercles, are observed, and these may in time wither, and later on—in months or years—true tertiary lesions may develop. The tendency of syphilis, luckily for mankind, is to expend its force on the superficies of the body, and it seems very probable, particularly in healthy subjects, that the lesions of the deeper parts are, in the main, due to various determining causes, such as traumatism (bones, joints, tendons, and fasciæ), antecedent pathologic processes (liver, spleen, kidneys, intestines, and testes), and to a neuropathic tendency (cerebrospinal affections). When any of the above-mentioned causes exist in untreated syphilis, the grave order of lesions may follow or coexist with the more superficial ones. Some of these mild cases, in persons previously healthy, sooner or later become grave,

and even malignant, but in general the gravity or malignancy of syphilis is due to some inherent defect in the constitution of the patient, to some diseased condition, or to a lowered state of health due to privation or bad habits.

The pathology of early syphilis is revealed to us in the cell-infiltrations constituting the essential lesions which are distributed in a symmetrical manner over the whole body. With the evolution of this new growth a diffusible poison is developed which is carried throughout the entire system and gives rise to the various phenomena (fever, debility, emaciation, headaches, neuralgias, arthralgias, periosteal pains, splenic engorgement, and sometimes pleuritis). With the destruction of the newly formed cells by treatment the tangible lesions undergo involution and disappear, and in proportion to the completeness of their cure so does the poison secreted by them grow less and less in potency and quantity. When a perfect cure does not take place, some of these morbid cells remain (in all probability in little masses around the blood-vessels, and not stored in the ganglia), but as they grow old they lose their vitality and increase slowly, and, having lost much of their virulency, produce very little, if any, of the diffusible poison. This is what takes place in tertiary syphilis, in which the new growths are indolent, aphlegmasic, and show a marked tendency to localization and to asymmetrical distribution. The gumma is the direct and feeble descendant of the virulent round-cell infiltration of the secondary stage of syphilis. Such, in brief, is the nature and extent of the syphilitic invasion, which, if unchecked, goes on more or less rapidly to produce tissue-change, to lower the standard of vitality, to attack organs whose integrity is essential to life and happiness, and to produce serious conditions, and even death.

(To be continued.)

A CONTRIBUTION TO THE SYMPTOMATOLOGY OF HAY-FEVER.

By WILLIAM M. CAPP, M.D.,
OF PHILADELPHIA.

THE symptoms of so-called "hay-fever," a disorder more graphically designated by Sajous as hyperesthetic rhinitis, and by others as vasomotor rhinitis, have been so often and so fully described that they have become familiar and are easily recognized. Amid the diversity of manifestations, certain underlying systemic conditions may be said to prevail. One of the latter, connected with the nervous system, has not been dwelt upon, if indeed, ever pointedly mentioned by the writers upon this subject, who have been, on the whole, so indefatigable in their observations. I allude to a certain tonic

spastic condition which, although slight in character, is general, rather than confined to limited areas, and in large measure accounts for many symptoms of the disease. It is not intended here to inquire into its cause, but it may be remarked that a central nervous irritation is probably caused by the presence of disturbing elements in the blood, presumably products of faulty or imperfect metabolism, which should have been eliminated from the system. Thus, may originate nerve currents with innumerable reflexes, which, in the disturbed equilibrium of the system are, in a measure, uncontrolled by the ordinary inhibition. In this manner the hyperesthetic condition of the mucous membrane of the nose, the fauces, and the palate may be accounted for. Indeed, the general cutaneous surface becomes sensitive, and its functions disturbed. Doubtless the mucous membranes are likewise affected. Patients with this disease experience during exacerbations a feeling of nervousness, a general state of tension, restlessness, and discomfort, and mental and physical excitation, with alternating periods of consequent depression, and an inability to command placidity or self-control. It is as if the vasomotor mechanism, by overaction, disturbed the free performance of function, so that nutrition and elimination throughout the body are interfered with.

The tonic spasm persists for a time, gives way, and is succeeded by an opposite condition of relaxation. A fit of sneezing or other slight cause may bring this about. Then secretions are unlocked and there is an excessive discharge from the nose, eyes, etc., possibly looseness of the bowels following constipation, excessive bronchial secretions subsequent to a dry and irritated condition of the membrane, perspiration uninduced by exertion after a period characterized by a dry, feverish skin. Probably all the involuntary muscles of the body reflect more or less the nerve disturbance, and doubtless other manifestations in the way of symptoms might be recorded. One of interest relating to the muscles of accommodation of the eye the writer has observed in his own case.

About six years ago, owing to a presbyopic condition, it was necessary to adopt during reading a +0.50 D. spheric lens, and at the same time to correct a moderate astigmatism which had been previously overcome by the power of the eye, and the existence of which had until then been unknown. A lens was worn constantly for near work, and was generally satisfactory except during an attack of hay-fever, when it seemed to augment the symptoms, and, indeed, was so objectionable as to cause annoyances relieved only by dispensing entirely with its use. During several attacks the usual daily near use of the

eyes was more comfortably accomplished without artificial aid than with it. During the last two periods the eyes accepted the cylinder correcting the astigmatism, but did their work better without the spheric lens.

If we suppose that in this case the presbyopia was relatively more dependent upon an asthenic condition of the ciliary muscle than upon an inelasticity of the lens, the increased vigor of the muscle at the particular periods may be attributed to the general exalted condition of the nervous system attendant upon hay-fever through the tonic spastic condition above mentioned. The writer has not heard of other similar cases, although doubtless there are such. It is a matter of common observation that the muscle of accommodation may sometimes manifest more strength of action when the general health is unusually vigorous, but in the case described, its increased vigor is manifested at a time when the systemic condition is rather one of depression.

THE ABUSE OF MEDICAL CHARITY.¹

BY FREDERICK HOLME WIGGIN, M.D.,

OF NEW YORK;

VISITING GYNECOLOGIST TO THE NEW YORK CITY HOSPITAL.

IN presenting this subject it has been my object to place before you a critical review of the recent literature, rather than to present merely individual views. To the sociologist there is at the present time no subject of greater interest or one more worthy of careful consideration and study than medical charity; or, rather, of its abuse, as it exists to-day, and the remedy which must be applied for its correction, so that the greatest possible good may be accomplished with the least harm to those who receive, as well as to those who give. It is only necessary to call attention to a few facts to demonstrate conclusively that, as at present administered, medical charity is demoralizing to both recipient and donor, and that the charity mentioned in the Good Book has been disregarded during the last quarter of the century now rapidly drawing to a close.

It was recently stated in an editorial in a leading medical journal that a person asserting that one-third or one-half of the inhabitants of this city are paupers would be deemed a person of unsound mind; yet it has been said by Dr. Stephen Smith, in a report to the State Board of Charity, that during 1895, 837,971 persons applied for, and received free medical treatment at 105 dispensaries in this city, and that during the same period 1,418,847 free visits were made to these dispensaries; also, that during the same year 78,000 persons received free medical and

surgical treatment, including free board, lodging, nursing, drugs, surgical dressings and appliances, making a grand total of 915,971 persons who claimed during one year to be unable to take care of themselves, out of a total of 1,870,000, or something more than 49 per cent. of all who live within our borders. Dr. Smith has also been credited with the statement that during the period from 1791, when the first dispensary was established in New York, to about 1870, the applicants for medical charity bore a ratio to the total population of only 1.5 per cent., against the present ratio of 49.7 per cent. Surely these figures are alarming, if correct, and, from the well-known reputation of their compiler for care and accuracy, there is no ground on which to question them. It is a significant fact that about the time when this increased ratio began to be manifest was the period which witnessed the establishment of the so-called provident dispensary, both in this city and London. Again, when we consider the amount of money expended in this city during one year for charitable purposes, it seems certain that something is wrong; either a larger number of the people are unable to help themselves than should be the case, or the public and private money contributed for this purpose is sadly wasted.

The *New York Herald* of June 6, 1897, contained an editorial, in the course of which was said:

It is wholly within the mark to say that Greater New York spends \$50,000,000 every year on charities. The figure is stupendous, and the statement seems incredible, but a very little study, not of results, but of official reports, will fully justify both the one and the other. In round numbers New York proper, that is, the lesser New York, devotes in the neighborhood of \$2,225,000 to its own reformatories and charitable institutions. In addition to this it appropriates nearly another \$2,000,000 to the independent asylums, hospitals, reformatories, and other aid societies. This makes the total of \$4,000,000 to begin with. To this may be added another \$2,000,000, devoted to the same uses by other municipalities now comprised in Greater New York. This \$6,000,000 is only a mere fraction of the whole. There are within the boundaries of Greater New York over 3000 institutions devoted to the help of those who cannot help themselves. Of these, but very few receive and disburse less than \$1000; the disbursements of many run far into the hundreds of thousands.

The recent action of the County Medical Society with reference to the free dispensaries and the frequent hospital abuses throws some light on the mystery as to where all the money goes. It shows very clearly that in this feature of charity administration money that is intended for the poor goes, in a surprising number of instances, to people who are not poor—to people even who comparatively are rich. The public dispensary, in other words, and the public hospital, where some generous philanthropist has provided for the essentially poor free medicines and free medical attendance, are either so loosely or unwisely conducted that they are working in the community a sort of social revolution. It is getting to be no longer medical attendance and medicines free for the poor, but

¹ Read at the Fourteenth Annual Meeting of the New York State Medical Association, held at New York, October 12, 13, and 14, 1897.

free for all. If the poor can crowd into the throng of well-dressed men and women who ride up in their carriages, there is no objection to their being served. Millions upon millions of dollars have been given by benevolent New Yorkers in endowments and appliances for the free treatment of the ailments of the poor. It is conservatively estimated that fully fifty per cent. of the people who take advantage of this generosity are people whose financial position puts them wholly beyond the scope of the charity; in other words, that fifty per cent. of the donor's money is diverted from the purpose for which he intended it, and practically filched from the poor to whom it rightfully belongs. Inasmuch as a very large percentage of the sums of money which New Yorkers give in charity every year is devoted to the care of the sick, afflicted, and injured, it is obvious that these inroads of the well-to-do on the money provided for the poor alone account for a very large share of the failure with which New York's charitable efforts are met. The thousands of dollars in drugs, time, and attention bestowed by physicians upon people who have no claim whatever upon either would probably suffice to care for all the really legitimate cases of sickness and poverty in the city. If anything like a corresponding waste and misapplication of funds exists in the various other channels in which New York empties her fifty millions of dollars of gifts every year, it is not difficult to understand how so many of the helpless remain uncared for, while they starve in the midst of plenty.

The figures already quoted would seem to show that in the last twenty-seven years the ratio of those unable to care for themselves out of our entire population, has increased by 47.5 per cent., and that it is only a question of time, if this state of affairs continues, before the great majority of the inhabitants of this metropolis will demand (for what is received as a gift to-day will be regarded as a right to-morrow) not only free medical service, but free food, free fuel, free clothing, and free lodging. As has been well said, are not all these things as requisite to promote comfort and prevent suffering as medical services? A socialistic state will be reached, bordering upon anarchy. That this condition of affairs is not confined to our own locality is proven by recent reports of investigations, published in both the medical and lay press, to the effect that about 25 per cent. of the population of all large cities, both in this country and Europe, are at the present time receiving free treatment from institutions originally designed to serve the poor.

Some of the facts which have been rehearsed were presented last January to the New York County Medical Society in the inaugural address of the President, Dr. Landon Carter Gray, and, as a result, committees were appointed by the county society for the purpose of investigating the manner in which medical charities, but more especially the dispensaries, of this city are administered. A joint committee resulted. The whole matter was carefully investigated, and it was readily demonstrated that greater abuses existed than had been considered pos-

sible. It was found that little or no effort is being made to discriminate between the unworthy and the worthy, and that practically all comers are welcome and receive treatment regardless of financial condition at nearly all of the 116 dispensaries located in this city.

Dr. J. B. Huber, in an able paper on "The Abuse of Medical Charity," recently read before the Alumni Society of the City Hospital, graphically describes the clientele of some of these so-called charitable institutions. He says:

True, he will find there the worthy poor, the worthy object of charity, but he will find there also, in at least equal number, quite another sort of patient; he will find the actor, the opera-singer, the gambler and bartender, and hobnobbing amicably with these, the policeman and the clerk, and the young man who earns a respectable salary; he will find the farmer from out of town, the man who owns houses, and the prosperous business man; he may find there the broker, the lawyer, the journalist, the bicycle girl, the man who wants to know if his disease will interfere with horseback riding, and the lady who has left her barouche around the corner; and he may even run across a stray railway president. Besides these he will find there those who, at considerable preliminary expense, exhibit upon their faces the penalties which Venus inflicts upon her too ardent devotees, and he may find there also the demi-mondaine, with the rich backer who, it is rational to infer, receives as much money in a night as many a medical man in the city earns in a month in the practice of his profession. This does not by any means exhaust the list.

Again, Dr. George F. Shrady, in the course of an elaborate and instructive article, entitled "A Propagator of Pauperism: The Dispensary," published in *The Forum* for June, describes the scene which may be witnessed daily at the institution to which he has given the sobriquet of "the diamond dispensary." He says:

The reception-room held about two hundred at a time; nobody was turned away; fully 50 per cent. of the applicants were well dressed, and 10 per cent. were finely dressed. Three women wore fur coats that had not been handed down from somebody else. There was an attractive display of fine millinery, and the men, more than half of them, bore no evidences of poverty. But all obtained free treatment supposed to be given to paupers—poor persons. Such instances as the following carry with them their own moral. During the examination of a dispensary patient a roll of bills dropped from her pocket, and the doctor picked it up and remarked: "Madam, this is a free dispensary, and as you are able to pay a fee for medical advice I must decline to treat you here." "Well," replied the woman, "that money is for something else; you are paid by the city and must prescribe for me." On being assured that the doctor received no salary from any source, the patient became indignant, and protested that she was entitled to attention equally with the lady who had preceded her, and from whom she had rented her house a week before.

The *New York Herald* of June 19, 1897, in the course of an article describing the visit of a reporter to a well-known clinic, said:

It was stated at the clinic that during the hours named the number of patients was sometimes as large as five hundred, and that the attendance yesterday was up to the average. There was certainly a continuous stream of men, women, and children coming in, and, at a rough and conservative estimate, the total must have been very nearly four hundred. No one was seen to arrive in a carriage, nor was any finely dressed man or sumptuously attired woman observed in the crowd, but, on the other hand, those whose dress and appearance denoted an extreme degree of poverty were certainly in a very large minority. The common unsophisticated idea of a dispensary patient probably is a person who, if he is not a pauper is next door to one, a person whose earnings suffice at most to do no more than keep a poor shelter over his head, a poor covering upon his back, and enough poor food in his body to prolong life—in other words, a person actually so destitute that medical attendance and medicines must be given to him outright, or for the merest pittance, or he must go without them. This may not be a correct definition of a legitimate dispensary patient. If it is, it is difficult to resist the conclusion that not more than one in twenty-five—the pen is tempted to write, one in fifty—of the applicants treated at the ——— clinic yesterday afternoon was a legitimate patient; not more than one in fifty was at all shabbily dressed; a large majority were fairly well dressed; one-third of them, it would be safe to say, were quite presentably dressed; a few, perhaps as many as one-fifth, dressed positively well. Much the greater number of the patients were women.

The following are a few instances out of many of the abuses which have come under the writer's personal observation: A number of years ago, while serving as district physician to an uptown dispensary, he was called to see a baby who was too ill to be brought to the institution. Upon reaching the abode of the little patient's parents, he was surprised to find evidences of prosperity rather than of adversity, and as he entered the door a well dressed man walked out. On being questioned, the mother said that the man was her husband; that he had plenty of work and good pay, and that the reason she had sent to the dispensary for a doctor was because every other inmate of the house had a physician for nothing whenever they cared for one, and she thought there was no reason why she should send for a pay doctor.

More recently, the case of a man came to my notice who lives in one of the largest and finest apartment-houses on the west side of the city not far from Central Park, and who pays several thousand dollars a year for rent, and who expends many thousands for living expenses. Requiring some special advice, instead of going to the office of the specialist he wished to consult, he went to his clinic at "the diamond dispensary," saying to his wife that he could not afford to pay a fee to the doctor as his expenses were too heavy.

Another instance was that of a wealthy and prosperous manufacturer, who lives in a thriving town not more than a hundred miles away, who, having

some nasal difficulty, wished to consult a specialist at his office, but did not desire to pay the doctor's usual fee. He, therefore, borrowed some clothes from one of his employees, and presented himself at the doctor's office. When admitted to the physician's presence, he regaled him with an account of the difficulty of earning a living and supporting a family. After examination, it was decided that an operation would be necessary before the patient could experience relief. On account of assertions as to limited means, a very small fee was asked for the operation, but when it was named the patient said that he could not possibly pay it, but could pay half the amount. This was accepted, and the operation performed. The patient experienced relief from his difficulty, and has since frequently narrated this story as a good joke, and as showing the limited business knowledge and acumen of physicians. The moral turpitude involved in his action was entirely overlooked.

In an article, entitled "From Him That Hath Not; or, How the Rich Rob the Poor by Getting Medicine and Treatment at Charity Dispensaries," by Winnifred Black, in the *New York Journal* of July 11, 1897, it was stated:

I saw well-dressed and well-fed women coming and crowding the wretched suffering of poverty from the door. The same observer, upon asking one of the well-dressed women why she frequented a place intended only for the relief of poor persons, received this reply: "If other people get medicines for nothing, I guess I can." Another reply to a similar question addressed to a prosperous looking girl, was: "Spend money for doctors when I can buy ribbons with it? Well, I guess not!" And again, a smart, prosperous business woman's answer as to why she came for free treatment, was: "Aint I a widow with a child to support?"

It would seem to be needless to multiply illustrations of what is daily occurring, for the instances quoted certainly show the spirit in which charity is asked and accepted; it is largely a desire to save money without apparently thinking that self-respect is lost in the effort, or that a wrong is done to the really poor, and to the physician who is certainly as much entitled to his hire as the clergyman or other members of the community, as he too has social obligations to fulfil.

Dr. Schweck, in the *Philadelphia Press* of June 11, 1897, in the course of a paper, entitled "The Dispensary and the Abuse of the Poor," says:

The woman who makes shirts for a dollar a dozen, the girl who stands behind a counter for four dollars a week, and the scrub-woman with others dependent upon her, who gets a dollar a day, all constitute our worthy poor. They have themselves and others to board and clothe; their time is worth more to them than that of the most successful business men. These are the people that are eligible for dispensary service, and should have the very best that can be given them. Here, to this place of charity, comes also

another class, a distinct class, the moral and lineal descendant of the ghouls, that follow in the wake of an army and rob the fallen soldiers; it is a class of people who constitute the vanishing point in the perspective of human affairs; they have money, but that is all. People of means who go to charity dispensaries and receive treatment free of charge, representing themselves to be too poor to pay for medical services, commit a criminal act; for they obtain what they are not entitled to, and do it under false pretenses.

Referring to the abuses of medical charity in other cities, the *New York Times* of August 16, 1897, says:

Hospital abuses in Chicago must have reached a point calculated to astonish even those New York doctors who have been so vigorous and persistent of late in denouncing similar wrongs that exist here. From a single Chicago hospital 245 undeserving recipients of charity have just been rejected; some because there was little or nothing the matter with them excepting a yearning for free food and lodging, and the rest because they could well afford to pay for the services of the private physician. The patients of the latter class are numerous enough here, but, as far as known, New York hospitals have not as yet become the resort for tramps to the extent to justify their name by tramping.

It is the writer's belief, founded upon his experience in the local hospitals, that a careful investigation of the inmates would reveal a similar condition of affairs here, if not a worse one.

In the *New York Times* of October 12, 1897, Superintendent Bauer of the Department of Public Charities of this city is credited with having reported to the Board a saving of \$1,313,471 in fifteen months as a result of investigations into the claims of the inmates of the various private charitable institutions receiving city aid. The bills of the institutions referred to showed that 26,561 persons were being supported, and the investigation demonstrated that 13,285 of these were unworthy objects of charity.

An instance cited by a commissioner as evidence of the necessity of making a careful inquiry into the claims of applicants for relief was that of a boy whose name had been carried for seven years on the books of an institution as a city charge, and \$104 collected annually from the city for his support; whereas he had in reality been living on a farm during this period of time.

The *Lowell* (Massachusetts) *Mail* of September 23, 1897, referring to the same subject, said:

Boston is having trouble with abuses of free dispensaries, as New York and other large cities have had for some time. So many rich patients go to the dispensaries that the poor, who really need them, are crowded out, and the struggling practitioners, who really need rich patients, are crowded out too. Stories have been told of people driving in carriages to the doors of the dispensaries to receive treatment gratis, all of which goes to prove what has often been stated, that those who are willing to ask for charity are not generally those who need charity the most.

The latest form of dispensary abuse has recently been reported in the *Medical Record*, which says:

A report comes to us, as we are about to go to press (as the country weekly puts it) to the effect that a physician has been dismissed from one of the most fashionable dispensaries in a neighboring city—of course, it could not occur in New York—for abstracting a 50-dollar bank-note from the purse of a patient. The pocketbook was left upon the dispensary desk while the lady entered the adjoining room to prepare for examination. The plea made to the governing board by the physician was, that he had been overworked, having treated over four hundred patients in the dispensary for the three days preceding the temptation which caused his fall, and during this time he had been unable to procure but one full meal. Hunger, and the means at hand to satisfy it, may have proven too strong a combination for his over-wrought nerves. This naturally did not weigh with the board. The clientele of the institution must be made to feel that while the patron is undergoing treatment his valuables are safe. The argument was used by one of the governors that, if the patients' money is to be taken from them they might as well go to a physician's office and be done with it. The crime of robbing a dispensary patient cannot be too severely punished, as such acts will deter many patients of wealth from patronizing these institutions. It is, therefore, most fitting that the culprit in the present instance will be forced to take his chances for the future in private practice.

It is a well-known fact that ever since the world began man has been seeking to obtain something for nothing, or without effort; and it is equally agreed that this is an immoral desire, and ends in disaster to those who indulge and practise it, as well as to those who aid and abet. From the evidence already adduced it cannot fail to be seen what an injurious work the so-called indiscriminate medical charity is doing, and that its tendency is to corrupt individuals and pauperize whole communities. The receiving of free treatment by those who are able to pay actually robs the poor, as only a limited number of persons can receive proper attention.

Dr. G. M. Roe, Medical Superintendent of the Boston City Hospital, in a communication to the *Boston Herald* of June 12, 1897, said:

It is a generally accepted fact among people who have had large experience in doing charitable work, that the first thing a man or woman will accept as charity is medical attendance. They will accept the free services of a doctor when you could not prevail upon them to accept rent or fuel, or anything of the kind, as a gift. The acceptance of gratuitous medical attendance is the first step towards pauperism. There is already a tendency towards what is generally known as "nationalism," a belief among the common people that the city and the State owe them a living, and that medical attendance, among other things, should be furnished by common taxation, regardless of the financial standing as individuals.

Dr. J. J. Stevenson, in the course of a communication on this subject to the *Mail and Express* of May 20, 1897, says:

One cannot shut his eyes to the terrible injury done to the poorer people by this perversion of trust. If food be

abundant and obtained without labor, it is wasted; if money be obtained without labor, it is wasted; "easy come and easy go" applies in both cases, and equally so to health. If recovery from disease be secured at the expense of self-denial, the memory of the cost will lead, in ordinary cases, to care, that recurrence of disease and attendant expenses may be prevented. But if the careless feel that treatment, medicine, and even diet may be had simply for the asking, there can be no reason for resisting the natural tendency to neglect the laws of health. The indiscriminate medical charity is but one phase of the morbid philanthropy which seeks to be doing something which appears to be good—a philanthropy which has done much to degrade man; it has done much to increase the dissatisfied class, and has been the efficient ally of the social agitator. The thoughtless charity of 1873 did much to give America the tramp; that of 1883 increased the horde; that of 1893 and 1894, in this city, converted great numbers of worthy families into mere receivers of alms, who soon lost self-respect and turned upon their benefactors with bitter reflections upon the charity that could provide such food and such clothes. Discontent no longer mutters, but speaks so boldly that the politicians are dismayed while the demagogues exult. The rights of ownership to property are denied because a *proletariat* exists. We are told again and again that the rich have acknowledged themselves as responsible for the wretchedness of the poor, having provided food and clothes in time of need, having established hospitals, dispensaries, and diet-kitchens for the sick, and distribution having been made in great part without careful inquiry as to the absolute need, and not requiring anything in return. It is not surprising that the reckless poor see in such careless giving an acknowledgment of the unequal distribution of wealth, and believe that it is founded on injustice; nor is it strange that the anarchist's cry is not for opportunity to earn by labor, but for such distribution of wealth as may enable all to enjoy the luxury of idleness.

Another physician, writing on this same subject in the *New York Evening Post*, said:

And there is another side to the story also. The free dispensaries, which are such worthy charities in theory have, through several causes, become dangerous menaces, not only to us, but to society in general; they absolutely encourage begging and dependence on charity. People who can well afford to pay for their treatment, and for medicines, have become so hardened that they will stand in line to receive their drugs for nothing; they will be indignant if it is suggested to them that doctors cannot afford to give them aid for nothing any more than any other class of men. It seems to them that we are employed by the city to help them, and in many cases they are not even grateful. Think of a dry-goods man who would be compelled to open his doors to a trade, and devote sometimes a day to dispensing his goods to them—even if the goods were paid for, his time would be lost. Where is the justice in making a distinction between the doctor and the merchant?

Dr. Douglas Hunt Stewart, who has made a careful study of the subject of dispensary abuses, in the course of a communication to the *New York Tribune*, says:

The financiering of many medical charities gives the impression that it is proper for a citizen to receive something for nothing. This is the teaching of socialism, which the "*Tribune*" has always opposed, and it is the code of the counterfeiter. The question of right does not enter into

the matter at all. Legally, no man has a right to steal a loaf of bread to feed his starving family; there may be mitigating circumstances, but the law brands such an act as theft. Is he any less guilty who steals a physician's services under vague pretenses? The only man who claims the right to receive alms is the highwayman, who puts a pistol to your head, and exclaims: "Your money or your life." Another class of recipients of charity may be compared to the street beggar who simply asks for money, and trusts to effrontery and persistence to obtain it. The third class would be the deserving poor whom everyone wishes to help, but who are too timid or too proud to avail themselves of the aid provided. This last class the dispensary often treats with scant courtesy, and deprives them of time and services necessary for the relief of their ills. It may be as hard for the worthy to raise the 10 or 20 cents demanded as for the moneyed pauper to raise as many dollars, yet the latter is the persistent seeker for free treatment to the detriment of those for whom the dispensaries were founded.

Again, in the course of an editorial in the *Evening Sun* for May 26, 1897, entitled "The Physician and the Dispensary," it was said:

Leaving the physician and the fee out of the question, surely it is right that the medical attention offered the needy should not be claimed by others. Many of the hospitals and dispensaries intended for the relief of the poor are supported by public money and private gifts which should not be devoted to those who can pay for medical advice. To permit knowingly such an abuse is entirely indefensible, and is in the nature of a breach of trust. It is besides an encouragement to fraud, and an incitement to that system of getting something for nothing, which may be termed "dead-beatism," and, therefore, it is immoral. The most extreme form of socialism when compared with the use of free hospitals by the well-to-do is laudable and commendable.

From what has gone before, it appears that not only is medical charity abused in all large cities, but this abuse is encouraged by loose and careless methods, if not from worse motives. The writer has been frequently told by physicians connected with dispensaries that they were well aware of the fact that well-to-do persons applied for free treatment, and that they were not sent away because it was known if they were turned off they would go to a rival concern and receive the desired treatment there. Consequently, other things being equal, they preferred to have as good a class of patients as possible. We have seen, as Dr. Colton has said, "that some patients are compelled to apply from a desire to save money at the expense of self-respect; others while paying for the treatment of ordinary diseases think that they cannot afford the fees of specialists; while another class is made up of persons sent to hospitals by physicians who do not care to operate; and a fourth class consists of taxpayers who imagine that they have a right to resort to institutions which they help to sustain."

There can also be no reasonable doubt that we physicians, as well as the managers of dispensaries,

are responsible in many ways for the existence of the present lamentable conditions.

In the writer's opinion, the first step which should be taken toward remedying the existing abuse should be an effort to educate the laity to believe that medical professional services have a pecuniary value, and that it is morally wrong for those able to pay even a moderate fee to try to get these services for nothing.

It would be a great aid in this direction if physicians connected with charitable institutions, in whatever capacity, were paid for their services. There certainly appears to be good reason why they should, and none why they should not be compensated. In this connection I will quote the following extract which appeared some time since in the "*Evening Post*:"

There is no more reason why the medical services rendered by the house-staff should go unpaid than there would be for trying to get for nothing nurses, attendants, rent, coal, milk, drugs and druggists, clerks and superintendents. The laborer is worthy of his hire, and if a thing is worth having, it is worth paying for. The physicians of this city are subjected to as deleterious a sweating system as any body of East-side tailors.

It has come to the writer's notice a number of times within the last few years, that members of the house-staff of the hospital, of whose visiting staff he is a member, though bright and well-educated young men who have secured their positions by reason of passing successfully a competitive examination, have been obliged to resign because they were only supplied with board and lodging for six months out of the eighteen months which the service calls for—they being unable to provide for themselves. There is certainly something wrong with a system which makes such sacrifices necessary, especially where a man is required to be constantly employed in the city's interests from 9 A.M. to 5 P.M.

A law should be enacted similar to that introduced by the joint committee already referred to, and which was passed unanimously by both houses of the legislature on April 14, 1897, but which failed to receive the signature of the Executive. This bill would have placed all institutions which dispense medical charity in this State under the direct care and supervision of the State Board of Charities, and, through them, of the local boards. These local boards should investigate the financial condition of all applicants. Of course, emergency cases should be treated first and investigated afterward. In speaking of this bill in its editorial column on May 26, 1897, the *Evening Sun* said:

With regard to the physician's attitude toward the abuse which the County Medical and other societies are fighting, some consideration is due him. Much of his labor and time are given gratuitously. Some of his patients are never able to pay him, and he does not press

them for payment, in which respect he is unlike the lawyer, who seldom fails to get his own. Others of his patients, it may be added, refrain from paying him so long as payment can be deferred, or even defraud him. Public opinion will, therefore, support the physician in his contention that the well-to-do patients of free hospitals are morally bound to go to him for advice.

In speaking of the investigation of the applicant for medical charity, the *Boston Herald* of June 12, 1897, said:

In Boston at present the instances of the abuse of medical charity appear to be far fewer than in New York or London, but it is none the less a fact that in this city, as elsewhere, there is reason for reform. This, it has been suggested, may be accomplished by two methods—popular education and more stringent regulation for the admission of applicants for hospital and dispensary treatment. If the people are more fully informed as to the investigation which each case receives before admission to the hospital, and if that investigation always involve something more than the mere statement of the patient that he or she is unable to pay, there would probably be fewer applicants for free treatment, and the private practice of physicians would be increased. Not long ago a man was operated upon gratuitously in one of the city hospitals, and was cared for also without charge in a ward for several weeks after the operation. He had declared his inability to pay for his treatment. The doctor who attended him realized the seriousness of the case and devoted all his energy and skill, as well as a great part of his time, in effecting the cure. About a week after the patient was discharged the doctor received a letter of thanks from him, and an invitation to visit him in New Hampshire and enjoy a few days of woodcock shooting. The writer enclosed a photograph of his home, which the camera depicted as a finely kept country house with a large stable in the rear. The lawn was ample and closely trimmed, and in the foreground of the picture several handsome horses were being held by stable-boys. The doctor did not accept the invitation, but he keeps the picture where he can see it, as a constant reminder that "all things are not as they seem." In this case cream masqueraded as skimmed milk.

Dr. F. T. Roger of Providence, R. I., in a practical and instructive paper before the American Academy of Medicine at Philadelphia, on "The Results of a Year's Experience in Endeavoring to Lessen the Dispensary Abuse in the Rhode Island Hospital," said:

The method adopted was to prominently display at the entrance of the dispensary a large placard stating that the services of the dispensary were given only to such patients as were too poor to pay, and that no others would be treated. There was the same statement on the case-card given the patient, and as a presentation of the card was an essential for admission, this fact was forcibly impressed upon all applicants for gratuitous service. Exceptions were made to this rule in emergency cases, such as recent accidents, cases of sudden illness, and cases in which a doubt existed as to ability to pay, and where delay in treatment would work hardship; and to the ignorant foreign classes who could not understand hospital rules. The plan has been successful, and during the year 1932 applicants were rejected, thus weeding out forty-one per cent. of unworthy applicants. The receipts of the hospital have been the same, and it is unfair to conclude that

the hospital is in any sense poorer; it has done less work, and has done quite as much in relieving suffering among the deserving poor. Those who failed to come, having a real ailment, must have consulted a physician, and presumably paid for his services."

The above plan was also advocated by Dr. Emma B. Culbertson, in a recently published article in the *Bulletin of the American Academy of Medicine*:

It should be a misdemeanor, punishable by a fine, for any one to receive free medical or surgical treatment by reason of false representation as to their financial condition, and applicants should be required to sign a printed slip declaring their inability to pay. By so doing, if they prove upon investigation to be amply able to pay for what they have received "they have thus incriminated themselves by declaring over their signatures that they have obtained by false pretense that to which they were not entitled."

Charitable institutions should not be allowed to charge nominal sums for medical and surgical treatment, nor should they make any charge for medicines or appliances, as such charges seem to ease the public conscience and make the individual believe that he is paying his way, and, therefore, has a right to go. It has recently come to the writer's knowledge that a lady, living in a large and fashionable apartment-house, visited a dispensary located near Fifth avenue, and where a charge of a dollar a month is made. Upon being taken to task by a friend for having visited a place intended for poor persons, the lady replied that needing a specialist, and not knowing where to procure one, she had visited that dispensary and had paid all that she was asked; and that if the fee had been twenty dollars instead of a dollar, she would have willingly paid it.

Dr. Douglas H. Stewart, in a letter to the *New York Tribune*, dated June 2, 1897, on the subject of the misuse of trust funds involved in present methods of management, says:

We desire to see that money left to institutions by will for specific purposes is applied in accordance with the intention of the donors. We believe that the bill endorsed by the medical societies and favored by the State Board of Charities, was a move in the right direction to do away with very great abuse and injustice to the over-burdened taxpayer and the needy poor, and that it should have received the approbation and assent of the governor. The State Board is not the representative of the medical profession alone, but of every person, be he donor or receiver of alms; it is the accredited and legitimate guardian of funds now squandered through unreasoning sentiment for the exploited and uninvestigated needs of the so-called poor.

Summary.—(1) That medical charity, as at present administered, is an unqualified evil, and is seriously menacing our existing social conditions; (2) that the application for free treatment of those able to pay the physician a moderate fee for his services robs the poor; (3) that all medical charitable institutions should be under the direction and control of State and local boards of charities, who should have the power to enforce their rules; (4) that all applicants for medical charity should be investigated by local charity boards, and the unworthy excluded;

(5) that no medical charitable institution should be allowed to charge nominal sums for medical or surgical service, nor should they be allowed to charge for medicines or appliances; (6) that *all physicians* connected with charitable institutions should be paid for the service which they render; (7) that it should be made a misdemeanor, punishable by fine, for any person to receive free medical treatment by reason of false representations as to financial condition; (8) that the financing of many medical charitable institutions involves as at present conducted a breach of trust; (9) that no State or city aid should be granted to private medical charities.

AN ADDRESS.

THE CAUSES OF A DECLINE IN THE AVERAGE INCOME OF GENERAL PRACTITIONERS OF MEDICINE.

BY CHARLES PHELPS, M.D.,

OF NEW YORK;

VISITING SURGEON TO BELLEVUE HOSPITAL.

THE attention of the medical profession of late has been somewhat anxiously directed toward a conceded lessening of its pecuniary returns. There seems sufficient reason for believing that the average income of medical men has been seriously diminished. It is true that at the present time a certain number of specialists, surgeons, and consulting physicians in large cities receive even extravagant compensation, but a majority of the members of the profession who compose its rank and file, the family physicians and general practitioners, have suffered a grievous pecuniary loss. This loss has been especially felt in this city, and the profound impression it has produced is demonstrated by the organized effort which was made during the past winter to obtain relief by legislative enactment. Actuated by a belief that abuses of medical charity are in great part responsible for the financial depression in professional business, medical societies and a very considerable number of individual physicians in New York were enlisted in an effort to restrict the charity of hospitals and dispensaries to those individuals who are its proper recipients. This attempt to obtain legislative relief, which was so energetically and enthusiastically urged by those who are beyond the necessity for such action, as it was by those less fortunately placed in life, failed to receive executive approval, and is now referred to only as evidence of the general recognition of the reality and extent of the evil which has been assumed.

It is a mistake to suppose that the shrinkage in the revenue of the great body of physicians is solely attributable to an unwarranted increase in gratuitous aid to the sick, or to any other single agency. The causes of all notable changes in social conditions are complex, and the most effective are likely to be general rather than specific. The business of professional men has a purely commercial

¹ The President's Address delivered at the Fourteenth Annual Meeting of the New York State Medical Association, New York, October 12 to 14, 1897.

aspect, and like that of the merchant, is not only influenced by individual aptitude, but is subject to conditions beyond individual control; it is governed by the universal law of supply and demand as evidenced by the general prosperity, or financial depression of the community. Its aspect may, of necessity, be radically changed by the introduction of new economics and the application to practical affairs of new ethical standards evolved from prevalent modes of thought and forms of mental activity.

In a review of the causes which may reasonably be supposed to account for the loss of professional income, the one which logically comes first may at the same time be regarded as of most essential importance. It is demonstrable that the total amount of sickness in the community has very considerably decreased, and the aggregate of professional fees must in consequence be correspondingly diminished. If it cannot truthfully be said that people who are well do not require the ministrations of the physician, it may be assumed that imaginary illness will always exist as a measurably fixed quantity, and that the number of those who are really ill primarily determines the amount and variation of the physician's annual revenue. The improved condition of the public health, which has resulted from advances made in the study of pathology and of general hygiene, and from the practical application of such knowledge in public sanitation, is beyond question. The discovery of the pathogenic germs as the direct causes of disease and of the conditions under which they are produced, propagated, and destroyed has been utilized in the prevention of disease by the adoption of measures for the comprehensive destruction of pathogenic microbes, and for the establishment of conditions under which their reproduction is limited or rendered impossible. The number of diseases which may be traced to the action of specific bacilli and which may be classed with those that are preventable is constantly augmented; and the study of preventive medicine has become of paramount interest to both surgeons and physicians, though it certainly has not been conducive to their pecuniary profit.

The practical work suggested by the conclusions reached in the laboratory has been so intelligently and efficiently directed in this city and elsewhere as not only to justify its theoretic basis and satisfy the medical profession, but even to convince the general public of its beneficence, notwithstanding the enormous expense which it has entailed and the apparent invasion of personal rights which is sometimes necessary. Specific instances of the eradication or limitation of disease by the Health Department of this city may readily be cited. Epidemic dysentery is now unknown. Variola has practically ceased to exist, and systematic compulsory vaccination by the agents of the Health Department has at the same time almost destroyed a source of once considerable revenue to the general practitioner. Typhus fever occurs only sporadically, and then is directly imported. Typhoid fever has become comparatively infrequent. The enforcement of a reasonable standard of purity of the milk-supply and of sanitary regulations in regard to plumbing has greatly diminished the number of gastro-intestinal disorders, as has better

hygiene of schools and tenement-houses those of the respiratory tract. The isolation of all cases of measles, scarlet fever, and diphtheria, and the subsequent employment of thorough disinfective measures has minimized the danger of contagion, and correspondingly reduced the frequency of their occurrence. Epidemic influenza, malarial fevers, and rheumatism, unhindered by official sanitary restrictions, pay undiminished toll to our profession.

It would be a grave injustice not to acknowledge the essential aid rendered to the sanitary authorities by physicians in private practice, who have not only made possible the enforcement of sanitary regulations which otherwise would have been impracticable, but have striven as assiduously for the prevention as for the cure of disease. Aside from the decrease in the number of cases of illness, some diminution in the physician's work may be fairly attributed to the employment of better methods of treatment by which the duration and severity of many diseases has been sensibly lessened.

The improvement in the health of the community which has resulted from a better knowledge of the proximate causes of disease, and from more efficient employment of preventive measures has been so gradual that its realization, as a fact related to a decrease in the aggregate of medical fees, is even yet imperfect. General forces which are gradual in their operation are not always immediately connected with their effects, and, as in this instance, may fail to be properly recognized if more direct and tangible causes are apparent.

The decrease of sickness may be estimated to some extent from mortuary records. From a table prepared through the kindness of Dr. Roger S. Tracy, Registrar of Records, it will be seen that the number of deaths occurring during the first eight months of the current year in this city from certain diseases selected as illustrative, and in total, is notably smaller than during the same period in 1895 or 1896. The comparison is necessarily confined to fatal cases; but as these have been found to hold a fixed relation to the whole number of cases in which illness is sufficiently severe to confine the patient to bed, it is all that is required for the purpose:

Total deaths, and deaths from certain causes during eight corresponding months of these different years are as follows:

Causes of Death.	1895.	1896.	1897.
Diphtheria.....	1194	1132	1034
Pneumonia.....	4094	4075	3200
Typhoid Fever.....	155	150	155
Malarial Fever.....	49	68	80
Phthisis.....	3523	3481	3243
Scarlet Fever.....	397	311	350
Diarrheal Diseases.....	2464	2380	1917
Respiratory Diseases.....	6019	5607	4542
Total Deaths from all causes.....	30,699	30,307	26,866

It will be observed that, while the total number of deaths was very nearly the same during corresponding months of 1895 and 1896, it was much less during the same period in 1897. This statement is independent of

the increase in population which makes the actual reduction in the death-rate appreciatively greater.

The ratio of trivial to serious illness cannot be statistically explained, but every physician knows that the balance is greatly in favor of trivial illness. It is similarly known that the lessened demand for the services of the physician in these minor ailments in which the patient may or may not be confined to the house, but not to the bed, is even more noticeable than the decrease in the number of more serious or fatal cases. The individual experience of the physician is corroborated by that of the pharmacist whose business reflects that of the physician, and indicates by its decrease that patients whether gravely or slightly ill have grown fewer.

Another reason for the leanness of the doctor's exchequer during the past year or two may be found in the general business depression, and in the resulting attenuation of the incomes of all sorts and conditions of men. This has necessitated the exercise of economy at the extremes of society, and, in fact, in every station of life. Medical services, long recognized by the practitioner as quite unnecessary, except as they allay apprehension or relieve *ennui*, have come to be more nearly appreciated at their exact value. The physician has been conscientious, as he has given the attention which has been demanded; now, it happens that when it is suggested that a daily visit is unnecessary, he is oftener taken at his word; or the person with some trivial ailment waits until the necessity is apparent before summoning the doctor or calling at his office. The little soreness of the throat, the slight cold in the head, the muscular pains here and there, the patient's suspicion of "malaria" or his certainty of "wind colic" no longer bring a consultation to the doctor and a prescription to the chemist as often as they did in a time gone by.

In the opinion of leading pharmacists, the growing habit among physicians of directing the use of the various tablets, triturates, and ready made medicinal combinations in place of complicated prescriptions to meet the therapeutic indications has much favored the tendency toward direct traffic between patient and apothecary. If the patient is of that class whose income affords no margin for luxuries and scarcely any for extraordinary expenses, he waits in the face of impending illness so long as he may, and when compelled to seek relief turns to charity, though unwilling, perhaps humiliated, and always suspicious of that which has cost him nothing, his poverty but not his will consenting.

The want of a proper adjustment of medical fees to the circumstances of the patient has undoubtedly injured to pecuniary disadvantage of the physician. The cost of medical services to people of affluence is not usually excessive, but to those depending upon a small annual stipend, and to those who, poorer still, are yet desirous of private medical attendance, it is, though perhaps not beyond the desert of the professional man, at least often disproportionate to the ability of the patient to pay. Many are driven against inclination to hospitals, clinics, and dispensaries who, to the extent of their means, would prefer to pay for medical services, but who are utterly unable to

meet the demands of the physician in whom they have confidence. It is not altogether the fault of the medical man, who is often enough ready to conform his fee to the ability of the patient to pay; but in this country we are so heavily taxed for conscientious work—the honest worker makes us pay so tremendously for his honesty—and that which is a little cheaper than the best is so atrociously bad, that unless the doctor is expensive he is naturally mistrusted. If, however, his casual connection with a college, hospital clinic, or whatever else it may be has inspired some family of modest means with confidence in a young physician, and who occasionally may be suspected of being modest in his charges, he is only too often impelled to make his fee quite as large as would the most eminent of his *confrères*, lest his professional position should be underrated; and if the eminent person himself should be consulted, of course he has his acknowledged position to maintain. The man whose income is not more than \$100 or \$150 per month, and whose absolutely necessary expenses leave little margin for accidents, may, without distress, meet the cost of casual and transient illness in his family, but is soon made bankrupt if it be more frequent or prolonged, though the physician exact no more than the minimum of established rates of compensation. The expense of even modest living has become so inordinate that the number of individuals of this class who are unable to make provision for emergencies has greatly increased; they may pay physicians' bills which, in the aggregate, and without reference to the amount of service rendered, are small, but must default in the payment of those which are larger, or must resort to the aid of medical charities. This, which is a proper use of medical charities, is a specific instance in which pecuniary loss has been suffered by the medical profession from the operation of a general cause—the resort to public sources of medical relief by a large class of people not absolutely poor who, under more favorable conditions of general business and of living, have heretofore been able to more or less generously contribute to the income of the private physician.

The abuse of medical charity, on the other hand, is independent of such general conditions as have been considered. The fact that funds designed by both public and private munificence for the relief of the sick poor have been diverted to the benefit of those who are beyond the necessity of charitable assistance, seems to be well established; and is generally believed by medical men to be largely responsible for a decrease in the business of the general practitioner. It is difficult to give this opinion statistical confirmation. The number of people treated in hospitals and dispensaries is certainly enormous, apparently constituting an undue percentage of the entire population, but the want of uniformity in manner of constructing reports in different institutions makes it impossible to know how far the figures given represent original patients. It is scarcely conceivable, for instance, that the 837,971 persons treated in the dispensaries of New York City, as reported for the year 1895, more than half the population at that time, were so many different individuals. It would, of course, be impossible to form

a numeric estimate for the proportionate number of those who are the recipients of medical charity who should be debarred by their ability to pay for what they receive. There can be no doubt that the evil is great; the result of concurrent individual observation is competent evidence, and making due allowance for a natural tendency to accept the most direct or apparent as the most effective cause of obvious phenomena, it must account for an appreciable part of the sum which has been subtracted from the aggregate medical income. The numerous and well-authenticated instances cited as occurring within the personal knowledge of physicians—of persons living in luxurious apartments or otherwise known to possess abundant means, the more than decent apparel of many other patients at the same institutions, the growing habit of physicians from the country in bringing the better class of their patients to city or private charities for consultation—indicating not only pecuniary loss to the medical profession, but still more lamentable loss of self-respect in the general community. The other and extreme instances in which dispensary patients are said to leave their carriages and servants around the nearby corner of a street, or in which a woman possessed of fortune beyond that of any other of her sex is said to have accepted medical charity not only at a dispensary but in the private office of its medical attendant, if true, as claimed, must be too exceptional to have more than a curious interest.

An unquestionable and flagrant abuse, not of charity, but in its guise, exists in the exaction of small fees from patients in clinics and dispensaries. That such institutions of a semipublic and professedly charitable character, with all the advantages of endowment, prestige, and organization, should enter into a competition with individual physicians in order that their already provided-for expenses may be reduced or their facilities for teaching may be increased, is a monstrous injustice. It is a direct and naked application to the practice of medicine of the principle upon which mercantile trusts are founded. An institution which claims exemption from taxation, or from damages in a suit for malpractice, on the ground that it is a charitable institution, certainly has no business to give medical treatment at cut rates to all comers, while it sends penniless but surgically uninteresting patients to Bellevue to be cared for at the public cost. A lying-in infirmary, founded by private beneficence for legitimate purposes of teaching, transcends its functions when it competes with the family physician for cases at his own rates, or a little less. These and similar encroachments upon private practice, stated and believed by reputable members of the profession to be well established, even though defensible, could not fail to diminish its aggregate emolument.

There is danger lest the proper uses and abuses of charity should be confounded. The hospital or dispensary patient who is comfortably clad, who evidently is of a better class than the majority, or the woman with perhaps a superfluous ribbon or some little personal adornment, the cost of which might possibly have paid a doctor's fee, is not necessarily a trespasser upon the benevolence of the public, or to be directed to the private office of its representative. The clerk or small shopkeeper, or other per-

son, who with his family has some refinement of feeling if not absolutely cultivated, and accustomed to decent surroundings, ought not to be herded with laborers in a squalid tenement that he may put by money for the expenses of some possible illness. He is entitled to have a proper regard for the comfort of his family, and even for appearances; and if his meager income reaches no farther, or will not compass what he rightly or wrongly believes to be adequate medical attendance, he may claim with right when sickness comes, such aid as public institutions can give, and should not be stigmatized as a pauper or as a dishonest claimant of the public bounty. The sharpest pangs of poverty are not felt by the poorest, and no lives are more pathetic than those which border upon penury, though they never surpass its limit.

The most effective of the causes further contributive to a decline in the business of the general practitioner are in part an outgrowth of the business methods which prevail at the present time, and in part due to what may be termed the complicated mechanism now employed in the treatment of disease. The growth of specialism, the multiplications of sanatoria, and the disposition of patients suffering either from acute illness of severity or from surgical disorders to enter public or private hospitals which have together made serious inroads upon general practice, have each this two-fold origin. There are mining, bridge, and electric engineers; real-estate, criminal, and patent lawyers; grocers who sell only tea, or perhaps butter and eggs; and butchers who are dangerous only to pigs or chickens, as the case may be. So too, there are trusts and monopolies which destroy the smaller traders. The subdivision of business and the limitation of the field of individual enterprise grows more and more complete from year to year, and he whom circumstance compels to row against the tide, if he survive, must drop behind. In the medical profession, specialties and specialists increase and the temper of the public mind improves, until little or nothing is left to general practice—even rheumatism, dyspepsia, appendicitis, and gonorrhea have been pre-empted. The country doctor who is at once physician, surgeon, gynecologist, and all sorts of specialists combined, still survives to some extent, and is likely to be a man of broader mind than his *confrère* who is potent only in some high degree of trituration. The analogue of commercial trusts and combinations exists in the foundation of medical schools, clinics, dispensaries, and minor hospitals. Medical faculties and medical boards have not failed to recognize the value of mutual aid and cooperation in the advancement not only of their semipublic but of their private interests. The number of these institutions, which is already in excess of public requirement, grows constantly larger, as men who are excluded and are emulous of their advantages form new combinations and establish for themselves new institutions. These references to present peculiarities and conditions of medical practice are not intended as a criticism, an expression either of approval or of condemnation, but simply in explanation, to a certain extent, of another fact *sub judice*. The introduction of appliances too complicated or too expensive, or requiring too much technic skill in their employment for the casual occasions

of general practice, has much enlarged the field of special treatment and correspondingly restricted the work of the general practitioner. In like manner, the recognized necessity for the maintenance of surgical asepsis, and the perfection of detail, the proper environment, the employment of specially trained surgical nurses and assistants which it involves, have compelled the surgeon to very generally remove operative cases to the hospital, and thus deprive the attendant physician of the after care of his own patients. The increasing number of sanatoriums established for the reception of cases of chronic disease, especially of phthisis and of the neuroses, in accordance with the present views of treatment, must, in an appreciable degree, detract from the income of the general practitioner to which such chronic cases largely contribute.

It has been thought that the profession suffers from an over-congestion of its ranks, and this, with the undue extension of the work of medical charities has been generally regarded as the essential, if not the complete, explanation of the present unsatisfactory pecuniary returns made to so many of its members. It is probably true that the number of medical men has increased out of proportion to the population. The medical profession has been made more attractive, its dignity has been greatly enhanced, its highest rewards have become as brilliant as those in any of the learned professions; and educated youth has naturally entered more freely upon its study. The half-educated and uncultivated more than ever swell the enormous classes of medical schools; the natural restlessness of the masses of people in a country in which no class distinctions exist, except such as come from the possession of wealth, constantly forces into the struggle for better place those who are entirely unfitted by education and social surroundings for the position to which they aspire, and perhaps attain. This plethora of recruits is equally notable in other professions, especially in the larger cities, and is more marked in this country than abroad where the maxim, *Sutor ne ultra crepidam*, is more carefully observed. The several hundred applications for a naval chaplaincy, though clergymen no more than cats are fond of the sea, is evidence of a redundancy of clerical endeavor; and the New York City directory is eloquent of the amount of legal talent at the disposition of the public. It is questionable, however, how far this accession to the membership of a profession, even if apparently over-large, is really a menace to its general prosperity. If any harm has been done to the medical profession it has been rather to the surgeons than to the general practitioner, whose case it is that has elicited sympathy and discussion. The surgeons of ability and skill, so few even in still recent years, have been disproportionately reinforced in numbers, and the changes in surgical methods have been such that the younger men have been enabled almost at once to meet their elders on nearly equal terms. If competition has become more intense in the medical profession, it is a result of a higher and more complex civilization, a greater density of population, and a consequent harder struggle for individual existence. The rivalry of charlatans and heterodox practitioners continues, as it probably always

will, but there is no apparent reason to suppose that it is more active or more successful than in the past.

Many of the causes which have been enumerated as showing the responsibility for a decline in the remunerative business of the physicians have been operative for a considerable time. The fact itself has been patent for scarcely more than a year, or at least, it has not been so notable as to provoke general discussion. Changes in social conditions are always insidious, usually unnoted until long after they are evident, and in time, often seemingly explosive. History teems with examples. In this instance, effects which have been thought to be individual experiences of only passing import were somewhat suddenly discovered to be general and possibly permanent.

In view of all these causes of decline it may be said that the only wonder is that the general practitioner has any practice left at all; but the world is large though the doctors may be many, sickness and death are the heritage of all mankind, and, as a matter of fact, we have not yet found our occupation gone.

The natural and fitting termination of a discussion which involves the etiology of grievances is in the indication of means for their removal; but it is easier to observe phenomena, to speculate upon their origin and to moralize, than to suggest a remedy—as we too often find in the study of our cases. The improvement in the health of the community is likely to be progressive, through the efforts of the profession which has already begun to feel the pressure of the crown of martyrdom. The general commercial depression and the consequent contraction of incomes which has led to an economy in medical attendance among people of moderate means, and even of moderate wealth, and has driven the poor to hospitals and dispensaries, is of course beyond our influence or control.

The injury which has been done to private physicians by the unwarranted methods of pseudo-medical charity is unquestionably capable of whatever relief the law can afford. It is only a minority of charitable institutions, and out of the whole number in this city—exceeding one hundred—not more than four or five have opposed necessary legislative and executive action. Such legal restrictions and supervisory provisions as are practical have only to be framed with sufficient care and judgment, and when proposed for enactment to be supported with energy and unanimity, to make it quite possible to overcome any selfish opposition which can be made. Remedial legislation, however, can never entirely obviate existing causes of complaint, except by a censorship so severe and a surveillance so complete as to be alike distasteful and foreign to the characters of members of an honorable profession. If the managers of hospitals, dispensaries, and college clinics remain regardless of their professional obligations to their fellows, and in their eager desire to purvey "material" for the instruction of students, or for their own exploitation, and welcome patients who, by reason of sufficient means, have no right to be accorded the privilege of the poor, no process of law can wholly restrain them. There are moral delinquencies, as there are crimes, for which no legal punishment is provided. It is a sophism to say that the public exposure to which the patient is

subjected is in the nature of a remuneration, or that a medical institution has the right to proffer, or the patient to accept, a charity which is not justified by even the semblance of poverty. No body of men has the right to debauch public sentiment or to impair the self-respect of a considerable class and to pauperize those who are capable of self-support—to stimulate the growth of the very evils which sociologists and philanthropists are struggling to limit by the discouragement of undeserved and indiscriminate charity. It is an injustice to society as well as to the medical profession for which the profession itself is in great part responsible. Its tolerance of methods which are too nearly akin to those of purely commercial pursuits and of a loosening of the bonds of professional obligation which bind physicians one to another in honor and fraternity, has made possible the very scandal which is now the subject of discussion and complaint. It is in a return to a higher conception of professional morals, and to its enforcement upon the few by an aggressive professional sentiment that the most complete protection to the many will be found. The constant inculcation of the fraternal duty which medical men owe to one another as the panacea for all the professional ills from which they suffer may grow wearisome, but in rehearsing the errors and grievances of a profession in which the general welfare is so peculiarly dependent upon the observance of the golden rule it is difficult to avoid usurping the ministerial office.

The undue or inconvenient increase in the number of practitioners of medicine, whether or not it is to be deemed an evil, is no more to be controlled than the growing disposition of people of moderate means to seek unnecessary medical advice. The profession cannot be surrounded by a Chinese wall; so long as it seems to offer desirable rewards new men will enter at will, within the limits of such restrictions as may legally be prescribed—and if we are jostled or too much crowded we must endure with the best grace we may. The longer course of study which is now necessary is certainly far from prohibitive, and more exigent demands upon the time and scholarship of the student, if made hereafter, while elevating the character of the profession will hardly decrease the number of its votaries. Competition grows more intense, whether the most urgent cause may be the diminished work to be done, or the greater number who stand ready to do it; learning, sagacity, assiduity, and tact—every honorable means is essential to honorable success. Let us be desirous of none other—let us avoid questionable methods; and if our tools must be sharp Heaven grant that they may always be clean. And you who find the struggle hard, who have learned that the realization of a high conception of professional honor oftener leads to business failure than to success, or may sometimes be inclined to falter or to grow faint at heart, take to yourself the adjuration of that fine gentleman himself, who never faltered and whose heart was always brave—William Makepeace Thackeray:

"Who misses or who wins the prize,
Go lose or conquer as you can;
But if you fail or if you rise,
Be each, pray God, a gentleman."

THERAPEUTIC NOTES.

Treatment of Ocular Neuralgia.—MARKOFF (*La Méd. Mod.*, August 21, 1897) advocates the use of cyanid of potassium and quinin in the treatment of neuralgia. Morphine, whether given internally or by hypodermic injection, has very little if any effect. Cocain has only a temporary action, and produces an artificial paralysis of the terminations of the nerves which is looked upon as the cause of a neuroparalytic affection of the cornea. Cyanid of potassium is administered in a warm solution of a strength 1:300 or 1:200 of which five to ten drops are instilled into each eye held widely open. This solution will keep well in a dark bottle in a cold place; but if it has lost its characteristic odor, its virtue has disappeared. The chlorhydrate of quinin is employed in a one-per-cent. solution which *must not contain any acid*. The following is an excellent prescription:

R	Quinin chlorhydrate	.	.	.	gr. i
	Morphin chlorhydrate	.	.	.	gr. ss
	Water	.	.	.	m. c.

M. Sig. Instil 5 to 10 drops into the eye. Repeat in fifteen minutes if necessary.

It is very seldom that a second application is required. The fundamental trouble will, of course, remain, but the neuralgia will disappear at once.

New Method of Removing Polypoid Growths of the Bladder.—In the *Jour. of Cutaneous and Genito-Urinary Diseases*, July, 1897, CHISMORE describes a method of locating and removing polypoid growths of the bladder by means of the suction exerted by an aspirator attached to a litholopaxy catheter, or other suitable tube. Through the medium of this suction the polypi are caught in the eye of the instrument, and by gentle traction and slight to-and-fro sawing movements are separated and drop into the reservoir of the wash-bottle. Two or three ounces of a hot boric-acid solution containing, if need be, a little cocain, is injected into the bladder and the point of the catheter is systematically passed over the wall of the viscus.

To the natural objection to this procedure,—that portions of the normal bladder-wall may be caught and torn off or injured,—Chismore claims, that the touch, if acute, will readily determine the difference in sensation, as the wall of the bladder occludes completely, and with a little thud, the eye of the instrument, while a polypus, being smaller and softer, is able to float a little way into the instrument and even then may only partially obstruct its lumen.

Airol in Diarrhea.—VENUTIS and BARBAGALLO (*Therapeut. Wochenschr.*, July 25, 1897) have used with success, in cases of acute and chronic diarrhea, airol in doses of from 2 to 5 grains. The remedy proved absolutely harmless, and especially in acute cases its action was prompt and reliable, so that it was not necessary to alter the usual diet. It was also found to be of service in some cases of tuberculous diarrhea, although larger doses were required.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM IN ADVANCE	\$4.00
SINGLE COPIES	.10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

CAUSES OF THE DECLINE IN PHYSICIANS' INCOMES.

THE shrinkage in the aggregate income of medical men during the last few years is a painful fact to which all members of the profession yield a reluctant but positive acknowledgment. Among many, more especially the young and recent recruits to the ranks of the profession, the scant remuneration has been the cause of bitter complaints, and the struggle for existence has proved painful and disheartening. Under such circumstances it is not easy to be philosophic; hope gradually fades into despair; the one most apparent source of the difficulty is hit upon as the effective cause of all visible wrongs, and the sufferer is in danger of wearing himself out in his efforts to right the one, only to find that the dragon's tooth has brought forth a greater crop of evils than is in his power to correct.

To take a broad and philosophic view of the situation, classify the various causal factors of the existing condition, and present them in proper proportion and relation, requires the mind of a master. This was most satisfactorily accomplished by Dr. Charles Phelps in his address at the recent meeting

of the New York State Medical Association in this city. The address is published in full in this issue of THE MEDICAL NEWS, and cannot fail to prove most interesting and instructive reading. Some of the causes of a depression in medical finances are recognized as permanent and unalterable, others are susceptible of immediate correction, and still others will correct themselves with the improvement in general commercial conditions. One of the facts which must be considered a permanent factor is the comparative infrequency of many once common diseases, the result of improvements in sanitation and hygiene. It is demonstrable that the total amount of sickness in the community has been very considerably decreased by the application to practical sanitation of the results obtained in the study of pathology and prophylaxis. It is the glory of the medical profession, however, that it can sink its own pecuniary interest in the eager pursuit and practical application of preventive medicine.

While we have not yet reached that millennial condition in which good health is contagious, we are rapidly arriving at the coveted stage of development at which health and physical endurance are becoming fashionable. The "interesting" invalid is no longer interesting. On the contrary, the young maid or woman who can lead at golf and ride the wheel without undue fatigue is the heroine of the hour. The fashionable physician who made his daily rounds to administer to fancied ills, meeting the demands of the case by satisfying the fancy, and calling again on the morrow at the insistence of the patient to pronounce upon the improvement, is finding his occupation gone.

The manifold ways in which the recent financial depression has had the effect of reducing the emoluments which have hitherto unceasingly flowed into the medical man's exchequer, are presented with most discriminating accuracy.

The abuse of medical charity in hospital and dispensary is arraigned as a most potent factor in the gradually diminishing income of the physicians of large cities. For this evil a prompt remedy exists in appropriate legislation, but the full corrective influence of legislative enactment may only be obtained by recalling the members of the profession to an appreciation of the professional obligations which bind physicians to one another in honor and frater-

nity, and to loftier conceptions of professional morals. In treating this part of the subject the address of Dr. Phelps has the ring of old-time professional dignity and self-respect. It is especially appropriate at this time and cannot be too constantly reiterated.

THE ABUSE OF MEDICAL CHARITY.

THE first gun of the autumn campaign against hospital and dispensary abuse was fired by Dr. Wiggin at the recent meeting of the New York State Medical Association held in this city. This subject has been seriously agitated for more than a year. Sufficient time has been allowed for a thorough examination of all the facts in the case, and the evidence is now in. Dr. Wiggin very wisely collected not only the facts which have been made manifest by recent investigations and in official reports, but also presented in a striking and graphic manner the opinions which are held in reference to this subject by authoritative writers in widely separated communities. It is apparent that not only is a gigantic imposition practised upon nearly all charitable institutions, but is carried to such an extent as to threaten a serious moral deterioration of a large number of people in the communities in which these institutions exist.

With this debauching of public conscience there also is inextricably associated an injustice and injury to the profession in depriving it of fair and honorable emoluments. In the righting of the first there will also be accomplished the restoration of the individual physician to his proper sphere of professional activity, with accompanying and adequate remuneration.

In the endeavor to correct these abuses, the medical profession deserves the willing assistance of all who have the good of the community at heart. In thus insisting upon a cessation of the baneful influences of indiscriminate charity, we will not diminish one iota the justice of the claim which the medical profession makes in its own behalf. The righteousness of the demand is recognized by those who personally do not feel the ill-effects of the abuse, and, as Dr. Phelps has said, the cordial cooperation of such men with those less favorably placed, in an endeavor to correct the abuse, is corroborative evidence that it exists and is recognized by all.

The only method of eradicating the evil is by means of legislative enactment. To carry an efficient bill through the legislative and administrative ma-

chinery, requires a united activity on the part of the entire profession. The existing condition has been of insidious growth, and is not the result of action by any coterie of men with designs upon the rest of the profession, but is the legitimate outcome of sharp and eager competition, the far-reaching results of which could not be anticipated, and became manifest only when acting in conjunction with the many other causes which have diminished the physician's income. The general financial distress of the last few years has made them strikingly evident.

Let us not deplete our ranks, nor alienate any of our brethren by throwing mud or applying undignified epithets to those who apparently are within the enemy's lines. Nothing is gained by the pot calling the kettle black. Let us recognize the fact that the fierce struggle for precedence in a hotly contested competition has created a condition which we seek to remedy, and when an efficient law has been enacted, no effort to resist its universal application need be feared. Let us not divide our strength into factions, each of which will take an extreme view, and whose motto will be, war to the knife and no compromise. The condition which exists is a silent outgrowth of conditions and circumstances for which the entire profession is to some extent responsible. Extremists on both sides are invariably wrong; the right way lies between. The need of settling this question is desperate and with united forces there is every probability that it will be speedily and rightly terminated.

ECHOES AND NEWS.

Death of Professor Stoeber.—The news comes from St. Petersburg that Dr. Stoeber was frozen to death during an ascent of Mount Ararat, in company with other members of the recent Geological Congress.

The Sanitary Institute of Great Britain.—This society recently celebrated its twenty-first anniversary by a dinner in London. The institute now has 2000 members and associates, and its annual income amounts to \$30,000.

Death of Dr. Luke Robinson.—Dr. Luke Robinson of San Francisco, one of the most prominent physicians in California, died suddenly last week of heart disease while on a Southern Pacific train in the San Joaquin Valley.

Typhus on the Pacific Coast.—According to Dr. Williamson, of the San Francisco Board of Health, the first case of real typhus fever ever recorded on the Pacific Coast

has recently been discovered at St. Luke's Hospital in that city.

Compulsory Insurance against Sickness.—The National Council of Switzerland recently adopted a bill which introduces a system of compulsory insurance against sickness by all persons not possessed of means sufficient to make their positions independent.

An International Leprosy Society.—The news comes from Berlin that the leprosy conference has appointed a commission of twenty, including Professor Virchow as president and Dr. Dyer of New Orleans, to prepare the way for an international leprosy society.

A Hospital Suicide.—A patient under treatment at the Long Island College Hospital, Brooklyn, N. Y., jumped from a second-story window last week. His skull was fractured, several ribs were broken, and he was so badly injured internally that he will die.

Death of Professor Heidenhain.—Professor Rudolphe Pierre Henri Heidenhain, incumbent of the Chair of Physiology at the University of Breslau, is dead. He was born at Marienwerder in 1834, and studied medicine and natural science at the universities of Koenigsberg, Halle, and Berlin, and experimental physiology under the direction of Professor Du Bois-Raymond.

Ambulance Classes for Sailors.—In England "ambulance classes" have been formed in which sailors are taught some of the simpler methods of treating accidents, and silver badges are given to those who pass the examinations. This has become necessary from the fact that the law requires only such vessels as carry more than a hundred persons to employ a medical officer.

X-Ray Photograph Not Admitted as Evidence.—Judge Henry M. Nevius of the Hudson County Circuit Court in Jersey City recently refused to admit as evidence in a suit for damages an X-ray photograph showing the nature of the injury received. His refusal was based upon the fact that the X-ray photograph has never been used as evidence in that State, and he did not desire to establish a precedent.

The Bicycle and Phthisis.—Last year, for the first time in the history of the State of Massachusetts, the number of deaths from phthisis in females was smaller than that in males. For five years the female death-rate from this cause has been steadily decreasing, and, as women have been riding the bicycle for about that length of time, the decrease is ascribed to the open-air exercise inaugurated by the use of the wheel.

Ship-Surgeons on Inland Steamers.—The Newport (R. I.) Medical Society is agitating the question of compelling Sound steamers and those which ply along the coast and on the great lakes, to carry ship-surgeons. The Sound steamers often carry as many as a thousand passengers, medical attendance is frequently required and is generally furnished, much to his discomfort and annoyance, by some medical man who happens to be a passenger.

The law on the subject is very lax, and steps are to be taken to induce Congress to make a change for the better.

Sanatorium for Incurables.—Buildings are being erected in Forestburg, N. Y., by the Sisters of St. Dominick, to be used as a sanatorium during the Summer season for patients from St. Catherine's Hospital, Williamsburg, L. I., and as a permanent home for incurables. The site is 1947 feet above the sea level. Patients in the first and second stages of phthisis will be received in order that they may have the benefit of the high altitude. The estate covers an area of 1173 acres, and the various buildings are separated from each other by a distance of from 1000 to 3000 feet. The architecture is of Medieval monastic style, and the buildings will be provided with all modern improvements, heated by steam, and lighted by electricity. When completed, the establishment will be the largest of its kind in the United States.

Yellow-Fever Notes.—Three deaths from yellow fever occurred on the British steamer "Honiton," during her voyage from Progresso, Mexico, to Boston, Mass. She is now in quarantine at the latter city, and the health officers have begun the work of disinfection.

The tramp steamer "Sonnehille" arrived at Baltimore last week with a case of yellow fever on board, and several of the crew not feeling well. She has been fumigated and is held in quarantine.

The news comes from Plymouth, England, that the British steamer "Medway" has arrived from Colon, via Barbadoes, and reports two deaths from yellow fever during the voyage. No other cases have developed.

A New York physician, practising at Grand Caymans, Jamaica, reports that an epidemic of what appears to be malignant typhoid fever is prevailing in Jamaica. It is not admitted that the disease is yellow fever.

Tobacco-Smoking and Genius.—In his work, *Introduction à la Médecine de l'Esprit*, M. Maurice de Fleury devotes a chapter to tobacco-smoking from the point of view of men of letters. The following are the opinions in epitome of three among the most eminent writers of the century. In the first place, Balzac: "The architect of that cyclopean monument which bears the name *La Comédie Humaine* professed a fanatical aversion to tobacco in all its forms, and was constantly employed in an endeavor to purge the *Régie*." In his books he invariably covers with contempt the characters whom he portrays as smokers, and an entire chapter in his "Treatise on Modern Stimulants" consists exclusively of fulminations against the weed and its worshippers. His, in fine, is the motto under which the devoted members of the *Société contre l'Abus du Tabac* wage an unceasing war. "Tobacco destroys the body, attacks the intellect, and besots the nations." Next, Victor Hugo, the author of *Les Misérables*, was likewise no smoker. As Théodore de Banville once said, "In the house of Victor Hugo, Peer of France, no one has ever even attempted to smoke." In this connection an anecdote suggests itself. One evening in the master's home one of the guests, Villiers de l'Isle-Adam, I think, was vaunting the beneficent effects

of a cigarette on a creative imagination. The great poet at once rose in revolt. "Believe me," he said, "tobacco is more hurtful to you than beneficial; *it changes thought into reverie.*" Finally, M. Émile Zola says: "I have no definite opinion on the question. Personally, I gave up smoking ten or twelve years ago on the advice of my medical attendant at a time when I believed myself to be affected with heart disease. But to suppose that tobacco exercises an influence on French literature raises a question of such magnitude that the most rigid scientific proof alone could dispose of it. I have known great writers who smoked without stint, but their intellects were not one whit less acute. If genius be a neurosis, then why seek to cure it? Perfection is such a very tiresome thing that I very often regret having broken myself of the tobacco habit. And as I know nothing more about the question I do not dare to enlarge upon it."—*The Lancet.*

Health Reports.—The following statistics concerning smallpox, yellow fever, cholera, and plague have been received in the office of the Supervising Surgeon-General of the United States Marine Hospital Service, during the week ending October 16, 1897:

CORRESPONDENCE.

NEW DRESSING FOR WOUNDS.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: Equal quantities of paraffin and unpurified beeswax melted together make an admirable surgical dressing when it is desired to apply an air-, water-, and germ-proof covering. The mixture may be completed by placing it in a narrow-necked culture-bottle and sterilizing over a sand-bath. When required for use, the preparation may be liquefied by heat within a few minutes. After being spread over the wound, either directly or after absorbent cotton has been applied, it immediately hardens and becomes firmly adherent. The heat of the melted mixture acts as a hemostatic, and, according to my experience, this dressing hastens regeneration. It does not irritate the skin, and may be easily removed. It is inexpensive and easy of application, and will hold in suspension almost all known antiseptic powders. My method of applying it is by means of a swab composed of absorbent cotton wound on a stick or probe.

SAMUEL H. FRIEND, M.D.

OUR BERLIN LETTER.

[From our Special Correspondent.]

GERMAN MEDICAL CONGRESSES DURING SEPTEMBER—A SUGGESTION TO SUBSTITUTE RUSSIAN KVAS FOR GERMAN BEER—THE NEW GERMAN PATHOLOGICAL SOCIETY—SANATORIA FOR CONSUMPTIVES—JUDGMENT SUSPENDED AS TO THE NEW TUBERCULIN—THE PSYCHOLOGY OF A CHESS CONGRESS.

BERLIN, October 16, 1897.

THE latter part of September is a favorite time for the meetings of medical congresses in Germany, and no less than four have been held during the past three weeks. At this time summer vacations are usually over, and the regular work of the semester has not yet begun, so there is a favorable opportunity for the gathering of medical men under propitious circumstances. The meeting of the Society of German Alienists at Hanover, of the German Society for Public Hygiene at Karlsruhe in Baden, of the German Scientists and Physicians at Brunswick, and the annual meeting of German Physicians at Eisenach, the *Arzte-Tag* as it is called, have all been well attended.

The last-named society is intended more especially for the discussion of subjects bearing directly upon the physician himself and his relations with his colleagues. A series of resolutions were drawn up containing suggestions for the legal regulation of quackery, and they occasioned a good deal of discussion. All were agreed as to the eminent desirability of the object proposed, but as to the means that would best secure it, there were many differences of opinion. In general, the impression seemed to be that until there is a radical change in the relations between the government and the medical societies, so that the latter would be entrusted with the framing of legal regulations relating to the practice of medicine, very little could be hoped for from legislation. In the meantime there was complete unanimity of opinion with regard

to the necessity for action which is extremely encouraging, and is bound sooner or later to gain recognition. The public will finally be educated to understand that the regular profession seeks sincerely the public good in its effort to suppress quackery, and then more efficient legislation may be anticipated. The organization of effort in this direction will prevent the matter from being dropped until something effective has been accomplished.

At the same meeting the discussion of the hygiene of public schools drew forth some complimentary remarks as to the recent American innovations in the matter of medical inspection of schools which serve to show how soon a good thing is appreciated, even at a long distance.

At the meeting of the German Society for Public Hygiene one of the main subjects discussed was the use of alcohol and the question as to how its ever-increasing consumption may be restricted. Here in Germany statistics seem to show that cirrhosis of the liver is almost alarmingly on the increase, though only in a ratio proportionate to the amount of beer and other alcoholic beverages consumed. Dr. Karl Frankel suggested the Russian drink kvas as a substitute for beer, which so many of the members of the congress at Moscow, though tasting it for the first time, had found so pleasant and refreshing. During the hot days at Moscow nothing seemed more palatable than this simple fermented liquor, which is not unlike our own popular root beer. Kvas contains scarcely one-half per cent. of alcohol, and most Americans who attended the congress would agree with Dr. Frankel that it would form an excellent substitute for beer during the heated term when the temptation to consume a good deal of liquid is almost irresistible.

Though there might seem to be enough medical societies and congresses, the recent meeting of the German Scientists and Physicians at Brunswick witnessed the organization of another. This is to be known as the German Pathological Society, and it is to hold its meetings each year in the same place and just after the sessions of the former society at the close of which it was organized this year. If the names of its officers are any guarantee of the character of the work which will be presented at its meetings, the proceedings of the new society may be expected to attract a good deal of attention. Professor Virchow is the president of the new society, and Professor von Recklinghausen, its secretary.

Two new public health sanatoria for consumptives were opened during the past week, the one at Albertsberg, the first in Saxony, with a great deal of *éclat* in the presence of royalty. Plans for many others and for extensive additions to those already existing are under consideration.

The treatment of tuberculosis in sanatoria constitutes, in the opinion of the German medical profession, the best means of combatting the disease. Professor Leyden's discourse at one of the general sessions of the congress at Moscow gave expression at once to this feeling, now so common, and to the reasons underlying it. There is no specific therapy for this dread disease despite all the claims which have been made, and the only thing left is to strengthen the vital resistance of the individual and so enable him to fight his own battle. For this, the regular

life, the constant watchful medical care, the plenteous nutritious diet, and, above all, the avoidance of every excess, all of which are so easy of attainment in a sanatorium, constitutes the best therapy yet found for consumption. Statistics in ever increasing number serve to show that such sanatoria are really working wonders. Most of the objections urged against them—the liability of contagion, dissatisfaction on the part of patients, and impatience of restraint—have disappeared before the actual experience of their good results. Government itself is now beginning to take an interest in the question of sanatoria for the consumptive poor, and wealthy philanthropists are coming to the realization that their establishment is calculated to be a matter of the greatest practical benevolence and charity.

As to Koch's new tuberculin, the editors of the *Deutsche Medicinische Wochenschrift* after having devoted considerable space to papers upon the subject have now resolved to close their columns for a time to its further consideration. It will take years to really decide the therapeutic value of the new serum, and discussion at present can only be illusory, the personal feelings of the observer too greatly influencing his judgment as to results. The use of the old tuberculin for diagnostic purposes seems to be thoroughly disapproved of here in the clinics for internal medicine. The reaction which occurs after the injection of tuberculin when tubercle bacilli are present is considered to be due to a necrosis of tissue around the bacilli and the absorption of toxic products therefrom. Such a septic reaction cannot be without danger, and necrosis of tissue may cause the further absorption of bacilli into the lymph- or blood-vessels and so institute an acute process. As the majority of people have encapsulated bacilli in the apices of the lung or somewhere in the bronchial glands without being in the slightest sense tuberculous, the occurrence of the reaction cannot be said to be definitely diagnostic of active tuberculosis. In cases where the bacilli have been completely shut off from the possibility of doing any harm by Nature's protective barriers of inflammatory lymph, there is danger that the quiescent condition may become active under the influence of the injected toxins. The injections are practically considered unjustifiable, except in the determination of the etiology of such serious affections as pleurisy or ascites where the patient's dangerous condition makes an experimental diagnosis with tuberculin less risky.

The International Chess Congress has been in session in Berlin for about two weeks, and the presence of the great masters of the game has given the occasion for some medical remarks as to the physiologic psychology of that species of the *genus homo* that plays chess. Strangely enough, considering the high estimation in which great chess-players are usually held by their immediate friends, the medical opinion of them does not seem very exalted. There have been some very pointed remarks made as to the questionable utility, as a means of recreation, of a so-called game which requires a mental tension and attention which is fatiguing in the extreme, and which must call for a large waste of intellectual energy. That the training incident to this continuous

nervous strain is not beneficial as regards other and more useful mental occupations, the best proof seems to be the sterility of great chess-players in other intellectual work. The exercise saps energy rather than trains faculties, and what of training it gives is so specialized to the game itself that it is of no use in other and more useful lines of thought. As to the great players themselves, they are usually typical examples of a complete one-sided development. This development affects principally the memory, the lowest of the intellectual faculties, and more especially, the coordination and retention of visual impressions—the first of mental aptitudes acquired in the course of evolution. On the whole medical opinion does not seem to favor the game in these days of hyperneurotic conditions, unless it be occasionally for the over-occupied business man whose thoughts as to mercantile details do not give him real leisure, except when absorbed in something, which like this, requires complete and absolute attention.

OUR PHILADELPHIA LETTER

[From our Special Correspondent.]

TOPICS FOR DISCUSSION AT THE AMERICAN PUBLIC-HEALTH ASSOCIATION MEETING—DEDICATION OF THE D. HAYES AGNEW MEMORIAL PAVILION OF THE UNIVERSITY HOSPITAL—BERI-BERI IN PHILADELPHIA—COLLEGE OF PHYSICIANS OF PHILADELPHIA, SECTION ON GENERAL MEDICINE—DR. R. C. NORRIS' ILLNESS.

THE Executive Committee of the American Public-Health Association, which convenes here on October 26th, has announced the following topics for discussion:—The pollution of water supplies; the disposal of garbage and refuse; animal diseases and animal food; the nomenclature of diseases and forms of statistics; car sanitation; steamboat and steamship sanitation; international committee on the spread of yellow fever; the relation of forestry to public health; the cause and prevention of infectious diseases; public-health legislation; the cause and prevention of infant mortality; the transportation of diseased tissues by mail; the period during which each contagious disease is transmissible, and the length of time during which a patient having a contagious disease is dangerous to the community; sanitation with special reference to drainage, plumbing, and ventilation of public and private buildings; the consideration of some method of international arrangement for protection against the transmission of infectious diseases; disinfectants; and an examination into the existing sanitary municipal organizations of the countries belonging to the Association, with a view to a report upon the most successful in practical results. The above general topics are to be supplemented by special papers at the meeting, and of these communications a daily programme will be issued during the course of the convention. Not the least prominent features of the meeting will be the exhibit of various appliances pertaining to sanitary matters and allied subjects. In addition to the trade displays, of which there are to be a large number, interesting exhibits from the municipal health boards of New York, Philadelphia,

Cincinnati, Baltimore, and other large cities will be held, comprising a practical demonstration of the application of city bacteriologic laboratories to preventive sanitation, together with the methods in use for dealing with endemic contagious diseases, and with sudden epidemics. These exhibits will be held in the Horticultural Hall, which is admirably adapted for the purpose, as well as being conveniently situated directly opposite the Hotel Walton, the headquarters of the Association. In Horticultural Hall will be located also the bureau of registration, the post-office for members, and a bureau of information.

The D. Hayes Agnew Memorial Pavilion of the University Hospital was formally dedicated with appropriate ceremonies on October 15th. Addresses were made by Dr. William F. Norris, the President of the Board of Managers of the Hospital, by Provost Harrison, by Dr. De Forrest Willard, by Dr. J. William White, and by Mayor Warwick. This new addition to the University Hospital was erected at a cost of \$160,000, to serve the purposes of a lecture-building, a hospital, and a surgical dispensary, and contains the most approved appurtenances in use. The first, second, and third floors contain amphitheatres where it is proposed to hold surgical, orthopedic, and gynecologic clinics, and the third floor also contains an operating-room for ophthalmologic cases; the ground floor is occupied by a surgical dispensary. The new building, which forms a companion wing to the William Pepper Clinical Laboratory, has a capacity of one hundred and sixty beds, with separate wards for children's diseases, for general surgery, for gynecology, for ophthalmology, and for otology.

Two of the coolie crew of a British steamship, which arrived at this port a few days ago, have developed typical symptoms of beri-beri, an outbreak of which disease occurred among the crew of the vessel during the early part of her voyage from India. In connection with this incident an interesting complication has arisen regarding the disposition of the patients, who, being Chinese, are forbidden to land, and are thus denied the advantages of proper hospital treatment while in port. Thus far the question of this privilege has been decided negatively by the officials, although should the steamer leave without these two members of her crew (and no law can compel her to carry them), it is hard to see how it is possible to avoid evading the Chinese exclusion law at least in the letter.

The last stated meeting of the section on General Medicine of the College of Physicians of Philadelphia was held on October 11th. The chairman of the section, Dr. J. C. Wilson, related the history of an interesting case of hemorrhagic pachymeningitis, with a large subdural abscess of the right frontal lobe. The patient presented early in the illness the clinical manifestations of enteric fever, but later developed monoplegia, first of the left arm, and then after the lapse of a few days, of the left leg; these signs were well marked for some time before death, which terminated a long illness. The patient's brain, which was demonstrated to the members of the section by Dr. Wilson, showed a collection of

fully six ounces of pus between the dura mater and the arachnoid of the right frontal lobe, together with a pachymeningitis of every grade of intensity; there were no thrombi in either the frontal or lateral sinuses, and the brain substance appeared to be in good condition. No lesions of the intestines were found to account for the early typhoid symptoms. Other *post-mortem* findings showed that the ileum was inflamed, and bound down by adhesions to the pubic bones, and also that the appendix was thickened and dragged from its normal situation by dense adhesions. There was slight local peritonitis in the right iliac fossa.

Dr. Charles W. Burr detailed the histories of two cretinoid cases. These individuals were brothers of the early adolescent period, and presented many typical physical peculiarities common to cretins; the mental development corresponded with that of a young child, and while not absolute idiots, memory of events impressed upon them was of a most transient and fleeting character. Dr. S. M. Hamill presented an interesting communication on "The Condition of Salivary Digestion in Anemia," which dealt with the changes in the quantity of saliva, and with its ferment power in this class of cases. Dr. D. L. Edsall, by invitation, read a paper on "The Gastric Conditions in Anemia," in which he considered the degrees of acidity of the stomach in the various anemias, and the relation of gastric lesions to pernicious anemia.

At a stated meeting of the Pathological Society of Philadelphia, held on October 14th, the following officers were elected for the ensuing year: President, Dr. W. E. Hughes; vice-presidents, Drs. F. A. Packard, C. W. Burr, Alfred Stengel, and John Guiteras; secretary, Dr. David Riesman; recorder, Dr. A. E. Taylor; treasurer, Dr. T. S. Westcott; curator, Dr. J. Dutton Steele.

The annual address was read by the retiring president, Dr. John H. Musser, who was able to report that the Society was in a most flourishing condition, having on its rolls over two hundred active members.

Dr. Richard C. Norris, Physician-in-Chief of the Preston Retreat, is seriously ill as the result of a slight wound which he received while operating upon a septic case. Septicemia of a severe type has set in, and although his attending physicians apprehend no immediate danger, his condition is considered to be serious.

Dr. H. L. Hale and Dr. J. A. Cramp have been appointed assistant-surgeons to Wills' Eye Hospital, to serve respectively in the clinics of Drs. Frank Fisher and J. W. Croskey.

The total number of deaths occurring in this city during the week ending October 16th, was 393, an increase of 48 from the number reported last week, and an increase of 30 compared to the corresponding week of last year. One hundred and sixteen of the total number were in children under five years old. There were 216 new cases of contagious diseases reported—10 more than last week, with 42 deaths from these causes. There were 137 cases of diphtheria, with 31 deaths; 51 cases of scarlet fever, with 4 deaths; and 28 cases of enteric fever, with 7 deaths.

SOCIETY PROCEEDINGS.

THE NEW YORK STATE MEDICAL ASSOCIATION.

Fourteenth Annual Meeting, Held at New York, October 12, 13, and 14, 1897.

FIRST DAY—OCTOBER 12TH.

MORNING SESSION.

THE meeting was called to order by the President, DR. CHARLES PHELPS of New York, who expressed the hope that the labors of the Fourteenth Annual Meeting would prove as interesting, and the scientific work as valuable, as they had in the past.

The Secretary then read the Treasurer's report, which showed a surplus in the hands of the Association amounting to \$6518.46. A communication was read from the American Medical Association asking that the New York State Medical Association contribute \$2000 to the Rush Memorial Fund. A resolution was offered by Dr. Manley of New York County, to the effect that the Association should appropriate \$2000 to the Rush Memorial Fund. After some discussion it was decided that the matter be laid over until Thursday morning when the vote of the Association would be taken.

The President then delivered the Annual Address, entitled

THE CAUSES OF A DECLINE IN THE AVERAGE INCOME OF GENERAL PRACTITIONERS OF MEDICINE.
(SEE PAGE 527.)

DR. SAMUEL W. SMITH of New York County read the first paper, entitled

ACUTE CATARRH OF THE MIDDLE EAR AS A SEQUEL OF LA GRIPPE.

Acute otitis media is a frequent sequel of *la grippe*, as evidenced by deep-seated pain, a profuse purulent discharge from the affected ear, and often perforation of the membrana tympana. As a result of neglect, deafness of greater or less degree occurs in seventy-five per cent. of all cases. If the disease extends into the mastoid, perioritis may appear over the bone and result in abscess, pachymeningitis, embolism, septicemia, and death. Leeches should be applied, and paracentesis early performed. The mastoid should be trephined if an abscess develops.

DR. LEROY J. BROOKS of Chenango County referred to the common occurrence of otitis media after "*grippe*," and said it was his custom to make use of the Politzer bag as soon as the earache appeared. This he used three or four times a day. He then irrigates the ear with a saline solution as hot as can be borne, using a nursing-bottle and tube for this purpose in the case of a child. These methods, when employed early and thoroughly, will prevent many cases from going on to more serious trouble. Paracentesis, which is much dreaded by the general practitioner, is a simple operation, and should be employed if there is any bulging of the drum.

DR. COHN of Erie County said that his attention was first called to this complication of "*grippe*" during the epi-

demic of 1891-92. He uses the Politzer bag, and adds to the water a few drops of chloroform, which has the effect of dilating the Eustachian tube, and affording almost instant relief from pain. Asepsis of the external ear is all important. Paracentesis, if made early and low down, will often prevent rupture of the drum. These cases become worse under the administration of quinin, therefore other antipyretics should be given to reduce the temperature.

DR. DAVIS of New York County agreed with the author that the general practitioner knows but little about ear diseases. He favors the administration of salicylate of soda to bring on profuse perspiration, and to relieve the intense nervous strain. Hot applications should be made to the ear, and a hot gargle ordered for the throat, which is usually involved.

DR. SMITH, in closing, said he did not think any man who had ever used the Politzer bag upon himself, when he had earache, would use it upon a little child, for the most intense pain results. He favored the use of leeches, paracentesis, and trephining.

WHAT SHALL WE DO TO BE SAVED?

was the title of a paper read by DR. T. J. HILLIS of New York County.

It dealt in a novel way with the abuse of medical charity, which, the author said, was not confined to cities alone, but is met with in the country as well, and that, if it were allowed to continue, a medical man not connected with a hospital would be a curiosity. The hospital, with its soup annex, is swamping the practitioner.

AFTERNOON SESSION.

DR. E. D. FERGUSON of Rensselaer County read a paper, entitled

A CURIOUS CONDITION OF THE APPENDIX VERMIFORMIS AS FOUND AT OPERATION.

The author showed two specimens illustrating unique conditions of the vermiform appendix. The first was removed from a man thirty-two years of age. The first attack of appendicitis occurred during March, 1893, and resulted in the formation of an abscess, which ruptured into the bowel. A second, but mild attack occurred during November, 1893, from which he recovered promptly. During December, 1896, he had pain, but was up and about the house until January, 1897, when he was first seen by the author. He then had high fever and pain, and a large mass was made out in the region of the appendix. He was given opium and strychnia, and an ice-bag was applied until the acute symptoms subsided. Operation was performed during February, when the disease was quiescent. It was found that the mass consisted of a portion of the cecum, lower part of the colon, small intestine, and omentum. The appendix at first was not found. While searching for it, a mass about the size of the last phalanx of the thumb was discovered between two coils of the small intestine. This proved to be the distal portion of the appendix which had been severed by gangrene. About two inches distant from the normal site of the appendix was an opening through which

a probe could be passed into the bowel. There was no evidence of pus. The stump was removed and the wound closed without drainage. This amputation of the appendix by gangrene probably occurred during 1893, at the time of the first attack.

The author exhibited a second specimen, showing circular gangrene of the appendix, which occurred in the case of a young man nineteen years of age, seen during the first day of an attack of appendicitis. He had previously had one mild attack of the disease. At the operation few adhesions were encountered, and, aside from hypertrophy of the distal end, the appendix showed little pathologic change. It was amputated close to the bowel, the stump inverted and buried by Lembert sutures. Upon close examination a narrow black line of commencing gangrene was found to completely surround the appendix.

The author expressed the opinion that cases of appendicitis should not be operated upon during a first attack, because between eighty and ninety per cent. will recover without surgical interference. Many of these first attacks are simply a catarrhal inflammation, and will recover under the use of the ice-coil, with scarcely any other treatment. No operation is more overdone than that for appendicitis, and the tendency of the day is to underestimate the risk.

DR. F. H. WIGGIN of New York County did not agree with the author in regard to postponing operation. All cases of appendicitis are surgical cases, although it is not always necessary to operate for a first attack. Mild measures, such as emptying the large bowel by enemata and applying cold to the abdomen, should be employed; but if the symptoms increase within thirty-six hours, the patient should be operated upon without delay. The pulse is a more valuable guide than the temperature. If it is 120 peritonitis of a serious character exists. Each case, however, should be studied by itself, and no general law can be followed. The mortality in these cases is not more than four per cent.

A paper, entitled

THE ABUSE OF MEDICAL CHARITY,

was then read by DR. F. H. WIGGIN. (See page 521.)

DR. WICKES WASHBURN of New York County said that his attention was first directed to this abuse as far back as 1883, when, upon investigation by the Charity Organization Society, a woman who applied at a dispensary for medical aid was found to be the owner of a house. He expressed the opinion that hospital and dispensary abuses can only be reduced by investigation, and that, in order to avoid confusion, this should be done by a central bureau. The speaker said that he was one of the members of the combined committee referred to in Dr. Wiggin's paper as being largely instrumental in passing the bill through both houses of the Legislature. He advised an amendment to the bill to the effect that instances of abuse on the part of charity institutions should be reviewed and passed upon by a judge of the Supreme Court in the district where such an institution is located. In this way, if the question were one of revoking a charter, the matter would not rest entirely with the State Board of Charities and would largely aid in doing away with the objections to the bill.

MR. JOHN HARSON RHOADES of New York attributed the abuse to the great multiplication of medical charities of this character in New York, and also to the ambition of young medical men to attach themselves to institutions already in existence, or to found new ones in connection with church charities, or independently, upon which they hoped to build reputations for themselves, and out of which they, individually, expect to earn a living and establish a practice. The secret willingness of many young practitioners to conceal facts which come to their knowledge, showing a patient's ability to pay, in the hope of securing such a patient for their private practice, is also a contributing cause. The difficulty of determining who are poor and who are able to pay, and the natural repugnance to close inquiry through fear of driving away those who are really entitled to aid—the honest poor who suffer in silence and who possess an honorable pride which prevents a disclosure of their true condition—was mentioned as an obstacle to correcting the abuse. Of still more importance, he considered the absence of a central bureau in the city where all cases and applications for charitable relief—medical or otherwise—may be investigated for the benefit of charitable institutions of all classes, sects, and kinds.

As a remedy he suggested: (1) The careful selection of young physicians for service in medical institutions and hospitals, the application of business principles in the profession, the dismissal or compelled resignation of all men appointed who prove careless, incompetent, or self-seeking—all of which lies with the medical boards. (2) The passage of a law which will compel all charitable institutions of every kind to establish a clearance bureau, which may easily be done in connection with the Charity Organization Society, each sharing in the expense of maintenance in proportion to the number of patients recorded against each. Such a law should compel all institutions to send a weekly list of the patients applying for relief, such names to be filed, tabulated, and investigated by the clearance bureau, and the result forwarded to each institution. When medical boards do their whole duty, without fear or favor, and when the State does its full duty in enforcing an intelligent and comprehensive system of investigation upon the part of all charities, public and private, sectarian and non-sectarian, the evil will be remedied, and not before. That it should be remedied speedily the true welfare of the commonwealth demands, for as it is now, what with loose, ill-guarded, and liberal charity, backed by extravagant pension laws, we are speedily creating a nation of paupers.

DR. J. E. JANVRIN of New York County heartily concurred in the conclusions of Dr. Wiggin. He said that he had had an interview with the Governor a few days before the expiration of the time in which the bill should have been signed, and that the reasons he gave for declining it were, first, that he was opposed to put so much power, especially that of revoking a charter, into the hands of any one board or commissioner, and second, he believed that any one who desired to do so had a perfect right to establish institutions, medical or otherwise, for charity or for the education of young men. The speaker also advocated a fixed salary for all house-physicians.

DR. E. D. FERGUSON of Rensselaer County said that this abuse, which has reached such a magnitude in New York, has not yet reached Troy, but that he is heartily in sympathy with the movement against it. He thought that as now framed there are legal objections to the bill which were the cause of the opposition to it. What is most needed, however, is the cooperation and support of the entire medical profession.

DR. WICKES WASHBURN of New York County said that but one opinion was expressed in Albany last winter, *i. e.*, that medical charity was greatly abused and that this should be remedied. It was insisted, however, that the profession should agree upon what was to be asked of the Legislature. The bill is, and was opposed by the medical schools, which hold out as an inducement the abundance of clinical material in New York City. The cooperation of these medical schools should be obtained.

DR. E. V. DELPHEY of New York County suggested that it should be a matter of ethics, and be considered contrary to the dignity of the medical profession for a man to serve in a dispensary or hospital which permits the abuse of medical charity.

DR. THOS. H. MANLEY of New York County expressed the opinion that the matter cannot be remedied by legal enactment, because the evil lies in the medical profession itself. The profession as a body should promulgate a rule in regard to this abuse, which, if disobeyed, will place the offender in condemnation. He suggested that the New York State Association set out in clear, definite terms, under what conditions a physician may connect himself with a hospital or dispensary service, and see to it that these conditions are properly regarded.

DR. J. R. MCGREGOR of New York County, considered the matter one to be settled by law. It is a question of obtaining something for which no equivalent is given, in other words, imposition, and the legislature should pass a law against this, as it does against other frauds. The speaker referred to the powers which worked against the bill at Albany and hinted that the Governor had not given his real reason for declining to sign it.

DR. JANVRIN then urged that a modified form of the bill be presented early in the next session of the Legislature in order that it may be passed over the Governor's veto, if this proves necessary.

Upon the motion of DR. THOMAS H. MANLEY the following resolution was adopted:

RESOLVED, That this Association is heartily in sympathy with the efforts being made to correct the hospital and dispensary abuse throughout the State, and that a committee of five be appointed by the president to represent the Association and cooperate with similar organizations in efforts to correct the said abuse.

SECOND DAY—OCTOBER 13TH.

MORNING SESSION.

DR. W. S. McLAREN of Litchfield, Conn., read a paper upon

STRICTURE OF THE RECTUM.

The subject was divided into two groups, congenital and acquired. The first variety is rarely seen, the indi-

viduals having this abnormality generally presenting imperforate anus and more or less arrest of development, and are considered as cases of the latter. Acquired stricture was subdivided into non-malignant and malignant. The former is caused by traumatism, dysentery, simple ulceration, tuberculous ulceration, and syphilis. Traumatism by violence is rare, but when it occurs is often due to the application of strong acids. Dysentery is not a common cause of stricture. By far the vast bulk of non-malignant strictures are caused by venereal disease, and they are often met with in the late stage of syphilis. Malignant stricture of the rectum is much more common than non-malignant. Obstruction of the bowel is the principal symptom, followed by a discharge of mucus caused by the irritation due to retention of feces. It is important to make a digital examination of the rectum in all cases of chronic diarrhea or constipation. The treatment is palliative or radical. In the former, measures are directed toward retarding the contraction by the use of bougies, and emptying the bowel by enemata and mild laxatives. In regard to the radical treatment, a difference of opinion exists as to whether the linear incision, as done by Mathews, is better than proctotomy. The latter operation is less dangerous and renders internal hemorrhage impossible, while the linear incision obviates future incontinence. Malignant strictures should be excised if not too extensive.

DR. E. D. FERGUSON considered the paper of great interest in that it described so satisfactorily the management of these cases. He prefers the linear incision, and emphasized the importance of dividing the stricture well down through the muscular coat, for if any fibers remain undivided, the process of contraction will continue. Dilatation with bougies will sometimes effect a cure, but the treatment is protracted and not unattended with danger. In cases in which the stricture is near the anus, immediate and satisfactory results are obtained. In cases where it is possible, the speaker makes an incision similar to that of Miculicz in pyloric stenosis.

DR. DOUGLAS AYERS of Montgomery County read a paper upon

PYOTHORAX IN CHILDREN.

The disease, which is a result of pleuritis, occurs most frequently during the first six years of life, and is rapidly fatal in infants. It is estimated that one-third of all cases of pleuritis in children go on to suppuration. The infection is usually a mixed one, streptococci and staphylococci being found as a rule, and streptococci and tubercle bacilli more rarely. The treatment consists of aspiration, incision, drainage, resection, and irrigation. The time to aspirate is at the time pus is discovered, and good results follow when this is done early. Often the pus is not completely evacuated by aspiration, and these cases should then be incised and drained. When drainage is not perfect, exsection should be performed. Recovery is generally rapid and no nidus is left for future trouble.

DR. FERGUSON remarked that the frequent occurrence of pyothorax in children is due to the great susceptibility of childhood to bronchial pneumonitis, the germs of which pass through the lung and infect the pleural cavity.

DR. JOSEPH D. BRYANT of New York County then read a paper, entitled

SOME UNUSUAL CASES OF APPENDICITIS,

which will appear in a later issue of THE MEDICAL NEWS.

DR. PARKER SYMS of New York County read a paper upon

THE SURGERY OF TUBERCULOSIS OF THE PERITONEUM,

which will also appear in a later issue of THE MEDICAL NEWS.

DR. W. E. SWAN of Saratoga County referred to a number of cases which he had seen at Johns Hopkins Hospital in the medical service of Professor Osler, who claims that many such cases recover without operation. In the same hospital he saw twelve cases which Dr. Kelly had operated upon. This operator claims that only fifty per cent. of those who recover are cured, *i.e.*, have no recurrence for five or six years. The speaker asked what Dr. Syms meant by "cured."

DR. SYMS replied that the term implied relief from symptoms. From a histologic standpoint, it is doubtful if the disease is ever cured. A case is not considered cured until two years have passed without a recurrence of symptoms. In 131 cases an apparent cure resulted in sixty-five per cent., but within two years a relapse occurred in a number, and the percentage of cures was brought down to twenty-one per cent.

DR. ELY VAN DE WARKER of Onondaga County said he had operated upon a case of this kind in 1883, which was reported at the time, and that the patient was still alive and well. Drainage should not be employed unless pus is present, which is rarely the case. The beneficial results obtained from this treatment are due, he thinks, to the thorough flushing of the abdominal cavity.

DR. SYMS, in closing, said he felt convinced that the great credit of effecting a cure in these cases should be given to the simple operation of laparotomy.

AFTERNOON SESSION.

DR. FREDERICK S. DENNIS of New York County read a paper on

TETANUS,

which will appear in a future issue of THE MEDICAL NEWS.

DR. ARTHUR Y. BENNETT of Erie County read a paper upon

MASSAGE AS AN OCCUPATION FOR THE BLIND,

in which he called attention to the large and increasing number of blind persons, most of whom are dependent upon others for their support, and said that the estimated number in this country is 56,000, of which 4398 are in this State. In order that many of these may become self-supporting, he advocates that they be taught massage in the State institutions, being trained in the anatomy and physiology of the body before they learn the practical work. He considers that the peculiar delicacy of touch which the blind possess makes them especially fit for this kind of work.

DR. CHARLES E. LOCKWOOD of New York County read a paper, entitled

A STUDY OF ALCOHOL, TOBACCO, TEA, AND COFFEE,
AND THEIR EFFECTS IN NERVOUS DISORDERS.

The author gave the results of an exhaustive study of the subject, and showed among other things that since 1870 the consumption of malt liquors in this country has been on the increase while that of distilled spirits has decreased. The fact was also demonstrated that the nations which consume the most alcohol are those whose criminality is least and whose vitality is greatest, although it must be remembered that this is but one factor in the case. Italy consumes very little alcohol, yet its criminality is appalling; Spain consumes three times less than Italy and its criminality is double that of the latter country. Norway, Sweden, and Denmark, with a population of about one-third, consume four times the quantity of alcohol used in Italy, and yet their criminality is relatively insignificant.

Alcohol was described as a stimulant in moderate doses, a narcotic in toxic quantity, and in a certain sense a food, inasmuch as it is almost entirely taken up by the system, and in that it prevents waste by retarding retrograde metamorphosis. Tobacco is a stimulant and sedative when used in moderation, and a relaxant, depressing and paralyzing when used in excess. The effect varies according to the habit, temperament, age, sex, and general constitutional conditions. It acts especially upon the spinal and sympathetic nerves and in lesser degree upon the cerebrum, cerebellum, and nerves of special sense. In large doses it is a virulent poison and acts principally upon the heart. It is a more powerful agent than alcohol in producing toxic amblyopia. Coffee and tea are nerve-stimulants in physiologic doses and nerve depressants when taken in toxic quantities. They act upon the brain by causing dilatation of its arteries, stimulate the accelerating and vasomotor centers, and also have a restorative action upon the voluntary and involuntary muscles when employed in moderation. Caffein in large doses depresses the respiration and pulse, and is a powerful poison. In immoderate doses, tea has a most injurious effect upon the nervous system.

THIRD DAY—OCTOBER 14TH.

MORNING SESSION.

The officers for the coming year were announced as follows:

President, Dr. Douglas Ayers of Montgomery County; vice-president, second district, Dr. C. E. Fritts of Hudson County; vice-president, third district, Dr. H. W. Carpenter of Oneida County; vice-president, fourth district, Dr. C. C. Fredricks of Erie County; vice-president, fifth district, Dr. N. W. Leighton of Kings County. Members of council: first district, Dr. W. H. Robb of Montgomery County; second district, Dr. E. M. Lyon of Clinton County; third district, Dr. W. L. Ayer of Tioga County; fourth district, Dr. Z. A. Lusk of Wyoming County; fifth district, Dr. J. G. Truax of New York County.

The matter of contributing to the Rush Memorial Fund was then taken up, and it was unanimously voted that

an appropriation of \$2000 be made from the general fund for this purpose.

The Secretary then read the paper of Dr. H. A. HAUBOLD of New York County, entitled

GENERAL CONSIDERATIONS CONCERNING AUTO-IN-
TOXICATION.

The author stated that recent investigations in regard to the poisons introduced into the body or spontaneously developed therein as a result of metabolism, make auto-intoxication a subject of considerable importance, and expressed his belief that the science of medicine will ultimately owe as much to physiologic chemistry as it now owes to bacteriology. As a rule auto-intoxication is secondary to infection. There is reason to believe, however, that the products of metabolism are as capable of being a causative factor in diseased conditions as are bacteriologic organisms.

DR. GEORGE TUCKER HARRISON of New York County read a paper on

ASEPSIS AND ANTISEPSIS IN OBSTETRICS, FROM THE
STANDPOINT OF PRESENT SCIENTIFIC KNOW-
LEDGE.

The author reviewed the history of asepsis and antiseptics of the puerperium from the time its importance was first recognized by Semmelweis during 1846, up to the present day. He protested against the too frequent examination and manipulation of the parts before labor, and also said there was no necessity to scrub the vagina previous to, or to administer douches during normal parturition. He emphasized the fact that by so doing the natural mucus secretion of the vagina, which besides lubricating the birth canal possesses germicidal properties, is washed away. He advocated external examination and cleansing of the outside parts only.

The Secretary announced that the President had appointed the following members to act as a committee to represent the New York State Medical Association in the matter of the hospital and dispensary abuse: Drs. Frederick H. Wiggin, S. B. C. McCloud, Parker Syms, A. H. Hubbell, and E. D. Ferguson.

DR. H. D. DIDAMA of Onondago County then read a paper, entitled

NON-ALCOHOLIC TREATMENT OF DISEASE.

The author earnestly protested against the use of alcohol in treating disease, and said that experiments have shown that even when used in small quantities it has a tendency to paralyze the higher brain centers. It is a depressant rather than a stimulant. It is not a food. It retards instead of aiding digestion. Its power to check the natural metabolism of tissues and delay the excretion of effete matter is not beneficial. The substitution of other drugs produces better results.

A paper upon

YELLOW FEVER

was read by DR. A. M. FERNANDEZ DE YBARRA of New York County, in which he emphasized the importance of allowing these patients liquid food only, even during convalescence. No stimulants should be admin-

istered with the exception of a little iced champagne occasionally.

The retiring President then introduced the newly elected President, DR. DOUGLAS AYERS, who thanked the members for the unexpected honor which they had conferred upon him, and said that he would do all in his power to make the next meeting of the Association a successful and profitable one, and asked the cooperation of all in urging a larger attendance at the annual meetings. The session was then declared adjourned.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

*Twenty-third Annual Meeting, Held at Louisville, Ky.,
October 5, 6, 7, and 8, 1897.*

DR. L. HARRISON METTLER of Chicago read a paper, entitled

NEUROSES OF GOUT,

in which he stated that the presence of uric acid in the system is not the cause of the neurotic manifestations in patients of gouty diathesis. The followers of Haig's chemic theory believe that they are caused by the presence of uric acid in the blood; that the acid affects the vasomotor system and so alters local nutrition. Others are of the opinion that the neuroses as well as the special symptoms of gout are but an expression of a purely neurotic diathesis—neurotic theory. Still others, with whom the speaker agrees, adopt the view that a nervous constitution, acquired or inherited, is the essential cause, the background as it were, of true gout and its manifestations. These latter may be aggravated or made to assume variable appearances by the associated auto-intoxication, which is but a product of faulty metabolism produced by the original altered innervation, *viz.*, that such gouty manifestations are the result of a trophoneurosis. He stated, further, that the altered innervation deranges the metabolic functions of the tissues, and as a result certain toxic excrementitious substances are overproduced or uneliminated, and finally these, reacting upon an unstable nervous apparatus, produce the various neuroses.

He maintained that the excrementitious products as revealed by the alloxmic substances in the urine consist of the combined uric-acid and xanthin bases. In gout the uric acid is frequently diminished in amount, but the increase of the xanthins explains the total increase of the alloxmic bodies. With Kalisch and some other investigators, he believes that it is the retention of the xanthins which causes the symptoms of gout. On the other hand, uric acid—which, as is now known, occurs only in the kidneys and when found in the blood has been reabsorbed—enters into combination in the blood to produce the urate of soda, which, for some unexplained reason, is deposited in the joints.

The symptoms of lithemia and of certain forms of neurasthenia, he believes, are also due to the retention of xanthins, as these diseases have many features in common with gout, chief of which is auto-infection. The uric-acid is significant in but one of these, *viz.*, gout, in

which it assists in the production of arthritic deposits. Such deposits can hardly be said to be the essential feature of gout, as they are very like certain deposits occurring in cerebrospinal meningitis, tabes, and other organic nervous diseases. The retained toxins, especially the xanthin group, are responsible for the symptom-complex characteristic of gout, lithemia, and neurasthenia.

Among the neuroses observed by the speaker are cephalalgia, epilepsy, chorea, convulsions, vertigo, pain—including neuralgia and psychic pain—hysteria, exophthalmic goiter, asthma, nervous dyspepsia, diabetes, multiple neuritis, facial paralysis, cerebral apoplexy, and aphasia. It will be seen that the speaker agrees with Haig and Munchison in assigning lithemia as the cause of many neuroses, but that he differs from them in giving the credit to an auto-intoxication of which uric acid is of less etiologic importance than the xanthin bases.

DR. J. M. BALL of St. Louis read a paper, entitled

REPORT OF SOME CASES OF OPHTHALMIC SURGERY.

The author gave an account of several cases of injury to the eye in which the proper surgical treatment proved satisfactory. One case of interest was a pseudoglioma, in which enucleation was performed. Another was the case of a man sixty years of age who had received 60 grains of quinin within twelve hours, and in whom the next morning there was total blindness. A diagnosis of quinin amaurosis was made.

THE REMOVAL OF ADENOIDS FROM THE VAULT OF THE PHARYNX

was the title of a paper by DR. L. C. KLINE of Indianapolis, in which he stated that there is great diversity of opinion regarding the use of anesthetics in the removal of adenoids. The majority of patients may be operated upon with equally good results by the use of cocaine. The author prefers the gradual operation to that made at one sitting, for the reason that there is less danger of subsequent hemorrhage and otitis. A forceps which the author uses was exhibited. When an anesthetic is employed a mouth-gag is necessary. In tuberculous cases the application of ichthyol is very beneficial. Various astringents may be employed with advantage, but surgery is the only sure means of affording relief.

DR. J. HOMER COULTER of Chicago followed with a paper, entitled

SURGERY OF THE AIR-PASSAGES IN CHILDREN.

He considered the subject one of great importance because of the high percentage of deaths from diseases of the air-passages during childhood, and because reflexes in childhood are more prominent and frequent than in adults. The parents of to-day should be taught that, with our modern methods, technic, and usually favorable prognosis, surgery in children is not the nightmare it formerly was. There is no longer any question of the bad effect of nasal obstruction upon adjacent organs. Any of the causes of nasal obstruction in children tend to septum deflection in adult life, and if for no other reason the physician is bound to give them all possible relief. Catarrhal deafness is almost always due to nasal obstruc-

tion. The entire field of pathologic conditions of the nose does not lie in the post-nasal space, nor is there any good reason why occlusion of the anterior chambers of the nose should not produce as many reflexes as does hypertrophy of Luschka's tonsil.

TREATMENT OF WOUNDS BY THE OPEN METHOD.

A paper upon this subject was read by DR. J. B. TAULBEE of Mount Sterling, Ky. Our present methods of treating amputations are different from those of a quarter of a century ago. A routine method is never a good one; hence each individual case is a law unto itself, both as regards irrigation and the kind of drainage, and whether or not temporary drainage should be instituted.

DR. F. F. LAWRENCE of Columbus, Ohio, read a paper, entitled

HYSTERECTOMY.

In what cases is hysterectomy justifiable? We must consider (1) how many patients would have died without this radical operation; (2) how many would have been hopeless invalids without it; (3) how many could have been cured by other means, and (4) the remote conditions or reflex results in those upon whom the operation has been performed. Hysterectomy is usually undertaken for cancer, pyosalpinx, fibromata, myomata, tuberculosis, and prolapsus. Hysterectomy for cancer is of doubtful utility, but when necessary should be done by the abdominal route. In pus-tubes the operation should be limited to those in which the walls of the uterus are involved in the diseased process. Simple adhesions are not sufficient reason for the performance of this operation. Small fibroids involving only the lower segment of the uterus should be treated tentatively. If the small fibroids are in the body of the uterus, they should be treated either by means of curetting, removal of the tubes and ovaries, or by hysterectomy, as the case demands. If the fibroids are small and occur about the time of the menopause, curettage, with electricity, is sufficient. For large fibroids growing after the menopause, hysterectomy is the only thing to be considered. In myomata or tuberculosis, this operation likewise affords the only prospect of relief. By removing the ovaries and tubes all of the diseased tissue is not taken away. Any method of operating should be judged by its safety from complications, the preservation of a firm pelvic floor, facility of operating, and the general results to both patient and operator.

DR. HENRY P. NEWMAN of Chicago read a paper, entitled

PELVIC DISEASE WITHOUT LOCAL SYMPTOMS,

in which he said that pelvic disease of an aggravated type is often present without noticeable local symptoms; that reflex symptoms begin in mere functional disturbances, and might become so serious as to endanger the life and health of the patient, and finally give rise to misdirected treatment, which does not recognize the existence of the real disease. It is necessary to understand the relative importance of pelvic irritation of certain obstinate and severe affections of more distant organs. This is very essential to a correct diagnosis in many

cases. Failure to exclude pelvic disease in the same manner as we exclude diseases of other important organs is unscientific and reprehensible.

DR. BAYARD HOLMES of Chicago contributed a paper, entitled

THE DIAGNOSIS OF SURGICAL DISEASES OF THE KIDNEYS, BLADDER, AND PROSTATE.

In his paper the author called attention to some methods of diagnosis of special value, and related at length his experience in their application, demonstrating by means of the Kasper cystoscope his method of catheterizing the ureters. He further demonstrated that the kidney could be exactly localized by auscultatory percussion.

DIAGNOSIS BY INSPECTION OF THE URINARY TRACT

was the title of a paper presented by DR. JOSEPH R. EASTMAN of Indianapolis. The use of the cystoscope is particularly important in the male. Its value in diagnosing vesical calculi, foreign bodies, neoplasms, and pathologic conditions resulting from gonorrhea, locating fragments after litholopaxy, etc., is positively determined. In the female its range of usefulness is still wider and its application more simple. The author clearly described and demonstrated the difficulties and technic of catheterization of the ureters.

In the discussion which followed DR. CORDIER said he had recently made some experiments with the X-rays in bladder work. He had, by placing a small photographic plate in the vagina and the rays above the abdomen, secured very excellent photographs. In the male the plate could be placed in the rectum and similar results obtained. Foreign bodies or calculi could be positively detected.

DR. LEON STRAUS of St. Louis read a paper upon

PRIMARY TUBERCULOSIS OF THE RECTUM, WITH REPORT OF CASES.

Tuberculosis of the rectum is a surgical disease. A thorough microscopic examination must be made in every case of suspected ulceration. The author reported four cases of removal of the ulcerated rectal tissue, and described his operation. Recovery followed in all but one of the cases. His conclusions are: (1) Primary tuberculosis of the rectum is not so infrequent as is generally supposed; (2) it is always surgical; (3) it cannot be diagnosed positively and invariably by the usual clinical symptoms, and (4) the microscope must be employed in order that a correct diagnosis may be made; (5) such cases can only be cured by thorough curettage or excision, or both; (6) some of the most hopeless cases are cured by repeated operations.

DISEASES OF THE RECTUM AND SIGMOID AS A FACTOR IN GENERAL DISTURBANCE

was the title of a paper presented by DR. J. R. PENNINGTON of Chicago. Various authorities are agreed that the *materies morbi* of a large number of somatic, mental, and nervous diseases have their origin somewhere in the gastro-intestinal tract. The importance of the rectum and sigmoid in many auto-intoxications is

entirely overlooked, and in consequence the primal defect is not located.

The next contribution, entitled

TREATMENT OF HERNIA IN OLD MEN,

was read by DR. A. J. OCHSNER of Chicago. It is a well-known fact that herniæ in men become more troublesome after the age of fifty. According to some authorities this fact is due to relaxation of the tissues, a tendency to obesity, and lowered vitality in general, but the author is convinced that the most important cause lies in the pressure exerted in evacuating the bladder and rectum, or the presence of an enlarged prostate. He described his operation for the radical cure of hernia in connection with castration for enlarged prostate. In cases in which there is simply hypertrophy of the prostate, the gland subsequently decreased in size very rapidly, affording much relief. If the surgeon has perfect control of his methods, securing perfect asepsis, the operation is absolutely safe. It relieves the patient of much discomfort, and every argument in favor of operation for the radical cure of hernia is applicable to the operation for resection of the spermatic cord for the relief of symptoms due to enlargement of the prostate gland. It is as yet too early to determine positively whether or not the favorable results obtained by the author in his cases would be permanent, but he had every reason to believe that such would prove to be the case.

DR. ROBERT T. MORRIS of New York read a paper upon

POST-OPERATIVE HERNIA IN CASES OF APPENDICITIS.

Operators are now using a much smaller incision than formerly, in order to avoid the subsequent occurrence of hernia. A pad over the seat of operation induces hernia by causing absorption of the new connective tissue as it is formed. The fibers of each muscle should be separated with the greatest care, and the same care is necessary in dividing the peritoneum. In closing the wound, each different layer of muscular tissue, as well the peritoneum and fascia, should be united with the same tissue from which it was separated in the beginning, so that the lines of muscular traction will not be disturbed, and then hernia is not so likely to result. The patient should be kept in bed for at least twenty-one days following the operation.

DR. JOHN YOUNG BROWN of St. Louis read a paper, entitled

SOME REMARKS ON APPENDICITIS,

in which he said conservatism had given place to knowledge in the treatment of this disease. The knowledge is now sufficiently comprehensive and accurate to afford a satisfactory working basis.

In the discussion which followed DR. MORRIS said that making a date to operate upon a case of appendicitis is certainly undesirable. The surgeon could not always wait until the third day. Rigor meant that toxins were entering the circulation and producing an impression upon the sympathetic system.

TUBERCULIN IN DERMATOLOGY

was the title of a paper read by DR. A. RAVOGLI of Cin-

cinnati, in which the author drew the following conclusions: (1) Tuberculin is a valuable aid in dermatology, both as a diagnostic and therapeutic agent. (2) In lupus it acts remarkably well as a systemic treatment, particularly in conjunction with other means for the purpose of reducing infiltrations. (3) After a large number of injections he has never observed any bad effects. (4) Old tuberculin had given more marked reaction, both general and local, than the new. (5) In cases over which no remedy had an influence, tuberculin promptly caused a disappearance of the eruption, healing of the ulcerations, and a general improvement in the condition. (6) If relapses occur after discontinuing the use of tuberculin the remedy should not be blamed. (7) To insure recovery, tuberculin must be used in small doses, administered at short intervals, and employed for a considerable time.

DR. B. SHERWOOD DUNN of Los Angeles, Cal., read a paper, entitled

MOTHERS AND DAUGHTERS,

in which he stated that higher education, according to many authorities, is detrimental to motherhood. He pointed out some of the fundamental errors in modern education and the training of girls, showing that, although upon the care of our children depends their lives and moral welfare, yet in our modern system of education not a word of instruction relative to the treatment of offspring is ever given to those who would become parents. He considered at length the necessity of the more careful physical training of girls. Labor, exercise, and food are important elements in training, and above all, they should have a proper knowledge of the physiologic functions peculiar to their sex.

FURTHER OBSERVATIONS IN THE USE OF HYDROGEN DIOXID IN THE TREATMENT OF BLEPHARITIS MARGINALIS

was the title of a paper presented by DR. S. C. AYERS of Cincinnati. This disease, unchecked, produces gradual destruction and atrophy of the hair-bulbs from chronic ulceration. Mercurial ointments have long been used and are well adapted to some cases, but irritating to others. An alkalin wash is very beneficial for softening the crusts; but in hydrogen dioxid the author thinks we have a remedy which both softens and dissolves. After using this drug, applied by means of a probe or scoop, the crusts may be easily removed.

DR. H. W. WHITTAKER of Columbus, Ohio, read a paper upon

CHRONICALLY DISEASED TONSILS.

Seriously diseased tonsils are frequently underestimated in importance and left untreated, when they undoubtedly are very injurious to the general health. Hypertrophy of the tonsil is found in childhood; hyperplasia in the adult. The causes which induce chronic tonsillitis may be predisposing or exciting. Among the former, the most important is heredity, and among the latter diphtheria, and the exanthemata are the usual causal agents. The author gave a comprehensive description of the symptoms usually present. Prognosis is good, providing excision

is properly performed. The voice is vastly improved both in tone and quality after excision of the tonsils, and no deleterious effects ensue.

DR. J. F. BARNHILL of Indianapolis presented a paper, entitled

HYPERTROPHIED FAUCIAL TONSILS.

The system suffers little or nothing from ablation of the normal glands. The author's classification is: (1) Those in which the patient claims never to have suffered inconvenience from the tonsils; (2) those in which quinsy or tonsillitis occurs one or more times a year; (3) a small, flat, yet pathologic gland. In all cases the diseased crypts should be cleansed. Pathologic tonsils frequently are a cause of reflex neuroses. Various methods of treatment were considered, and the merits of each pointed out.

DR. FRANK P. NORBURY of Jacksonville, Ill., read a paper upon

INSANITY OF ADOLESCENCE,

in which he drew the following conclusions: (1) Adolescent insanity is a pure psychosis, dependent upon hereditary factors and acquired conditions, which especially inhibit the higher psychic centers and later the sensory motor functions of the cortex. (2) That the vasomotor and trophic centers are involved. (3) That the sympathetic nervous function is disturbed, which, in females, is apt to eventually result in suppressed menstruation, or even sexual excitation, producing nymphomania. (4) Masturbation is a complication which, in the male, is apt to cause reflexes.

THE TREATMENT OF CEREBROSPINAL SYPHILIS

was the title of a paper read by DR. A. E. STERNE of Indianapolis. In the treatment of syphilis of the brain and cord ordinary therapy is wholly inadequate, if not entirely wrong. The dose of the iodids is too small; the potash salt is inferior to the sodium salt, particularly when large doses are employed. The syphilitic lesions of the brain and cord may involve the meninges, the brain and cord tissues with gummy formation, the bony parts, and the blood-vessels. The author drew attention to three important points in diagnosis and therapy: (1) In producing reflexes with the percussion-hammer there occurs a second prolonged contraction across the muscle at the point of the blow; (2) the iridic reflex to light is sometimes difficult to determine, and is not always present; (3) when capillary pulsation occurs it indicates high arterial tension, and serves as a guide in the use of heart-stimulants.

THE MOTOR NEURON IN PRACTICAL DIAGNOSIS

was the title of a paper read by DR. HUGH T. PATRICK of Chicago. The author made a concise statement of the more practical relations of the neurons of the motor tract. A neuron, as he explained, is simply a nerve unit, and the motor-tract is entirely composed of two distinct sets or neurons, an upper and lower. A lesion of either causes paralysis, but the customary accompanying symptoms are radically different in the two groups. The *rationale* of these differences was briefly indicated, and it was explained that in a lesion of the upper neurons

the paralysis is spastic, accompanied by increased deep reflexes, absence of atrophy, and change in electric reactions. On the other hand, in a lesion of the lower neurons, the accompanying and distinctive signs are flaccidity, loss of deep reflexes, the occurrence of atrophy, and the reaction of degeneration. It was further stated that it does not make any difference which part of the neuron is affected, the result in all respects being exactly the same.

DR. ZENNER of Cincinnati read a paper upon

TOBACCO NEUROSES.

In very many instances tobacco is only one of the many causes of an existing malady. Among the other factors often conjoined with it which make a correct diagnosis more difficult are alcohol, coffee, mental-strain, worry, etc. Syphilis often plays an important part. The neuroses traced to tobacco are functional diseases of the heart, amblyopia, tremor, vertigo, neurasthenia, some forms of neuralgia, rarely angina, and the lesser nervous disturbances, epilepsy, various psychoses, and even paresis has been attributed to it, although it seems without sufficient reason. The treatment is abstinence. The mere lessening of the amount usually fails altogether. Frequently, abstinence of a year or more permits a return to the use of tobacco in moderation without resulting harm.

A very instructive and exhaustive paper was read by DR. HOMER M. THOMAS of Chicago, entitled

EXPERIMENTAL WORK ON THE PENETRABILITY OF VAPORIZED MEDICAMENTS IN THE AIR-PASSAGES.

Do vapors enter the alveoli of the lungs? All observers have questioned such a possibility. The greatest difficulty has been in the instruments for vaporization, in that they have failed to break an oil into sufficiently fine particles. The author related in detail the results of his experiments, which had been made mostly upon animals during the past two years, and gave his reasons for believing that under proper conditions the medicament will enter the healthy lung, even to the alveoli. A variety of microscopic slides were exhibited, taken from the lung of a patient by whom inhalation had been practised shortly before death, and which plainly showed the oil-globules in the alveoli.

EPISTAXIS IN THE MOST SERIOUS FORM, WITH REPORT OF A CASE NECESSITATING LIGATION OF THE COMMON CAROTID

was the title of a paper presented by DR. MAX THORMER of Cincinnati. The author considered serious only those cases in which the ordinary styptics fail to check the hemorrhage. He referred to four instances in which the radical operation of tying one or both carotids was practised, two of which proved fatal. The paper closed with a reference to his own case, which was that of a man struck with an iron ring across the bridge of the nose and right side of the face. Unconsciousness and profuse bleeding from the nose followed. The patient was removed at once to the hospital and the nose plugged. During the next eighteen days the nose was tamponed repeatedly, both anteriorly and posteriorly, but each time after the removal of the packing the hemorrhage started afresh within a short time.

The patient, becoming almost exsanguinated, with high pulse and temperature, an operation was decided upon. The common carotid was ligated. The hemorrhages did not recur, and the patient was discharged one month after the operation.

DR. WILLIAM E. WIRT of Cleveland contributed a paper upon

THE TREATMENT OF SCOLIOSIS,

in which he referred to the use of dry heat at a high temperature for the treatment of this condition. He recalled the fact that he had originated this treatment three years ago, and had been experimenting extensively along this line ever since. He explained in detail the apparatus used to enclose the heat about the joint, and by reference to several well-authenticated cases, showed the certain value of dry heat in the therapeutics of scoliosis.

DR. A. H. CORDIER of Kansas City, Mo., read a paper, entitled

SOME PHASES OF EXTRA-UTERINE PREGNANCY.

This condition is not recognized and diagnosticated as it should be by the general practitioner. The application of common sense and good judgment is the best guide in bringing about a successful termination of ruptured tubal pregnancy. If a blood-vessel is injured and bleeding, it should be tied. The diagnosis is usually not very difficult. A very important point is the menstrual history, which should be thoroughly investigated. A tube having once ruptured will continue to give trouble. The dangers of the condition far outweigh the dangers of good surgery. Operation should be performed at the earliest possible moment. No case is devoid of danger until the bleeding vessel is firmly tied.

THE TREATMENT OF SUPPURATING FISTULOUS TRACTS.

This paper was read by DR. E. J. SENN of Chicago. The primary dressing should not be disturbed for four or five days, when, if necessary, it is removed and repeated. Nitrate of silver or other caustics should not be used, as the granulations are only superficially destroyed, leaving a necrotic area. If the granulations are persistently sluggish, the wound should occasionally be packed with gauze, saturated with balsam of Peru, as this agent stimulates the regenerative capacity of embryonal cells without impairing the vitality of the surrounding tissues. In the author's hands, most obstinate fistulæ have yielded under the treatment suggested, where previous antiseptic irrigation proved of no value.

Amendments to the Constitution, enlarging the duties of the secretary and providing a salary for his services, were adopted. Action was taken with regard to the permanent preservation of the "Transactions of the Association."

A resolution rescinding action previously taken relative to the reported quarantining of Louisville by the State of Indiana, was unanimously passed.

The following officers were elected: President, Dr. John Young Brown of St. Louis; vice-presidents, Drs. A. J. Ochsner of Chicago, and A. P. Buchman of Fort

Wayne; secretary, Dr. Henry E. Tuley of Louisville, Ky.; treasurer, Dr. Charles A. Wheaton of St. Paul. The next meeting of the Association will be held at Nashville, Tenn., the second Tuesday in November, 1898.

THERAPEUTIC HINTS.

For Gastric Ulcer.—

℞	Codeini phosph.	} aa	gr. v
	Ext. belladonnæ		
	Bismuthi carb.		gr. i
	Lactose		3 i.

M. Ft. chart. No. xv. Sig. Take two or three powders daily.—*Leube*.

For Lumbago.—

℞	Potassii iodidi	3 ss
	Tinct. opii deodoratæ	3 ii
	Spts. lavandulæ comp.	3 i
	Spts. ætheris nitrosi	3 ss
	Aquæ destillatæ	3 xii.

M. Sig. Take two tablespoonfuls twice daily.—*Brodie*.

For Acute Mania, with Motor Excitement.—

℞	Ext. gelsemii fld.	3 iii
	Syrupi acidi citrici	3 ii
	Aquæ destillatæ	3 xi.

M. Sig. A teaspoonful to be taken every two hours until physiologic effects are produced.—*Bartholow*.

For Melancholia.—

℞	Zinci valerianatis	} aa	3 ss.
	Ferri valerianatis		
	Quininæ valerianatis		

M. Ft. massa et in pil. No. xxx div. Sig. One pill to be taken three times daily.—*Wilson*.

For Sciatica.—

℞	Tinct. cannabis indicæ	3 vi
	Syr. acaciæ	3 iss
	Aquæ destillatæ, ...	q. s. ad. 3 vi.

M. Sig. A tablespoonful to be taken every four to six hours.—*Neligan*.

For the Removal of Superfluous Hair the following is recommended:

℞	Tr. iodi	3 parts
	Ol. terebinth.	6 parts
	Ol. ricini	8 parts
	Spiritus	48 parts
	Collodii	100 parts.

M. Sig. The affected part is to be painted with this mixture once daily for three or four successive days.

When the collodion scab is removed the hairs will be found imbedded in its lower surface.—*Putte*.

For Hypertrophy of the Tonsils.—

℞	Iodi pur.	gr. i
	Potassii iod.	gr. ii
	Tr. opii	gr. xx
	Glycerini	3 iv.

M. Sig. With this mixture the tonsils are to be painted morning and evening; it should also be used as a gargle, diluted in the proportion of one-half a teaspoonful to a glass of warm water.—*Moure*.

ORIGINAL ARTICLES.

THE CLINICAL IMPORTANCE OF IMPACTED AND ADHERENT PELVIC TUMORS.¹

By HENRY C. COE, M.D.,
OF NEW YORK.

SOME apology would seem necessary for introducing a subject which apparently is of interest only to specialists. A little reflection, however, will convince every one that it closely concerns the general practitioner, for his attention is frequently directed to phenomena, the proper appreciation of which would lead to the inference that he has to deal with a condition which can only be treated surgically in order that the patient may be saved serious trouble in the future. The subject is not new; neither is there anything new in regard to the early recognition of carcinoma of the cervix uteri, yet it is notorious that in spite of the stress which is laid in every monograph and text-book upon the importance of recognizing the initial symptoms of this disease, not one case in fifty in this country is referred to the surgeon during the operable stage, while the histories of these unfortunates show that local pains, atypical hemorrhage, etc., which should have awakened the gravest suspicion, are explained as due to neuralgia, or the climacteric, no local examination being made until too late. For the same reason, pelvic neoplasms often remain unrecognized for a long period, while the pressure-symptoms to which they give rise are misinterpreted. There is another reason why this subject is of special interest; it clearly illustrates the close relation between gynecology and general medicine, a union which ought not to be disturbed any more than that which exists between obstetrics and the diseases of women.

I need not enumerate the different varieties of intrapelvic neoplasms, or call your attention to the elementary fact that a growth varying in size from that of an English walnut to a baseball may possess neither clinical nor pathologic interest so long as it is freely movable and does not press upon adjacent vessels or nerves. But let such a tumor, whether it be a cyst or subperitoneal fibroid, become impacted in Douglas' pouch, or surrounded by inflammatory exudate, and the entire situation is changed. Marked symp-

toms arise, and the patient's comfort, general health and perhaps even her life are concerned. This may be illustrated by briefly citing the history of a case seen within a week. The patient, a strong, healthy primipara, aged thirty-five years, had never had any local symptoms whatever until after the birth of a child five months ago, the labor being a protracted one and terminated by the use of forceps. The pelvis was of normal dimensions, and dystocia was supposed to be due to rigidity of the soft parts. Convalescence was afebrile, and the patient soon resumed her household duties, but found that she tired easily, had a sensation of pressure at the lower end of the spine, and was obliged to micturate at frequent intervals, this act being followed by severe tenesmus. Menstruation returned, and was normal. The natural inference was that she was suffering from the retroversion so common after difficult parturition, lacerations of the pelvic floor, subinvolution, etc., but local examination revealed a hard, immovable tumor filling the posterior cul-de-sac, and apparently adherent to both uterus and rectum. It is probable that this neoplasm (either an ovarian or subserous uterine fibroma of long standing), was carried up out of the way during pregnancy, undoubtedly increasing in size under the influence of the physiologic congestion of gestation, and, when the uterus was suddenly emptied, dropped down into the cul-de-sac, where it became impacted. It is easy to see how serious might have been the result had this occurred at an early stage of pregnancy.

It may be stated, in brief, that the points of interest to the general practitioner in connection with impacted pelvic tumors are as follows: The symptoms which they occasion are often referred to diseases of the pelvic or abdominal viscera, and patients are treated for a long time without relief, when the condition is mechanical rather than inflammatory or functional (neuralgia). The amount of pain and visceral disturbance frequently is entirely out of proportion to the size of the new growth, and distant organs may be affected (as the kidneys, through pressure on the ureters). Even when the presence of the neoplasm is recognized its importance may be underestimated. Finally, the complication of these tumors with pregnancy and parturition is so important as to deserve the most serious attention.

As regards their relative clinical importance, intrapelvic tumors vary according to their anatomic char-

¹ Read at a Stated Meeting of the New York County Medical Society, October 25, 1897.

acter, mode of development, and locality. Thus, a pus-sac or dermoid cyst would naturally give rise to more serious symptoms than a simple ovarian or parovarian cyst; a rapidly growing cystoma possesses more significance than a small subperitoneal fibroid. The inflammatory exudate thrown out around a pus-tube, suppurating cyst, or dermoid, or a ruptured ectopic, produces various disturbances aside from mere mechanical pressure. Again, a tumor impacted in Douglas' pouch possesses more clinical importance than an intraligamentous growth of the same size and variety, or one adherent to the upper border of the broad ligament. It is self-evident that in estimating the seriousness of the condition in a given case, and the indications for operative interference, all of these factors must be considered.

For practical purposes we need only refer to tumors situated in Douglas' pouch, since these are the most common, and attended by the most characteristic symptoms. The most obvious effects resulting from the presence of an impacted tumor are those due to pressure. The uterus, from its mobility and intimate relation to the neoplasm, is apt to be first affected, ante- or lateroflexion, less often prolapsus, being a result. Retroflexion and ascensus are due rather to accompanying adhesions than to mechanical pressure. *Procedentia*, occurring in a young woman with a firm pelvic floor (with the exception of certain rare cases of acute displacement), should be regarded as an evidence of probable pressure upon the organ from above. Following this clue, I have, on several occasions, discovered unsuspected neoplasms which had not given rise to local symptoms. It is an evident fact that the rectum is always more or less encroached upon by growths situated in the cul-de-sac, the degree of occlusion of its lumen varying with the size of the uterus and the intimacy of its adhesion to the parts. The bladder naturally shares in the pressure effects produced upon the uterus, dislocation of the viscus causing traction upon the fixed point, the neck, with the attending disturbances. Still more serious are the results of direct pressure caused by fibroids in the lower uterine segment, secondary malignant nodules, etc. Prolonged impaction may lead to cystitis and pyelitis, and perhaps terminate fatally.

The results of pressure on the intrapelvic portions of the ureters by growths in the lower uterine segment or at the base of the broad ligament, are well known. It is interesting to note that in not a few instances the cause of a hydronephrosis has been found to be occlusion of the duct by the pressure of a tumor so small that it had escaped notice. In a previous paper I have called attention to the importance which a small exudate in the broad ligament may assume through its relation to the ureter.

The general venous congestion of the pelvic organs in connection with impacted tumors is frequently noted upon the operating-table. Varicose veins of the labia and hemorrhoids present external evidence of obstruction to the circulation. The tendency of impacted growths to become adherent to neighboring organs is a matter of common knowledge, especially in the case of dermoids of the ovary. In many instances the inflammatory process seems to be due simply to prolonged friction of opposed serous surfaces, but in others there is evidence of general pelvic peritonitis. It is a common fact that where the adhesions are found most firm and extensive, there may have been no history of a previous attack of pelvic inflammation, and the patient is remarkably free from pain.

The difference between an impacted and an adherent tumor is an important one from both a surgical and an obstetric standpoint. When the neoplasm is attached to the uterus and rectum, the pressure effects already noted are exaggerated. If the small intestine or appendix be adherent to the tumor, other disturbing effects are noted, which need not be enumerated here. The intimate relation of an intrapelvic cyst to the hollow viscera, especially to the large intestine, favors septic infection of the cysts-contents, and the discharge of the contents of a dermoid from the rectum or bladder is sometimes the first indication of the existence of a tumor. A small growth, which previously gave rise to no symptoms whatever, may, under the influence of pregnancy, not only increase in size, but from adhesions, be permanently imprisoned in Douglas' pouch. This is well illustrated by the following case, which is one of the three that have been under my observation:

The patient had never had pelvic symptoms. After a normal pregnancy, during which I had examined her several times with a negative result, as the labor pains began a cystic tumor the size of a lemon could be felt behind the uterus, which I was unable to push upward. However, as the head descended the cyst slipped out of the way and delivery was soon effected. Subsequently, I could not detect the tumor, the patient being quite stout. I lost sight of her for nearly three years, when she returned during the fifth month of pregnancy. The cyst was again detectable in Douglas' pouch, considerably larger than before, and firmly adherent. It still caused no symptoms. A few days later the growth was removed by abdominal section, and proved to be a dermoid cyst with a long pedicle, which was attached by recently formed adhesions to both the uterus and the rectum. Pregnancy was not interrupted, and spontaneous delivery occurred at term.

The importance assumed by the small fibroid in the lower uterine segment is entirely out of proportion to its size. This is illustrated by a case in which

a tumor had existed for a period of ten years without causing symptoms until it compressed the ureter, with resulting hydronephrosis. Yet it was necessary to deliver the woman by means of a Cæsarean section, and the growth, insignificant though it was, eventually caused the patient's death from the kidney disease which had been induced.

The symptomatology is especially interesting to the general practitioner. As has been stated, many intrapelvic tumors of long standing are accompanied by singularly few symptoms, and those ill defined. Local pain naturally directs attention to the pelvis. As in the case of carcinoma of the uterus, the more severe, throbbing, and lancinating pains are due rather to the accompanying inflammatory process than to the mechanical pressure of the growth. Pain emanating from abnormal conditions of the sacral, sciatic, and genitocrural nerves is often mistaken for rheumatism, and is treated as such. In a case now under observation an impacted ovarian tumor gives rise not to local but to reflex intercostal neuralgia and also hemicrania, exaggerated at the menstrual periods. There is no dysmenorrhea, or in fact any other symptom, except a slight sensation of pressure upon the rectum. Colicky pains, localized in the appendic region, etc., are common in connection with extensive intestinal adhesions. In two instances, sudden dislocation of a subperitoneal fibroid into the pelvis closely simulated rupture of an ectopic sac. The rectal symptoms are quite characteristic, chief among which is a feeling of obstruction in the passage of fecal matter, and tenesmus following defecation, with a sensation as if the lower bowel were not completely emptied. Whenever these symptoms are mentioned I always think of possible compression of the rectum by a tumor. More or less complete occlusion of the lumen, indicated by the small caliber of the fecal movement, of course, suggests such a condition, in the absence of symptoms of malignant disease of the part. Chronic proctitis is often present in these cases. On more than one occasion I have been led to suspect the presence of an intrapelvic growth in a young girl by reason of obstinate hemorrhoids, which could not be explained in the ordinary way. In one instance this was the only symptom, if I may so call it, of an impacted dermoid. The bladder is so sensitive to all disturbances of the pelvic equilibrium that one would expect frequent micturition and tenesmus to be common, and such is the case. In fact, these sometimes furnish the only evidence of the presence of a growth which encroaches upon the pelvic organs. These same symptoms, it should be added, also accompany ureteral troubles, to which allusion has been made. In the absence of satisfactory evidence of disease of the urinary tract it is

always well to bear in mind the possibility of pressure upon or dislocation of the bladder by a neoplasm.

As far as the uterus is concerned, the symptoms referable to the tumor, though not characteristic, are useful because they lead one to examine the pelvis which, in the absence of less definite symptoms might be neglected. Flexions give rise to dysmenorrhea. Menorrhagia, referable to the hyperplastic endometritis, which is the result of the uterine congestion induced by the presence of the tumor, is rather an important symptom, especially in unmarried women in whom menstruation has previously been normal. This, in connection with the pressure symptoms before mentioned, should lead the practitioner to insist upon an examination, which can be efficiently made per rectum.

As regards the question of diagnosis, it is assumed that we are not considering those cases in which there is a clear history of long-standing pelvic trouble, or in which the sudden onset, severe pain, febrile disturbance, etc., indicate an acute inflammatory process. Neither do we consider cases in which the growth has reached such a size as to be appreciable to the patient. We are concerned, rather, with those conditions which, because of the slight local and general trouble occasioned by them, are apt to be overlooked.

The detection of tumors in Douglas' pouch by the bimanual method is an elementary procedure; the differential diagnosis belongs to higher education, in which no man ever attains more than the first degree. Rectal palpation should never be omitted; in young girls it alone is permissible. Fortunately, the information thus obtained is often conclusive. Having established the presence of an intrapelvic growth it remains to discover its probable origin, character (whether solid or fluid, cystic or purulent), relations, fixation to neighboring organs, and to draw some inference in regard to its rate of growth—all of which have a direct bearing upon the prognosis and treatment. If the result of the examination is not entirely satisfactory it should be repeated with the aid of anesthesia.

With recognition of an impacted pelvic tumor the question of treatment at once arises. Two points must be considered: the present comfort of the patient, and her future safety. With the first the size of the growth has little to do. A tender ovary, the size of a walnut, may cause greater distress than a fibroid the size of a grape-fruit. Pain then, constant, severe, aggravated at the menstrual period, and increasing in spite of local treatment, electricity, etc., is a sufficient indication for operative interference. Marked pressure-symptoms increasing in severity, so that life is rendered unbearable, furnish,

in connection with steady growth of the tumor, ample excuse for an operation. Add to this evidence of suppuration, accessibility to the vaginal fornix, etc., and it will be seen that many factors must be considered in a decision as to the proper course to be pursued.

I do not propose to renew the discussion of the relative advantages of the vaginal and abdominal route for the removal of small neoplasms situated in Douglas' pouch. There is always a strong temptation to resort to the former method, not only because the operation would appear to be easier and attended by less disturbance to the patient, but because she naturally shrinks from celiotomy if it can possibly be avoided. I doubt not that many of my hearers, like myself, have had occasion to regret the choice of the vaginal route. It is interesting to note that surgeons here and abroad who were the strongest advocates of this method of removal of all, or nearly all, intrapelvic tumors are rapidly shifting their position and limiting its application to cases in which there is ample room for manipulation, and good reason for apprehending the presence of pus or some infective material which it is desirable to keep out of the peritoneal cavity. It is now quite generally acknowledged that only an imperfect idea of the extent of pelvic adhesions can be obtained through a vaginal incision, and, moreover, that the conservative treatment of diseases of the adnexa, now so generally practised, can be carried out more thoroughly and intelligently when the entire field of operation is exposed to view. Since one can seldom determine before opening the abdomen the exact relation and extent of adhesions of the neoplasm which is firmly fixed in the cul-de-sac, it would seem wise (except under the conditions mentioned) to approach these growths by the abdominal route. Even when the small size of the tumor would seem to justify the choice of the vaginal route the decision in a given case is, of course, determined by the skill and experience of the individual operator; but the occasional operator will be on the safe side if he elects to open the abdomen in every case in which he proposes to extirpate a tumor. For the purpose of simple incision and drainage there is no difference of opinion regarding the propriety of operating *per vaginam*.

The enucleation of impacted intra- or extraperitoneal fibroids is often not only exceedingly difficult, but it is attended by a high degree of shock, even when the loss of blood is moderate. This leads us to a consideration of the treatment of impacted tumors complicating pregnancy. As I have already shown, these are especially dangerous because they commonly do not give rise to symptoms

which arrest the attention of an inexperienced observer, especially during the early months. In the case of the dermoid cyst to which I referred, as in those of two others seen with colleagues, the growth was either discovered during an ordinary perfunctory examination, or if known to exist before was recognized simply as a movable cystic ovary. This leads me to emphasize the importance of the routine examination of women during pregnancy, even though the *accoucheur* may have attended them on one or more previous occasions. This is insisted upon in all advanced text-books, but unfortunately, except by the specialist, is too infrequently practised. If it is regarded as a grave reproach to the physician who fails to discover a marked pelvic contraction until labor has well advanced, how shall one hold himself blameless when he does not discover an impacted pelvic tumor until parturition occurs, the patient having been under observation during several months?

With regard to the treatment of such growths before the seventh month of pregnancy, there is little room for difference of opinion. If repeated, careful attempts to dislodge the mass, with the patient in the knee-chest position (under anesthesia if necessary), are unsuccessful, the question of interference at once arises. Previous to the fourth month, or perhaps a couple of weeks later, the induction of abortion may be elected, though even this is fraught with some risk if a solid tumor encroaches to a marked degree upon the lower uterine segment. In a fatal case, which I saw in consultation, it had been impossible for a three-month's fetus to pass. After four or four and one-half months, in the interests of both the mother and child, I would insist upon the choice of celiotomy even when the tumor is small and accessible *per vaginam*. It is unnecessary to add that with our modern methods of operation and after-treatment the risk of interrupting the pregnancy is reduced to a minimum. Should premature delivery occur, as indicated by my experience, no harm results. I have never attacked an intrapelvic neoplasm by the vaginal route in a pregnant woman, through fear of hemorrhage, infection, and interruption of pregnancy by reason of the necessary traction which must be made upon the uterus, save in one instance, in which I opened the abdomen at the fourth month and found such firm and universal intestinal adhesions that I was obliged to close the incision and open a large ovarian abscess through the posterior vaginal fornix. Fortunately the uterus was not infected and pregnancy continued a month longer. The frequency with which dermoids become adherent in the cul-de-sac, and their liability to undergo degenerative changes renders it imperative that they

should not be allowed to be subjected too long to pressure by the growing uterus. If a patient is not seen before the seventh month, and there are no urgent symptoms, I would be inclined to temporize at least a month longer, in the interests of the child, and then perform celiotomy as before. The induction of labor, under these circumstances, offers little more chance for the child, and exposes the mother to practically the same risks as does labor at term. Celiotomy must eventually be performed even if it does not become an urgent necessity a day or two after delivery because of complications resulting from mechanical injury to the tissues.

The question of the proper treatment of impacted uterine fibroids during the early months of pregnancy was forcibly brought to my attention by a case recently seen in consultation. A tumor was recognized in the cul-de-sac as early as the third month, but was supposed to be ovarian. On opening the abdomen it was found to be a sessile, subserous fibroid. The patient was exceedingly anxious to have a child, so the idea of hysterectomy was not entertained. In order to check the growth of the fibroid, which then was not larger than an orange, the adnexa were removed. Unfortunately, the increased blood-supply incident to pregnancy caused the tumor to grow rapidly, so that when I saw the patient two months later there was no question as to the impossibility of delivering a living child *per vias naturales*. The choice accordingly lay between the immediate induction of labor and Cæsarean section near or at term. The latter proposition being rejected, there was nothing to do but to induce labor and deliver the immature fetus, which was effected with great difficulty and only after embryotomy. The woman is now, of course, without any hope of offspring. Should I have a similar case under my own care, I would either induce labor at the beginning of pregnancy and later deal with the tumor in as conservative a manner as possible, or, after opening the abdomen, perform a myomectomy if possible. Abortion doubtless would follow, but hemorrhage could be controlled, and subsequent conception would not be rendered impossible. Before undertaking such an operation, however, permission should be obtained to amputate the uterus if it is evident that there is no chance of safely removing the tumor, assuming that the idea of a Cæsarean section or Porro operation is not entertained.

The management of labor at term, when complicated by adherent pelvic tumors, is discussed in all text-books on obstetrics, and need not be reiterated here. The problem presented is purely a mechanical one, and, while the safety of the mother is paramount, such a method of procedure should be adopted,

if possible, that insures the delivery of a living child. If the tumor is cystic, and it is evident that the head cannot pass without a dangerous amount of compression, tapping is indicated, or even incising of the sac, with thorough disinfection. Some anxiety will naturally be felt for a few days subsequently, and the attendant should be prepared to perform celiotomy without delay if threatening symptoms develop. In the presence of a solid, impacted growth, the decision as to the proper method of operation will be governed by the size of the tumor, its locality, and the degree of encroachment upon the birth-canal. It should be remembered that thick-walled dermoids intimately attached to the uterus are commonly mistaken for fibroids.

The performance of celiotomy does not necessarily imply Cæsarean section or supravaginal amputation. It has been suggested (and successfully practised) to perform ovariectomy or myomectomy, then to close the abdomen and deliver the child *per vaginam*; but no fixed rules can be laid down, since each case must be left to the individual judgment of the attendant.

To summarize briefly: Impaction, and especially adhesion, of an intrapelvic tumor invests such a growth with an importance out of proportion to its size. The first indication of the condition may be the occurrence of certain pressure-symptoms referable to the rectum and bladder which are often erroneously referred to diseases of these viscera. Local pain, if present, is more or less constant, and is often of a neuralgic character. Such symptoms suggest the propriety of a careful examination. The prognosis and indications as to treatment are determined by a thorough appreciation of the size, character, and site of the tumor, and its attachment to adjacent organs. The possibility of pregnancy, with the added risks entailed, is always to be considered. The treatment is surgical, celiotomy being preferable except in the presence of suppuration. In early pregnancy there is a choice between removal of the tumor and the induction of abortion, with subsequent celiotomy. At a later stage the most heroic method is really the most conservative as regards both mother and child. If the tumor is first discovered during parturition, there is often no alternative but a prompt Cæsarean or Porro operation.

Alvarenga Prize.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, amounting to \$180, will be made on July 14, 1898, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published, and must be received by the Secretary of the College on or before May 1, 1898.

THE CLINICAL VALUE OF THE WIDAL TEST FOR ENTERIC FEVER.¹

By W. GILMAN THOMPSON, M.D.,
OF NEW YORK;

PROFESSOR OF MEDICINE IN THE NEW YORK UNIVERSITY; VIS-
ITING PHYSICIAN TO THE PRESBYTERIAN AND
BELLEVUE HOSPITALS.

I HAVE gathered data regarding the Widal serum-test for the presence of typhoid fever from five of the larger New York hospitals; namely, from my own service and that of others of the visiting staff of the Presbyterian and Bellevue Hospitals, from the service of Dr. Frank W. Jackson at Roosevelt Hospital, from the service of Dr. A. A. Davis at St. Luke's Hospital, and from examinations made by Dr. George P. Biggs, Pathologist to the New York Hospital.

Altogether 503 cases have been analyzed, 157 being undoubted enteric fever. The tests in some few of these cases were made by the New York Health Board at the municipal laboratory; in other cases by the pathologist or other physician in the hospital in which they occurred; in every instance by experienced bacteriologists. In a large proportion of cases the blood was furnished to an examiner who had no previous knowledge of the patient, and the test was often witnessed and confirmed by others, so that any element of prejudice for or against its value may be eliminated. As for the manner of applying the tests, the extensive experience of those who made them leaves no room for criticism. Identical cultures and identical methods were employed simultaneously in those cases which responded and in those which did not. Both serum and blood were used, usually in proportions of 1-10, but in some instances, stronger, in others, weaker, the serum being obtained by means of a fly blister. Dr. Egbert Le Fevre, of the University Medical College division of Bellevue Hospital, employed twenty-four-hour cultures from stock tubes, grown in bouillon and agar. Dr. George A. Tuttle, of the Presbyterian Hospital, used cultures of bacilli transplanted at intervals of two to three weeks from which fresh cultures were grown in beef peptone bouillon for twenty-four hours in an incubator. For most of his tests he used dried blood dissolved in water, the dilution being 1-10 or 15. In some cases serum was employed. A large proportion of all the cases herein reported were tested more than once, many of them, especially the doubtful ones (or those in which clumping was observed without complete loss of motility), from three to five or more times. In general, the intensity of the reaction appeared to increase decidedly as the disease advanced, although

slight variations in degree were noticed from day to day by all observers,

One case, reported by Dr. Tuttle, gave no reaction upon the fifth, sixth, seventh, and eighth day of the disease, but did give a strong reaction during convalescence. Several cases without reaction when first tested, four days later were doubtful or suspicious, and four days later still, gave a good or strong reaction. Dr. Tuttle's table, compiled from cases at the Presbyterian Hospital, showing increase in intensity of the reaction as the disease progressed, is as follows:

Case.	Day of disease. Day of first test.	Reaction.	Day of second test.	Reaction.	Day of third test.	Reaction.	Day of fourth test.	Reaction.
1.	4th.	None.	8th.	Good.				
2.	7th.	Slight.	16th.	"				
3.	Doubt- ful.	Suspi- cious.	2 days later.	Suspi- cious.	4 days later.	Fair.	6 days later.	Good.
4.	"	"	1 day later.	"	"	"	"	"
5.	6th.	None.	10th.	Good.				
6.	Doubt- ful.	"	4 days later.	Fair.	14 days later.	Strong.		
7.	7th.	Suspi- cious.	11th.	Good.	21st.	Strong.		
8.	8th.	None.	10th.	Suspi- cious.	14th.	Fair.		
9.	9th.	Good.	16th.	Strong.				

No general difference in intensity of reaction is reported in cases occurring at different seasons of the year.

In answer to the question as to "how soon in individual specimens does the reaction appear, and how long does it last?" Dr. Tuttle replies as follows: "In a large majority of the specimens, the reaction is present as soon as the preparation can be placed under the microscope, and lasts indefinitely. In a few cases ten, fifteen, or thirty minutes may be required to develop the reaction. If there is no loss of motility of the bacilli at the end of fifteen minutes, no reaction is reported. If there is to be a reaction, decided loss of motility will be noticed within five minutes. Sometimes with the ordinary dilution of blood there will be immediate, absolute loss of motility without clustering. If the reaction is feeble, a considerable number of the bacilli may recover their motility after a varying length of time, two, three, or four hours, but when the reaction is strong they appear to be killed at once."

Following is a brief summary of the results obtained from the 503 patients with diseases of all kinds whose blood was tested:

1. Cases diagnosed clinically as typhoid fever, in which the tests were positive: 157.

¹ Read before the Section on Pathology and Bacteriology at the Sixty-fifth Annual Meeting of the British Medical Association, at Montreal, September 2, 1897.

2. Cases diagnosed clinically as undoubted typhoid fever, in which the test failed completely, 6. One of these was tested on the seventh day, and one on the eleventh. One was tested three times, and died of intestinal perforation the day following the last negative test.

3. Ratio of failures of the test in undoubted typhoid fever, 1:26, or nearly four per cent.

4. Cases diagnosed clinically as probable enteric fever, in which the test failed, 11. One of these subsequently developed inguinal adenitis.

5. If the failures in probable cases be added to those of undoubted cases of typhoid fever, the total ratio of failures of the test in typhoid fever rises to one in $9\frac{1}{4}$, or 10.8 per cent.—nearly eleven per cent.

6. Cases decisively diagnosed as other than typhoid fever, in which the test was positive, 20. In a few of these cases the test, though positive, was not considered strong enough to suggest a typical typhoid reaction.

7. Ratio of these misleading cases, as compared with the genuine ones, one in eight (nearly), or approximately, twelve per cent.

The diagnosis of some of these twenty cases was as follows: Carcinoma of pylorus; meningitis (variety?); nephritis and uremic coma (reaction excellent); appendicitis, with perforation (reaction excellent); chronic endocarditis (examined three times; Le Fevre); pneumonia (examined several times; failed after eighth day; Le Fevre); endometritis (moderate fever for ten days which subsided after curetting); suppurative subdeltoid bursitis (see below); acute bronchitis; pleurisy, with effusion (serum 1-10); diarrhea (blood 1-10); acute endocarditis (blood 1-10, feeble reaction); malarial fever (serum 1-10); malarial fever (serum 1-10); malarial fever (blood 1-10, reaction moderate on sixth day, absent on eighth day; Jackson); acute articular rheumatism; general miliary tuberculosis.

8. Cases diagnosed clinically as other than typhoid fever, and in which the test failed, as expected, 309.

I will not recite all the varieties of disease, numbering upwards of forty, in which the reaction has commonly failed, but the following examples will convey a fair idea of their diversity. They are furnished for the most part by Drs. Tuttle and Le Fevre. The latter for two months tested the blood of every patient admitted to the wards of the University Medical Division of Bellevue Hospital. His data were compiled for me by Dr. G. L. Wickes of the House Staff.

Malarial fever (tested during paroxysm; plasmodium present), 15; carcinoma, 18; pulmonary tuberculosis, 17; pleurisy, 7; pneumonia, 10; perito-

nitis, 3; rheumatism, 11; septicemia, 10; gonorrheal rheumatism, 7; chronic nephritis, 12; cardiac diseases, 14; *la grippe*, 4.

The Widal test is unquestionably ingenious and it constitutes a most instructive and suggestive bacteriologic demonstration, but is it more than this? Is it of genuine, practical diagnostic value to the clinician? The great majority, fully seventy-five or eighty per cent. of cases of typhoid fever need no confirmatory test beyond the plain history and symptoms, and the remainder, in which such a test if accurate and exclusive would be invaluable, are chiefly (1) cases of enteric fever seen very early in the course of the disease, principally in private practice; (2) cases of obscure sepsis; (3) severe or protracted cases of malarial remittent fever; (4) certain cases of typhus fever and of acute miliary tuberculosis; (5) various atypical forms of enteric fever.

I. I have inquired as to the earliest day of the disease at which the reaction has been distinctly observed in genuine cases of typhoid fever, with the following result: At the Presbyterian Hospital it has been found once on the fourth and once on the fifth day; at St. Luke's Hospital, once on the fifth and once on the sixth day; at New York, Roosevelt, and Bellevue Hospitals, each, once on the sixth day. (It is of course to be remembered that patients with this disease usually first present themselves at the hospital as late as from the eighth to tenth day.) It must be admitted that the reaction may be obtained toward the end of the first week, although the reported tests which would confirm an earlier diagnosis (those much oftener seen in private practice, at summer hotels, in institutions, and in course of epidemics) are few and uncertain.

Some interest attaches to the opposite extreme—the duration of the reaction during and after convalescence as a means of estimating the prolongation of immunity. Most of the hospital cases from which these statistics are derived soon disappear from observation after convalescence, and often, the reaction having been once obtained, it is not sought again. Thus, at St. Luke's Hospital, the last day of the reaction in any case reported is the thirtieth, at Roosevelt Hospital the forty-fourth, and at Bellevue Hospital the forty-fifth day, with earlier cases on the fortieth and forty-second day. Dr. Tuttle assures me that he has found it four and six months after the occurrence of the disease, and several times at the end of a year, and in the case of my own blood, which he tested for me, the reaction was decided four years after I had had the fever. Another case has been reported to me, occurring in private practice, in which the reaction was present eight years after the illness. It is difficult to believe in these extreme cases, that

the presence of the reaction is more than mere coincidence, again demonstrating its uncertainty.

Further examination should be made in this direction, for if the reaction is shown to be again obtainable after a period of immunity, a subsequent disease might occur and be wrongly diagnosed as enteric fever.

Dr. J. W. Brannan¹ succeeded in obtaining the reaction from dried blood which had been kept for four and seven weeks, respectively, and clinical experience favors the belief that immunity after enteric fever is lasting, except in rare instances.

II. In septicemia, with obscure pus foci one is often perplexed to differentiate the disease from enteric fever; and again, a severe septic infection may mark an existing enteric fever. There is a very troublesome class of cases in which certain typical symptoms of enteric fever, such as the eruption and intestinal hemorrhage, are wanting, as well as any ascertainable evidence of a pus focus. Yet the temperature and other symptoms suggest enteric fever, rather than septicemia, and pus may be discoverable only after protracted illness. It is in just such cases that the test proves unreliable, if not positively misleading. Two cases from my own service will illustrate:

The first is that of a man whom I suspected of having had typhoid fever for a fortnight. He had typical temperature and some abdominal pain. The Widal test was negative. The symptoms then became locally distinct, and a diagnosis of subphrenic abscess was confirmed by operation. Reliance upon the Widal test in this case would have been justified, yet in the second case it was wholly misleading. A young man presented typical symptoms of enteric fever for a fortnight, but without eruption or hemorrhage. The Widal reaction was very positive. He had a painless swelling over the right shoulder which he declared had existed for many months, and which in no wise troubled him. However, I aspirated the swelling, suspecting pus, and after an extensive suppurative deltoid bursitis was subsequently evacuated the temperature immediately fell to normal and the patient promptly recovered.

Reliance upon the Widal test in this case would have led to a continuation of the treatment for typhoid fever until the patient became perhaps hopelessly septic.

III. In the diagnosis of typhoid from malarial fevers of remittent type we possess a vastly more reliable test in the demonstration of the plasmodium malariae, and the uncertainties of the serum test are illustrated by the preceding data, in which it was negative in fourteen cases during the paroxysm, in which the

plasmodium was found, and at the same time was positive in three other cases.

IV. The complete failure of the test in differentiating between typhus and typhoid fever is shown by the case above quoted from Dr. Le Levre, in which the presence of a purpuric eruption with temperature led to the suspicion of typhus fever, and consequent isolation, of the patient. The serum test failed, but the subsequent course of the case proved it to be unquestionably typhoid and not typhus fever. The failure in differentiating between typhoid fever and acute miliary tuberculosis is illustrated by a case cited above.

Conclusions.—From the foregoing brief study of 503 cases of all kinds in which the Widal test was applied, the following conclusions may be drawn:

1. While the test is positive in the large majority of cases of enteric fever, and negative in the greater number of other diseases, there is a margin of error of eleven to twelve per cent. on each side of what might be called the normal line, between cases in which the test fails where it ought to succeed and succeeds where it ought to fail, in order to make it of real clinical value.

2. This total of twenty-three per cent. of possible error includes unfortunately just those cases in which there is the greater doubt upon the purely clinical side.

3. As a genuine diagnostic aid the test has about the value of the Diazo reaction in typhoid urine, or the study of leucocytosis in pneumonia; that is, it is confirmatory in connection with appropriate symptoms but misleading if positive reliance be placed upon it.

4. The fact that an expert bacteriologist is required to make the test is offset by the ease of transportation of specimens of dried blood which long retain the power of reaction, and it is greatly to be hoped that further possible improvement in technic may place this most ingenious test upon a firmer practical basis than can at present be claimed for it.

EUROPEAN METHODS IN THE PRODUCTION OF ANTITOXIN AND VACCINE.¹

By C. T. MCCLINTOCK, M.D.,
OF DETROIT, MICH.

INSPECTION of the most important laboratories of Germany, France, Austria, and Great Britain reveals the fact that the methods in use for the production of diphtheria antitoxic serum and vaccine are much the same everywhere, and these methods have been published so often that comment is unnecessary. The chief interest in what I have to report lies in the comparison between the methods and

¹ "Sero-diagnosis of Typhoid Fever," *New York Med. Jour.*, March 27, 1897.

¹ Abstract of a Report to the Michigan State Board of Health.

results of our own country and those of Europe. In Germany any one may manufacture antitoxin, but before it is allowed to be sold it must be tested by a government official. For this purpose there is in Berlin a small laboratory in charge of Professor Ehrlich, which is the government's control or testing-station. The actual testing is done by Ehrlich's assistants. Dr. Banhoff, who was in charge of the station at the time of my visit, was very kind in showing and explaining their methods.

By far the larger part of the serum used in Germany is produced by Farbwerke, chemical manufacturer (formerly Meister, Lucius & Brünig), at Höchst, near Frankfort. This is known as the Behring serum. Professor Behring lives at Marburg, but occasionally visits the laboratory at Höchst. The laboratory, stables, and equipment are good, and well planned for the purpose. After preparation the serum is turned over to an official who takes a sample from each lot, and forwards it to the control station at Berlin. The bottling and labeling of the serum is under this official's direction. The government control or testing-station is soon to be moved from Berlin to Frankfort, in order to be near this laboratory. Another chemical firm, *Chemische Fabrik auf Actien* (formerly E. Schering) of Berlin, also manufactures antitoxin. The records of the control station showed, at the time of my visit, that during the three years following the introduction of antitoxin, the Schering laboratories had only had ninety-four lots of serum tested. A still smaller quantity is produced by a firm in Hamburg.

At the control station each sample of serum is tested: (1) for strength or number of antitoxic units; (2) a relatively large amount is injected into a white mouse, to see if there is a possibility of poisoning from the preservative added; (3) cultures are made to determine whether or not bacteria are present. A sample of the serum is preserved, and if it is thought advisable it is retested every few months to see if its strength is retained. I was rather surprised to learn that ordinarily only one guinea-pig is used in determining as to whether the serum was of the strength claimed or not. Should this one test, however, fall below the claims of the manufacturer, the serum is then carefully tested by two assistants working separately and checking each other's work. It has been recognized for some time by every competent observer that our tests are very unsatisfactory and unreliable. One bacteriologist would report that a given serum contained only a half or a third the number of units which another had found. Several months ago I had a bottle of serum divided into four equal parts. One of them was sent to a bacteriologist at Ann Arbor, another to Detroit, another to Philadelphia, and the

fourth to New York, with requests for an accurate test of the number of antitoxic units in each cubic centimeter. Every one of the bacteriologists to whom this serum was sent has had large experience in testing antitoxin. The reports made were as follows: (a) 150 units per c.c.; (b) 175 units per c.c.; (c) 100 units per c.c.; (d) 250 units per c.c. There is, however, nothing strange in such variations, if we remember that the foundation of the test is the strength of the toxin, or in other words the lethal dose of a poison. My colleague, Dr. Houghton, supplies me with the following data bearing upon this point:

No. of Guinea-pigs.	Weight, Grams.	Quantity of Toxin Injected.	Result.
1	285	.05 c.c.	Died in 48 hours.
2	268	.03 "	Died in 48 hours.
3	551	.024 "	Died in 72 hours.
4	491	.02 "	Died in 72 hours.
5	560	.018 "	Lived.
6	475	.015 "	Lived.
7	406	.015 "	Died in 72 hours.

36	286	.005 "	Died in 8 days.
37	298	.005 "	Lived.
38	252	.004 "	Died in 4 days.
39	302	.004 "	Lived.
40	287	.004 "	Lived.
41	276	.004 "	Died in 12 days.
42	268	.004 "	Lived.
43	226	.0025 "	Lived.
44	245	.001 "	Lived.

Examining the results obtained from the injection of pigs of approximately the same size (250 to 300 grams), we find that the smallest quantity of poison proving fatal was .004 gram. (see pigs Nos. 38 and 41). The next smallest quantity was .005 gram. (see pigs Nos. 34 and 36). The largest quantity injected which did not cause death was .01 gram. A marked difference is noted in the reaction of pigs which were injected on the same day, *e.g.*, No. 14, which weighed less than No. 41, yet remained alive

after receiving two and one-half times as much poison as the latter, which died in twelve days. The difference in time required for the same amount of poison to prove fatal is also very great, *e.g.*, No. 38 and 41, also No. 17 and 24, etc.

One might conclude from the results of the injections (pigs No. 17 and 27) that .008 cubic centimeter was approximately the minimum fatal dose of the poison, while if the conclusion were arrived at from an examination of the whole table, .04 cubic centimeter or .05 cubic centimeter would be the quantity chosen, although one dose is nearly twice as great as the other.

What the result might be if the one factor or the other were used in standardizing an antitoxin may be gathered from the following tables, giving experiments especially made to determine this point :

SERUM I.

No. of Guinea-pigs.	Weight.	Quantity of Toxin Injected	Quantity of Serum Injected.	Result.
1	255 gms.	.08 c.c. No. 79	.002 c.c.	Remained alive.
2	279 "	.08 " "	.001 "	Died in 40 hrs.
3	265 "	.08 " "	.00066 "	Died in 40 hrs.
4	287 "	.08 " "	.0005 "	Died in about 40 hrs.
5	265 "	.08 " "	.0004 "	Died in 36 hrs.
6	252 "	.08 " "	.00066 "	Died in 36 hrs.
7	294 "	.08 " "	.002 "	Remained alive.
8	280 "	.08 " "	.001 "	Died in 48 hrs.
9	252 "	.08 " "	.00066 "	Died in 40 hrs.
10	285 "	.08 " "	.0005 "	Died in 40 hrs.
11	254 "	.08 " "	.004 "	Died in 36 hrs.
12	250 "	.08 " "	.00033 "	Died in 40 hrs.
13	270 "	.05 " "	.001 "	Remained alive.
14	252 "	.05 " "	.0005 "	Remained alive.
15	307 "	.06 " "	.00033 "	Remained alive.
16	280 "	.05 " "	.001 "	Remained alive.
17	275 "	.05 " "	.0005 "	Remained alive.
18	292 "	.055 " "	.00033 "	Remained alive.

SERUM II.

No. of Guinea-pigs.	Weight.	Quantity of Toxin Injected	Quantity of Serum Injected.	Results.
1	300 gms.	.08 c.c. No. 79	.00033 c.c.	Died in 48 hrs.
2	287 "	.09 " "	.00033 "	Died in 48 hrs.
3	265 "	.1 " "	.00033 "	Remained alive.
4	300 "	.09 " "	.0005 "	Died in about 48 hrs.
5	350 "	.1 " "	.00066 "	Remained alive.
6	320 "	.095 " "	.002 "	Died in 55 hrs.
7	280 "	.08 " "	.00066 "	Died in 36 hrs.
8	270 "	.08 " "	.001 "	Died in 30 hrs.
9	312 "	.06 " "	.001 "	Remained alive.
10	262 "	.05 " "	.0005 "	Remained alive.
11	287 "	.05 " "	.00033 "	Remained alive.
12	252 "	.05 " "	.001 "	Remained alive.
13	260 "	.05 " "	.0005 "	Remained alive.
14	282 "	.05 " "	.00033 "	Died in 9 days.

The same toxin was used and the same method of injection employed in the experiments detailed with serum I. and II. The serum tested was from different horses. If 8 mg. is taken as the minimum fatal dose of toxin, and ten times this quantity used in testing the serums, both would be condemned as very weak, while

if 5 mg. were taken both samples would show a strength of approximately 300 units to each cubic centimeter. It is not necessary to comment on the importance of the difference between the results obtained from the use of the one factor or the other in determining the strength of a given sample of serum, as it is evident that such variations in the results as are obtained from a careful application of the test *may* be the cause of a great discrepancy if compared with subsequent tests. A given serum might be made to appear nearly worthless, or much better than it is claimed to be. Comparing the results of single injections, some marked variations appear. Thus, in the last table, pig No. 3 was smaller than pig No. 6, yet remained alive after receiving a larger dose of the toxin and one-sixth as much antitoxin as the latter animal, which died in fifty-five hours.

I was glad to note that at the Berlin control station they have had the same experience, and finally concluded that the test was wholly unsatisfactory and abandoned it, or rather modified it. The modified test, they claim, gives much more uniform results. I am having some careful comparisons made between the old and the new method of testing and will report the results at a later date.

During the past year the manufacturers of antitoxin have vied with each other in producing high-potency serums; *i.e.*, those which contain a large number of antitoxic units in a small bulk of fluid. Two years ago the best serum to be had contained, as a rule, 100 units per cubic centimeter; during the past year, however, much of the serum used was said to contain 500 or more units per cubic centimeter. This meant, of course, that the amount of serum to be injected was reduced to one-fifth the former bulk—a very manifest improvement. It has been noted by those giving close attention to the matter that high-potency serums rapidly decrease in antitoxic power. I learned that this observation is confirmed by the German authorities. At the government station they told me that all the high-potency serums very soon lost a considerable portion of their antitoxic power. At the Behring laboratory they confirmed this and stated that they had ceased marketing any antitoxin of over 250 units per cubic centimeter. Unfortunate though it may seem to be, we must, for the present at least, return to the use of much larger quantities of antitoxin, if we want to be sure that we have a product which will retain its potency for a reasonable time.

It still remains for some investigator to devise a method for concentrating antitoxin, such that the volume of liquid to be injected will be small, and the serum will retain its potency indefinitely. Many comments have been made in the medical press on a dry serum of this kind (Behring's preparation). But

at the control station I was told that none of this material had been offered for testing, while the director of the Behring laboratory commented unfavorably upon the product. It is easy enough to produce a dry or precipitated antitoxin which will show a very high potency. But these dry serums dissolve very incompletely and the bulk of liquid after dissolving is at least as great as that of the original serum.

I found that the dosage, or number of antitoxic units, used in Germany and Austria is lower than in this country. Dr. Ganghofner, of the University of Prague, has lately published a seventy-page supplement to the "Handbuch der Speciellen Therapie inner Krankheiten" on the serum treatment of diphtheria. This is an admirable summary of the theories, methods, and results of this treatment. He says: "I am in the habit of administering in recent cases of one- and two-days' standing 600 antitoxic units (Behring's simple curative dose). When the children are more than ten years of age I give 1000 antitoxic units, even in the milder cases. The injection is repeated in accordance with the course of the disease, often a single dose sufficing. If, however, symptoms of laryngeal affection are observed, or if the case is in a more advanced stage, under all circumstances, and even in small children, an injection of 1000 antitoxic units is given at once, and it is usually repeated before the lapse of the next twenty-four hours; often after twelve, or even after six hours; finally, a third injection is given. I have rarely exceeded a total quantity of 2000 to 3000 antitoxic units."

It should be said, however, that a few men in Germany recommend larger doses. In France it appears that large doses of a relatively weak serum are used. In England the tendency seems to be toward large doses.

The results of treatment have been often published, and I need refer to them but briefly. On the whole the results obtained on the Continent are excellent, while in Great Britain they are relatively poor. But the most striking results yet obtained are those reported from our own country. The reduction in mortality, as shown by the health reports of cities like Detroit, New York, and Chicago, as well as those of the American Pediatric Society, have not been equalled in Europe. This shows that we have had good antitoxin. Ever since antitoxin was introduced I have periodically examined samples of all the serums made in this country and all that were obtainable from Europe, and while there have been many variations, the serum made in this country, with one exception, has been uniformly good. The results show that it has been skilfully used.

In regard to vaccine, I may say that I did not give so much attention to this subject, although visiting a number of places where it was produced. The tendency everywhere in Europe is to use the liquid vaccine. As is generally known, the "bad arms" that follow vaccination are for the most part due to pus-producing bacteria which are inoculated along with the vaccine. Thus far no one has succeeded in producing an aseptic vaccine on points, while it is possible to produce a germ-free liquid vaccine. This has the additional advantage that it preserves the potency of the virus much longer than the dry point. There is no question but that vaccination should be an aseptic surgical operation, using an aseptic vaccine. I was told in Vienna, at the vaccine station where many thousands are annually vaccinated with fluid vaccine, that "bad arms" are practically unknown. While in Great Britain I noticed the reports of a number of trials of parents who refused to allow their children to be vaccinated. The cause given for the refusal was always that some child had been made seriously ill and its life endangered as a result of vaccination. As before said, these bad results are due to impure vaccine, or lack of care on the part of the operator.

NOTE. Since writing the above paper I have received a copy of Ehrlich's article, entitled: "*Die Werthbemessung des Diphtheriaheilserums und deren Theoretische Grundlagen.*" This is a detailed study of the whole question of antitoxin-testing, the nature of toxins, etc. Ehrlich also points out the great variations which may be obtained in testing the toxicity of any given toxin. In his new test he uses as a starting-point a dry serum of carefully ascertained power, which is preserved under very favorable conditions. The details of his method are too numerous to give here. He claims, however, that with it an almost chemic accuracy may be obtained. It is earnestly to be hoped that this will prove true.

WHAT CONDITIONS INFLUENCE THE COURSE OF SYPHILIS?¹

By ROBERT W. TAYLOR, M.D.,
OF NEW YORK;

CLINICAL PROFESSOR OF VENEREAL DISEASES IN THE COLLEGE
OF PHYSICIANS AND SURGEONS; VISITING SURGEON
TO BELLEVUE HOSPITAL.

(Continued from page 520.)

SYPHILIS in healthy persons, male and female, as a rule, runs a mild course, and its poison is eliminated from the system if active treatment is instituted at the proper time. Much depends upon the intelligence and docility of the patient, who, if he enjoys ordinary good health and will follow up energetically,

¹ An address read at the Twenty-first Annual Meeting of the American Dermatological Association, Washington, D. C., May 6, 1897.

but very carefully directed treatment, may, I am confident, be cured. This comforting assurance may be given to the majority of patients seen in private practice, who, in general, are intelligent, realize the gravity of their condition, and resolve to so conduct themselves and regulate their habits that their vital processes can resist the depressing influences of the syphilitic poison and be able to undergo the strain put upon them by long-continued medication. Thirty-years' study and observation of the nature and treatment of syphilis has convinced me that in most cases a cure is possible, whereas, in years gone by, we groped in ignorance, pursued faulty, and even harmful, therapeutic methods, and never felt ourselves masters of this insidious and far-reaching infection. The scope of this essay will not admit of the full consideration of the treatment of syphilis, but in view of the fact that the cure of the disease absolutely depends upon a well-regulated course of therapeutics, it is germane to the subject to briefly outline the essential points. The disease should be attacked as soon as the secondary manifestations show themselves. Then a rational and vigorous treatment should be begun and persisted in for five or six months, at the expiration of which time a cessation of medication may be allowed for two or three weeks.

In the very early days of the secondary stage insoluble mercurials may be used in pill form (protiodid, salicylate, tannate, or thymolo-acetate), but it is always best to begin inunction treatment as early as possible and to follow it up vigorously. The patient should be carefully watched and all good influences brought to aid his digestive, and stimulate his vital processes. When rendered necessary by the poisonous features of the disease, the use of iodid of potassium should be resorted to, but the main reliance will be placed upon the mercurials in inunction form, by injections, and perhaps by fumigations. Vigorous and intelligent treatment more or less promptly influences and attenuates the virulent infection, which will gradually subside, and in most cases in previously healthy persons a cure will result within two or three years, and in some cases much sooner. The mercury destroys the newly formed and nascent cells, and as they die so does their poisonous power wane. In many cases we see no visible lesions or very simple ones after the first rash. Cases thus treated may be called mild, and in private practice it is the rule, when patients are intelligent and docile, and submit fully to treatment, to see this benign course of syphilis. Such cases may, therefore, be taken as the standard of comparison with other forms of syphilis now to be considered.

There are many persons who, though not abso-

lutely sick, are not really well. In this category are included cases of anemia, flabby and poorly nourished individuals, blonds with light reddish hair, persons suffering with malnutrition, and even those who are mildly neurasthenic. Then again, we observe cases in which the health is impaired by worry and grief, by business cares, doubts, dreads, and excitements, also by insomnia. All such may be said to suffer from lowered vitality, and in them syphilis is apt to run a more or less severe course. In the treatment of these cases we may not experience the quick response to the administration of mercurials; the manifestations may be rather slow in disappearing, and others may show a tendency to reappear. The cure, therefore, is not produced quite as quickly as in the benign cases, but although the case may hitch and halt, neither physician nor patient should falter. In America, syphilis in women runs about the same course that it does in men, but the female sex is much less frequently attacked by cerebral and cerebrospinal affections than are men. Women as a rule are less addicted to alcoholics than males, and they are not called upon to overtax the brain as many men are, consequently they present rather infrequently evidences of specific nervous affections.

Syphilis in the poor and ignorant is mild or severe, and sometimes malignant in its course. Perhaps the greatest of all drawbacks in the treatment of syphilis in the poor is to establish in their minds a realizing sense of the gravity of the affection. Consequently, it is in these individuals that we so often see the disease run a chronic and severe course. They are careless in following treatment, and as a rule cannot be induced to remain under medical care any length of time after the disappearance of their specific lesions or the cessation of the discomforts. This is the keynote to the severity and malignancy of syphilis among the lower orders of our population. Then again, many poor people are addicted to alcoholics which act harmfully upon them and render the course of syphilis severe and protracted. In this class of patients the food is very commonly inadequate in quantity, of poor quality, and among many (Italians, Poles, and Hebrews) fish and the starchy articles are eaten and very little, if any, animal food is used. The nutrition of these people is, usually below par, and few of them possess that systemic resistance which holds them up when in the grip of syphilis. Then again, they are other factors which tend to render syphilis severe in the lower classes. They are commonly uncleanly, and as a result the microbes of the skin act upon syphilitic lesions and induce in them ulceration and perhaps phagedena and gangrene. While in private practice it is very rare to see pustular eruptions, in the lower classes these lesions are

very common. Then again, uncleanness leads to the development of mucous patches and condylomata lata upon the vulva, anus, axillæ, umbilicus, and upon other parts, and these lesions aggravate and lengthen the course of the disease.

Severe forms of syphilis are observed in varying grades of intensity. As a rule, the secondary lesions are numerous and distributed symmetrically over the whole body, and the influence of the specific poison is severe (neuralgias, headaches, joint bone, and muscular pains, etc.). One rash runs an indolent course and is soon followed by one of more severity which becomes complicated with pyogenic infection, and thus we come to see ecthyma, impetigo, and variolaform syphilides and rupia. In these cases there is more or less prostration and little reparative tendency, while in very severe cases fever, sometimes head symptoms, great emaciation, and even marasmus may exist. Then again, in unhealthy persons, particularly in the lower orders, we may observe what is called precocious malignant syphilis, which is an entirely different condition from true malignant syphilis. Precocious malignant syphilis is noteworthy for the reason that it usually begins in the severer forms of the disease in which ulceration attacks the various lesions. Then while these degenerating secondary lesions are appearing, ulcerating, and cicatrizing, and old are being replaced by new lesions, gummatous infiltration, of the mouth, eye, subcutaneous tissues, bones, and joints, and the cerebro-spinal system, may develop more or less extensively. Thus we see men covered with secondary lesions in whom tertiary lesions have appeared precociously, while at the same time the health is at a very low ebb, and there may be present aphasia, hemiplegia, coma, and other nervous disturbances. Such briefly is precocious malignant syphilis. In these cases, as a rule, want of treatment or imperfect treatment and impaired resistance to the virus, are the underlying causes of the serious course of the disease.

Malignant syphilis is undoubtedly, as claimed by Neisser, a rare and peculiar form of the infection. Its chief characteristic is that it is essentially a secondary condition and is in no way associated with tertiary syphilis. Patients thus afflicted show evidence of profound systemic poisoning in the high fever, loss of flesh, abject marasmus, insomnia, and pains in various parts of the body. There also may be present such grave symptoms as aphasia, epilepsy, coma, and paralyses. In these cases the nervous affections are not due to gummatous deposit, but rather to the round-cell infiltration around the vessels, chiefly of the membranes of the brain. The cutaneous lesions are at first erythematous and papular, with the general disposition, arrangement, multiplicity,

etc., peculiar to the secondary period and without the localization and comparative sparseness of the lesions as observed in precocious malignant syphilis. These early manifestations very soon undergo degeneration and as a result goodly sized ulcers, rupia, large ulcerated plaques, and even gangrenous surfaces are produced. None of these lesions, except the rupia, resemble in their course tertiary syphilitic ulcers with their peculiar mode of increase and with their occasional tendency to become serpiginous. Malignant syphilis usually begins early in the secondary period, and very uncommonly later than the end of the first year of infection. This form of syphilis is very rare indeed, and in it a fatal issue is often observed. Its course may be protracted so that a year may elapse before death occurs or a cure is affected. Malignant syphilis is due to the lack of resistance on the part of the individual to the severity of the infection. It seems that the poison meets in the tissues of the person attacked such a condition of receptivity that it is generated in large quantity and with a peculiar virulence which affects the whole organism.

In some cases there is evidence of impaired nutrition in persons thus attacked, but it is sometimes surprising to observe malignant syphilis in very strong and robust subjects of good habits. It seems that in spite of the vigor of their health these patients lack that something which constitutes what we term partial immunity to the syphilitic virus. In short, their tissues present fertile culture-grounds for the exuberant growth of the syphilitic infection and the poison is produced in large quantities, while the cellular elements are much more sparsely proliferated.

The persistence of the syphilitic infection beyond the secondary period results in the production of a certain morbid state, the evolution of which is slow, uncertain, and often insidious, and the lesions of which are deeply seated in the subdermal connective tissue, mucous membranes, and other structures, and which is called tertiary syphilis. By far the most potent cause of tertiary syphilis is absence or insufficiency of treatment in the secondary stage. But in addition to this cause there are others which result from lowered nutrition and weak resistance on the part of the tissues, as we have already seen. Then, again, certain diseased conditions, yet to be considered, may act as secondary factors in the development of this late and erratic stage of syphilis. No systematic description of this morbid state can be given, and the best that can be done in this direction is to sketch the more frequent and striking types of what the French term *tertiarism*. In some cases we see the serpiginous syphilide, which is merely an indication of a persistent tendency of the skin to

undergo chronic creeping ulceration produced by pyogenic microbes. In many of these cases the patients seem perfectly well, and the only morbid condition remaining is this vulnerability of the skin. In some cases there may be more or less severe cachexia. Another form of tertiary infection shows itself in ulcerating tubercles of the skin and subcutaneous tissues, which usually appear during the third or fourth year and then recur by persistent but interrupted attacks extending over very many years and over many portions of the body. In these cases a morbid condition has been engrafted upon the skin early in the infection, which may persist for many years, and in some instances is never cured. Still another form of tertiary syphilis is seen in the development of large tubercles in the skin, which are dry and scaling, run an indolent course, and successively attack all portions of the integument. In many of the cases included in the last two categories there may be visceral or cerebrospinal complications. The development of subcutaneous gummata is one of the most common evidences of tertiary syphilis. These deeply seated infiltrations may attack in succession all parts of the body at longer or shorter intervals and occupy many years in their slow and aphlegmatic course. In some cases of late gummata the health is not materially affected, in others more or less severe cachexia is present. In these cases visceral, nasal, pharyngeal, laryngeal, tracheal, and cerebrospinal gummata may also coexist or alternate irregularly with the cutaneous manifestations. Then, again, sometimes cases are observed in which bone- and joint-lesions attack successively many of these structures and cause severe and continued pain. In these cases it is not uncommon to observe well-marked cachexia and perhaps brain symptoms. Tertiary syphilis may follow a mild or a severe and protracted secondary stage, or it may develop in subjects who have no knowledge whatever of the primary and secondary periods. Many tertiary lesions yield readily to treatment, but they are frequently followed by others. In some cases tertiary cachexia much prolongs the course of the disease.

One of the most formidable complications of syphilis is tuberculosis, and it is only too clearly proven that tissues attacked by syphilis become perfect hotbeds for the fructification of the tubercle bacillus. This destructive and deadly symbiosis is seen in the secondary and in the tertiary periods. In early secondary syphilis, even when well treated and in seemingly healthy subjects, bronchitis or pneumonia may develop and upon them acute miliary tuberculosis may supervene and carry off the patient. Then, again, when syphilis runs a severe course, in some truly malignant cases, tuberculosis supervenes and

quickly kills the patient. We also sometimes see men and women who are being properly treated and who towards the end of the first year of infection begin to lose weight and strength, and are attacked by pulmonary symptoms. Some of these cases are benefited and cured by change of climate and treatment, but many are promptly carried off by this virulent tuberculous complication. Gummatous infiltrations of any or all of the viscera are liable to be attacked by tuberculosis, and syphilitic sarcocele is not infrequently the seat of this second invasion. When considering the factors of gravity in syphilis, we unfortunately must accord to tuberculous infection a prominent place. Chronic alcoholism is a powerful factor in inducing the development of severe and extensive lesions of the skin and mucous membranes, of cerebral disorders, of a debilitated condition of health, and causes the disease to run into its tertiary stage. It is then very chronic and visceral lesions are of frequent occurrence, and deeply seated infiltrations of the skin and mucous membranes develop, which show a marked tendency to soften and form abscesses and ulcers of great persistency. Alcoholism in the lower classes is, next in order to the absence of treatment, the most frequent cause of tertiary syphilis. When arterial or visceral degeneration has not been produced and with the cessation of the alcoholic habit, much encouragement may be given to such patients as to their ultimate cure, provided they will abstain from alcohol and systematically follow the treatment.

In malarial subjects the course of the disease is frequently severe, the condition of ill health is well-marked, neuralgias are very frequent and the specific lesions are copious and extensively distributed. Bright's disease is a factor of much gravity in patients also infected with syphilis, and in many cases its course is very severe. Then again, we sometimes see men and women who have advanced kidney degeneration in whom syphilis runs a surprisingly mild course. Diabetic subjects who contract syphilis are very commonly profoundly influenced by the infective process. Their lesions are extensive and show a tendency to ulceration, and the general depression of health is very marked. When in the course of syphilis specific brain lesions lead to glycosuria or diabetes insipidus, these grave constitutional conditions become factors in the production of a general breakdown of the system. The various morbid blood states, such as scurvy, the hemorrhagic diathesis and hemoglobinuria, are serious complications of syphilitic infection, and in patients suffering from them it is common to observe a severe course of the disease. Influenza is frequently seen to be the cause of great systemic depression, and it may become a factor of

much gravity in syphilitic patients, in some of whom severe pulmonary affections occur. Rheumatism and gout are not uncommon complications of serious import in syphilitic patients, in some of whom the specific lesions are materially modified by this harmful symbiosis. The debility following various infective processes, such as typhoid fever, diphtheria, erysipelas, and the exanthemata sometimes renders the course of syphilis severe for a long or short period. I have, however, in some cases, been astonished at the extreme mildness of secondary syphilis in patients who had a short time before infection recovered from erysipelas, typhoid fever or diphtheria. Cancer sometimes attacks epithelial hyperplasia in late syphilis (mouth and anus), and ultimately causes death.

When it is remembered that syphilis expends its morbid action largely and extensively upon the blood-vessels, the fact strikes one that in old persons the severity of the attack is very much influenced by the condition of the vascular system. Upon the integrity of the patient's blood-vessels, therefore, hinges in a large degree the greater or less severity of syphilis. In old persons arteriosclerosis is common, and may involve more or less of the circulatory apparatus. Instances of this involvement combined with syphilis are not at all uncommon. Besides vessel changes, visceral lesions, general debility, an unstable condition of the tissues, and the systemic morbid effects produced by vicious habits and indulgences, are undoubtedly factors of gravity in syphilis of advanced life. A review of my own clinical experience has convinced me that in many elderly persons of vigorous physique and good habits syphilis runs a comparatively mild course; in less vigorous persons it is more severe; but that in poorly nourished, weakly, and underweight individuals, in the nervous, excitable, neuropathic, and over-studious (brain-workers from all classes) it is often severe and even disastrous in its effects. Further, I have observed the malignant combination of arteriosclerosis and syphilis, and the grave effects of antecedent visceral disease.

Early and efficient treatment, however, is most essential, and by it the course of the disease in the aged may be much modified, may be rendered mild, and in many cases a cure may result.

Kangaroo Tendon and the Dingley Bill.—The appraisers of the Custom House are in a tangle as to how to classify kangaroo tendon in order to fix the duty upon this valuable material. In the attempt to bring it into the country under a low rate of duty, the importers designate kangaroo tendon as "animal integument." But whether the kangaroo's integument includes his tendons is too profound a question for the officials.

CLINICAL MEMORANDUM.

A CASE OF VERY LARGE THORACIC ANEURISM.

BY A. ALEXANDER SMITH, M.D.,
OF NEW YORK;

VISITING PHYSICIAN TO BELLEVUE HOSPITAL; CONSULTING
PHYSICIAN TO GOUVERNEUR HOSPITAL AND
HOSPITAL FOR RUPTURED AND
CRIPPLED.

THE case was that of a colored man, aged forty-three years, a waiter by occupation. He was admitted to Bellevue Hospital, January 30, 1891. He gave a history of syphilis occurring twenty years before. One year previous to admission to the hospital he began to have pain in the right upper sternal region on coughing or swallowing. At

FIG. 1.

External appearance of aneurismal tumor.

this time there was no change in the voice. The pain continued with varying intensity, usually being worse at night. About two months before admission he noticed a slight and painful elevation near the sternoclavicular articulation, which gradually increased in size and constantly became more painful. Shortly after this, the pain, which was of a gnawing character, often radiating down the back and right arm, became so intense that he was obliged to stop work. He consulted a physician who told him that the tumor was an abscess, advised him to apply a poultice and return within two days, when it could be opened. The enlargement was peculiar in shape, presenting the appearance of a diminutive haystack. Had it been incised, as proposed, it undoubtedly would have been very unpleasant for the physician, but would have saved the patient much subsequent suffering. On exam-

ination he was found to be well nourished and of good muscular development. There was great dyspnea on exertion.

A diagnosis of aortic aneurism was made, and it was thought to involve the vessel at the junction of the ascending with the transverse arch. The heart was enlarged and displaced, the apex beat being at the sixth left intercostal space, and in line with the nipple. At this time the growth, externally, seemed to be about the size of a

FIG. 2.

Profile view of the same tumor as above.

walnut. It constantly increased in size with accompanying displacement of the surrounding tissues, first of the three upper ribs on the right side and finally of the sternal end of the left clavical. At no time was there marked difficulty of deglutition, nor any change in the voice. Twenty months after entering the hospital the pain became so severe on the slightest exertion that he was obliged to remain in bed. At this time the skin over the tumor became so much darker that a rupture at that point was feared. During the latter part of November, 1892, nearly twenty-two months after he came under observation, the external portion of the tumor projected more than before, and on December 16th, a slight rupture occurred, and a few drops of blood escaped. On December 18th, quite a decided hemorrhage occurred. Still he continued to live for three days longer, when a portion of the tumor wall sloughed away, leaving an opening about an inch and a half in diameter, through which a clot projected and acted as a valve, preventing immediate death from hemorrhage. The

patient lived about half an hour after the occurrence of the last rupture.

At the autopsy the aneurismal tumor was found to involve the ascending, transverse, and upper portion of the descending aorta. Large as it was, the resulting displacement of the trachea was but slight, and its lumen not diminished. The esophagus too had escaped compression. The tumor measured eight inches in its long diameter and five inches in the short. Its depth from before backward was four and a half inches. The largest portion equaled in size the head of a new-born child. I have not been able to find any record of so large an aneurismal tumor in this situation.

MEDICAL PROGRESS.

Results of Ligature of the Subclavian Artery During One Hundred Years. — MICHAILOW (*Centralbl. für Chir.*, September 18, 1897) has made a study of 557 cases of aneurism treated by ligature of the subclavian artery, either alone or in conjunction with ligature of the carotid artery. Something more than half of these operations were done before the days of antiseptic surgery.

Of 70 cases of ligature of the subclavian and the carotid arteries during the same period, 45 were cured or improved, while 25 were not improved or died. In 18 instances the subclavian and carotid were tied at different times. Of these patients, 15 were improved and 3 not improved. Michailow says that the ligation of the first portion of the subclavian is no longer as hopeless an operation as it formerly was, and the results now obtained by ligature of the third and fourth portions of this vessel are far better than they once were. The treatment of aneurism within the thorax by the Brasdor-Wardrop method of distal ligation is worthy of further trial. The immediate ligation of both the subclavian and carotid arteries is necessary.

Substitute for Whitehead's Operation for Hemorrhoids. — EARLE (*Vir. Med. Semi-monthly*, October 8, 1897) has secured good results from an operative procedure, which he holds in higher esteem than the popular Whitehead operation. Like the latter, Earle's operation is intended for those patients who present an entire ring of internal and external hemorrhoids. The internal hemorrhoids are first grasped individually between two clamps, the pile being divided between them, and the cut surface closed by a continuous suture of catgut. The suture may be quickly applied by passing the needle over and under the clamp, leaving the turns of thread loose so that this instrument may be withdrawn. When this has been done the suture is drawn tight. The internal hemorrhoids having all been treated in this manner, a skin incision is made to the right and left of the anus directly over the dilated subcutaneous veins, and roughly parallel to the anal margin. Care must be taken not to have this incision pass the anterior or posterior commissure. The skin is reflected back, and the veins are dissected free, ligated, and removed. The superfluous skin is cut away, and its

edges united by a continuous catgut suture. By this means the writer claims to obtain all the advantages and none of the disadvantages of the more formidable Whitehead operation.

Recognition of Diabetic Blood.—The method described by WILLIAMSON (*Centrabl. für Inn. Med.*, August 21, 1897) rests upon the fact that diabetic blood has a stronger power of decoloration of a solution of alkanin methyl blue than normal blood. The method is so extremely sensitive that a single drop of blood suffices for the test. In a small test-tube are mixed 40 c.mm. of water, 20 c.mm. of blood, and 1 c.cm. of a watery solution of methyl blue (1-6000), and 40 c.mm. of liquor potassæ of a specific gravity of 1.058. For comparison a similar mixture is made with normal blood. Both test-tubes are then placed in a hot-water bath for three or four minutes. If the blood contains sugar, the mixture will become yellow. This test proved accurate in the case of eleven persons having diabetes, while the action was wanting in the blood of 100 non-diabetic patients. Lyonnet and LeGoff have tested this method in a number of cases and found it reliable.

Koch's New Tuberculin in Surgical Tuberculosis.—EVE (*The Lancet*, September 18th) has treated eight cases of surgical tuberculosis with Koch's new tuberculin. The results were not very encouraging. His impressions of the new remedy may be summarized as follows: Some slight, though no markedly favorable influence may be exerted in cases of early tuberculosis of joints, or in those in which no evidence of softening of caseous material exists. But the effect when caseous material has broken down, and especially if the disease has become septic, is negative. In nearly every case a considerable rise of temperature occurred after doses of from 1 to 2 mg. had been reached, and sometimes before. The pyrexia in some cases was very great, amounting to a rise of 7° F. Other unpleasant symptoms followed the administration of larger doses, such as vomiting, malaise, headache, and prostration. A local reaction was not observed.

Dislocation of the Semilunar Cartilage of the Knee.—BARKER (*The Lancet*, September 18, 1897) has operated upon six cases of partial or complete dislocation of the semilunar cartilage of the knee. From a study of the knee-joint during operation he satisfied himself that if the internal meniscus, which was the one affected in all his cases, is completely dislocated, no amount of manipulation or movement of the joint can restore it to its original position. Even if this were possible the action of flexion would immediately drag it into the joint again. The knee is by no means a simple hinge-joint, and the mechanism of its movements is far from clear, either in the dead or living. What appears to take place is this: In the first place, during flexion the point of contact between the femur and tibia appears to shift backward a little, which of itself would relieve the pressure on the anterior curve of the meniscus and push the posterior curve backward. But in addition it would incline the internal lateral ligament somewhat backward, and in this way drag the semilunar cartilage back through the attachment to the

lateral ligament. Apparently, one at least of the functions of the posterior crucial ligament is to prevent the femur from slipping too far backward, for it is rendered tense during flexion. Whether the explanation of the causes of the displacement of the meniscus be correct or not, the fact remains that during flexion in the living joint it may be seen to slip backward. The actual dislocation, however, is due to the nipping of the edge when the limb is extending, which fixes it between the two bones and prevents it from moving forward, while the capsule, being rendered tense by extension, is torn away from it more and more until there is nothing to prevent the cartilage from again slipping into the middle of the joint. It follows that in a knee-joint in which a partial slipping has more than once occurred, an operation should be performed which will prevent the complete dislocation from taking place. If there is complete dislocation there is more reason for immediate interference before the semilunar cartilage becomes altered in shape and texture. The cartilage should be stitched to the capsule of the periosteum, and only removed in those cases in which its form is greatly altered.

Enforced Hyperemia of the Apices of the Lungs.—Acting upon the suggestion of Rokitsansky, that tuberculosis and mitral insufficiency are incompatible because of the unusually high pulmonary hyperemia which the latter disease produces, JACOBY (*La Méd. Moderne*, September 22, 1897) has made an attempt to produce an artificial congestion of the apices in tuberculous subjects, hoping thereby to assist the body to overcome the invading bacilli. The patient is placed in a recumbent position with the shoulders lower than the hips, and the head slightly raised. A rubber jacket is worn which fits so snugly at the waist, neck, and arms, as to be water tight, but which has some fulness over the upper part of the chest. At the upper part of the jacket there are several rubber tubes about the size of the little finger, and so directed that when streams of water are forced through them, the water will strike the chest wall in front and behind the clavicles. At the waist of the jacket is an escape pipe. To provide for the comfort of the patient, the back of the garment contains a couple of air-cushions. From a reservoir, which is constantly heated by an alcohol lamp, water is pumped with considerable force through the tubes. The shock of the streams against the chest-wall, as well as the heat, produces a degree of hyperemia in the region of the apices sufficient, according to the writer, to materially benefit the patient. Of the twelve patients so treated, cough and expectoration were evidently benefited in nine. In one patient the cough was increased. In two instances it was necessary to give up the treatment on account of the cerebral congestion produced, due, according to Jacoby, to the fact that these patients were not given sufficient time in which to accustom themselves to the new conditions. Treatment should not exceed thirty minutes, and should be administered twice daily. To assist in producing apex hyperemia, the patient should spend not less than six hours every day in a recumbent position with the hips and legs elevated above the shoulders.

THERAPEUTIC NOTES.

Lactic Acid in a Case of Arthritis Deformans.—ZOLOTA-VINE (*La Med. Moderne*, September 18, 1897) used lactic acid with success in an old case of arthritis deformans, administering daily 10 drops of this drug upon an empty stomach, and allowing no food for an hour and a half afterward. The disease had lasted for ten years, and for a year the patient had not been able to leave her bed. The dose of the medicine was gradually increased to 40 drops daily. At the end of three weeks the action of the acid was manifest; the articular pains were so relieved that the woman was able to get out of bed and walk a little; the circumferences of the joints diminished slightly; nutrition improved and abdominal pains disappeared. No other medicine was used, and the only external treatment was a light massage. Improvement continued until the patient, at the time of writing, could walk without a cane and attend to her ordinary occupations.

Creosote in Gastro-enteritis in Infants.—On account of its antiseptic power ZANGGER (*La Presse Medical*, August 7, 1897) employs creosote in the gastro-enteritis of infants, using the following formula:

℞ Creosote	m. ii j
Alcohol	m. xv
Distilled water	℥ iii.

M. Sig. One teaspoonful three or four times daily.

In acute cases, vomiting and diarrhea cease after three or four spoonfuls of the medicine have been administered. Often the cure is complete in a few days. In cases which have lasted a week or ten days before treatment is commenced, the creosote will arrest the vomiting, but has little effect upon the diarrhea which has to be treated in the usual manner with calomel, bismuth, etc.

The Application of Guaiacol in Gonorrheal Epididymitis.—GOLDBERG (*Deut. med. Wochenschr.*, August 5, 1897) is a firm believer in the efficacy of guaiacol in the treatment of gonorrheal epididymitis. The drug is either painted directly upon the scrotum or a mixture of guaiacol and glycerin, equal parts, is employed for this purpose.

Ichthyol in Tuberculosis.—FRAENKEL (*La Med. Moderne*, August 7, 1897) extols the use of ichthyol in tuberculosis, having employed the remedy in some thirty cases. In incipient stages, the cough disappears in a few days. If the lesions are more extensive it may continue for some weeks or even months. Expectorations become more liquid and less abundant. All the symptoms are much improved. Twenty to forty drops of a mixture of equal parts of ichthyol and water should be taken four times daily. A little peppermint may be added to disguise the taste. In spite of its disagreeable odor and taste, the remedy produces no unpleasant gastric symptoms.

Simple Vertigo of Arteriosclerosis.—According to a writer in *La Presse Médicale*, September 15, 1897, simple vertigo, occurring in connection with arteriosclerosis, is a condition which is little understood, and often overlooked or badly treated. It is observed most frequently in private patients accustomed to careful analysis of their sensa-

tions, and presents the following symptoms: On waking the patient, who is of middle age, and has atheromatous degeneration of the arteries, feels a dull diffuse headache and is vaguely apprehensive. Suddenly on slight effort, such as sitting up in bed, he has a sense of constriction about the chest, while there is a cold sweat on the face, the limbs seem weak, and then the attack ceases, loss of consciousness not having occurred. These attacks may also come on at another time during the day, and may increase in severity with short periods of syncope. Treatment is to be directed to the general arteriosclerosis of which the vertigo is only one symptom. Iodid of soda should be taken continuously for years. In the beginning of the treatment trinitrin should be administered as well. At the same time the diet and mode of living should be thoroughly regulated. The prescriptions recommended are:

℞ Sodii iodid	℥ i
Aq. dest.	℥ iv.

M. Sig. A tablespoonful to be taken in milk or water twice daily after meals.

℞ Spir. glonoin	gtt. xxx
Aq. dest.	℥ x.

M. Sig. From three to six dessertspoonfuls during the twenty-four hours.

Ligation of the Dorsal Vein of the Penis for Functional Impotence.—MURRAY (*Jour. Amer. Med. Assoc.*, October 9, 1897), acting upon a suggestion of Bartholow, that ergot injected near the dorsal vein of the penis is of service in some cases of insufficient erection, tied the vein with resulting success in four out of the five cases in which he attempted the operation. The fifth patient was a sexual hypochondriac who suffered from impotence, which was not caused by a too rapid emptying of the vessels of the penis, and the case was, therefore, not suitable for this operation. In one of the remaining cases the difficulty was slight, and perhaps might have been cured without an operation; but in three of the patients the insufficiency of erection was plainly due to dilatation of the dorsal vein. All of these patients were naturally vigorous in this respect, and all had been guilty of sexual excess either in the form of masturbation or coitus. The ligation of the vein was followed in a few seconds by a powerful erection, necessitating the application of ice and the administration of large doses of bromids; but after a few days this too great susceptibility to erection passed away, while the penis retained its normal power of strong erection under natural stimulation.

Mechanical Treatment of Seasickness.—RAWLINS, an English physician, says that the elevation of the extremities will quickly relieve the symptoms of seasickness by increasing the arterial pressure, and thus diminish the anemia of the nervous centers due to the enfeebled action of the heart. The application of warm flannel bandages to the legs and arms will increase the effect produced by the simple elevation. In this way he was able to make two ladies comfortable during a journey to India, who had previously suffered seriously from severe seasickness.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, OCTOBER 30, 1897.

THE MARINE HOSPITAL SERVICE AND A NATIONAL QUARANTINE SYSTEM.

EVERY thinking person, unless blinded by personal or local prejudice, must recognize the necessity for a more intimate Federal supervision of quarantine and public health than obtains at the present time. The recent conduct of quarantine affairs by local authorities is a scandal and a disgrace to civilization!

Subsequent to an epidemic of dengue, yellow fever appeared during the latter part of August at Ocean Springs, Miss. Quarantine against the infected town speedily followed the discovery of the true nature of the disease, but not quickly enough to prevent the scattering of hundreds of summer visitors and panicky residents throughout neighboring and distant places. As nearly as can be determined, from this one focus of disease, yellow fever has invaded five States and nearly a score of cities and towns.

Fortunately the epidemic thus far has made slow progress and the mortality has been comparatively small; but the dread name of the disease has alone been sufficient to terrorize many and has led to brutal encroachment on personal rights, even to murder, and to unreasonable interference with travel, trans-

portation, and trade. The commercial relations of New Orleans with outside communities have been cut off, and business has been stagnant for weeks, causing losses to merchants which already amount to many millions of dollars. From a city in Alabama, where the disease only recently appeared, a banker writes: "The great majority of our people are greatly alarmed and have 'refugeed' in large numbers to more Northern places. As a result of this condition of affairs business is *absolutely paralyzed*." Similar conditions prevail to a great extent on the Gulf coast from Mobile to Galveston, while the States of Alabama, Mississippi, Louisiana, and Texas are given over to terror and anarchy, masquerading under the name of "local" quarantine.

That this disastrous condition of affairs is due to a lack of uniformity in quarantine laws and a want of authority in their enforcement is plain to all. Every State, nay every community having a board of health or health-officer, has its own quarantine regulations which vary much in efficacy and in manner of enforcement. It thus follows that a State maintaining a rigid quarantine against the outside world may be unsuccessful in efforts to exclude the disease on account of the lax precautionary measures practised by a neighboring State.

The origin and course of the present epidemic proves the utter untrustworthiness and inadequacy of local quarantine. Nearly all previous epidemics have taught the same lesson. A uniform law with adequate authority to sustain its impartial and fearless enforcement is the only defense against these perennial invasions. Some department of the National Government is the proper agent to enforce such a law.

Uniformity and authority can be secured in no other way. The first duty of this branch of the Government, however constituted, should be the establishment of a National quarantine worthy the name. Later, it should assume the conduct of matters of public health on a broad and scientific basis.

In the establishment of this new Department of Public Health we have at hand an available and substantial foundation upon which to build, *viz.*, the Marine Hospital Service. This position has also been maintained by Dr. Jerome Cochran at the meeting of the American Medical Association in Atlanta, May 5-8, 1896. Few, except those personally interested, know what varied and vital functions this

department of the Government exercises and has faithfully performed during the last few years. Aside from a hospital service, it successfully manages one-half of the twenty-four quarantine stations of our seaboard; it examines life-savers, pilots, and candidates for the revenue service, and inspects immigrants at eight important ports of entry; it has investigated scurvy, cholera, yellow fever, smallpox, plague, with especial reference to their causation and prevention, and in its hygienic laboratory has studied diphtheria, pneumonia, vaccinia and smallpox, enteric and malarial fevers, and has tested various disinfectants; it has instituted inquiries concerning water-supplies and the disposal of sewage and garbage in cities and towns, and has investigated cases of water pollution; it has studied foreign and domestic quarantine administration, from which it has collected and tabulated sanitary reports and statistics of great value, and, last but not least, has been a most active and persistent opponent to the antivivisection legislation which has so long threatened us.

Such is the institution upon which it would seem most advisable to build a Department of Public Health. It possesses the confidence of the people, is already organized, has expensive and effective plants at appropriate stations, and simply needs to be enlarged and endowed with new functions and more ample powers, to fulfil all the requirements.

THE CHARITIES COMMISSIONERS' FATAL PRECEDENT.

ON more than one occasion the Charities Commissioners of this city have apparently acted in opposition to the best interests of the institutions within their jurisdiction, and, as history will testify, have seemed to be entirely insensitive to the rights of the physicians constituting the medical boards of the city hospitals. We need only refer to the flagrant misuse of power in which they indulged last year in experimenting with a quack medicine for the cure of the alcoholic habit, and which THE MEDICAL NEWS combated to a victorious end.

Recently the personnel of the Board of Charities Commissioners has undergone an important change in the accession of Dr. Stephen Smith to the presidency, and it is but natural that the medical public should anticipate an improvement in the attitude of the board toward physicians. The last official act

of the Commissioners, prior to the change mentioned, is so fatal to the best interests of the city hospitals, and to a continuance of the high professional standard which has been maintained in the medical boards, that we are constrained to refer to it. The fact that the appointee in this instance is in every way worthy the honor conferred upon him cannot excuse an official, responsible commission from the offense of rescinding established rules for the purpose of accomplishing a specific transitory object.

The power of making appointments to the medical staffs of the various city hospitals has hitherto properly been in the hands of the Commissioners. The respective medical boards have, however, exercised a salutary influence upon the constitution of the medical staffs by reserving the privilege of nominating candidates. Time has so consecrated this method of procedure that no one, heretofore, has sought admission to a visiting staff save in this way. The most recent appointment to the medical board of Bellevue Hospital was made in a manner entirely at variance with traditional methods. A vacancy occurring in the fourth, or non-collegiate, division of that hospital, the medical board in accordance with the rule of the Charities Department nominated a candidate in the usual way, but for some reason best known to themselves the Commissioners rejected the nomination—the nominee being an eminently representative man—assigning no reason and asking no other nomination. The appointment hung fire during the entire summer, much to the astonishment of those interested. During this time a new candidate presented himself before the Commissioners, and it was known that his candidacy was warmly espoused by at least one of them. The problem which confronted the Board of Charities Commissioners upon the eve of its disruption was how to avoid appointing the regular and legitimate nominee, and to appoint a man who had not been regularly nominated, but who apparently possessed an enormous influence. The members of the board evidenced their resourcefulness, when put to the test, by introducing at the last meeting before the departure of the outgoing president, a motion to amend the rules of the department so that the nominating power be taken from the medical board and vested in the Commissioners themselves. It is needless to add that the favored candidate promptly received his appointment.

It requires no considerable feat of imagery to depict the demoralization which will eventually result if this hasty and nepotistic action is not rescinded. In the future it may be expected that the physician who can make the deepest impression of *personal worth* and *ability* upon the Commissioners, in other words, he who wields the greatest "influence" will secure the appointment. All the safeguards which had been placed around the appointing power to keep the hospital appointments free from politics have been abolished, and our city hospitals are in danger of falling into the hands of men who will use their positions to advance personal interests and emoluments, at the sacrifice of science and of the patients whom circumstances confide to their care.

In anticipation of such a result we respectfully call upon the Board of Charities Commissioners of the city of New York to reconsider its action, and restore the just and equitable mode of accession to the visiting staffs of the various city hospitals—a system which has so well served the public interests during past years.

WOOD PAVEMENT FOR STREETS.

As the question of street pavement is always an active one in American cities, it may be worth while to notice an article on wood pavement by Amat in the *Bull. Gen. de Therapeut.* This pavement, which is much used in London, Paris, and some other European cities, has found little favor here. Amat compares its advantages and disadvantages with those of granite blocks and asphalt. With reference to cleanliness, he places them in order of merit as follows: asphalt, granite, wood; with reference to quiet, they stand wood, asphalt, granite; and with reference to cheapness, granite comes first, then wood, and lastly, asphalt. In durability, the order is granite, asphalt, wood; but for ease of repair, asphalt, wood, granite; and for safety of the horses, wood, asphalt, granite.

Thus it will be seen that, although asphalt presents great advantages, the two requisites of quiet and security for horses in which wood excels it, must give the latter the preference, unless it can be shown that in some way it is detrimental to the public health.

Unless unusual precautions in the way of sweeping, washing, and disinfection are daily carried out, a

wood pavement is certain to give off considerable odor, and even the deepest portions of the blocks are found to contain ammonia.

The dust arising from the wear of wood pavement is insignificant. In the streets where traffic is most constant, not half an inch of the pavement is worn away in a year—and the most of this is washed or swept away. A macadam roadway under similar usage loses four or five inches.

Bacteriologic investigation by Miguel showed that only a small number of bacteria penetrate the wood block while the upper layer contains millions. Thus he found from a million to a million and a half of germs in a gram of sawdust from the upper surface, and from five hundred to four thousand in a gram of sawdust taken from the block two inches below the surface. The pavements tested were ten years old.

Rolst and Nicoles who repeated these experiments but reduced the sawdust to a fine powder, found more than twenty times the number of bacteria reported by Miguel, *i.e.*, fifty millions to eighty millions at the surface, and forty thousand to four hundred thousand two inches below the surface. The pavements tested were about five years old.

Putting aside altogether the bacteria which have penetrated into the deeper portions of the block, it is still evident that dust from the surface layer must be heavily laden with microbes. Just how unhealthy wood pavement is, or, whether it plays any part whatever in the production of disease, still remains unproved; though the above experiments make it extremely probable that wood pavement does not compare favorably with either granite or asphalt from a hygienic standpoint.

ECHOES AND NEWS.

Epidemic of Typhoid in a School.—Forty cases of typhoid have occurred in the Boys' Industrial School at Lancaster, Ohio. The source has been traced to a foul water-supply.

Emperor William and the Leprosy Conference.—The members of the Leprosy Conference recently in session at Berlin were received at Potsdam by the Emperor and Empress of Germany.

Li Hung Chang's Woman Physician.—The chief physician of Li Hung Chang's household is a woman named Hu King Eng, a graduate of the Woman's Medical College of Pennsylvania.

Measles at Esquimaux Island.—Measles is prevalent among the Indians of Esquimaux Island, Labrador, and more than thirty deaths have occurred in the tribe, which numbers about two hundred persons.

Investigation in an Orphan Asylum.—The New York State Board of Charities is making an investigation of the allegations of cruelty to children by the managers of the De Peyster Orphan Asylum at Tivoli, N. Y.

Medical Director Tryon Ordered to New York.—J. R. Tryon, recently Surgeon-General of the Navy, has been detached from the Bureau of Medicine and Surgery, and ordered to New York as general inspector of the New York Naval Hospital.

Glass Tooth-Filling.—Glass, prepared by a new patented process which renders it soft and malleable, is now used by dentists to fill the cavities in teeth. It is said that it answers the purpose admirably, and is less conspicuous than gold.

Poisoned by Verdigris.—Four hundred emigrants on the Italian steamer "Agordat," bound from Genoa, Italy, to Santos, Brazil, have been poisoned by verdigris from the soup kettles in which their food was cooked. It is feared that many will die.

Pasteur Memorial Fund.—More than \$2000 have been contributed in India to the Pasteur Memorial Fund. A Pasteur Institute is to be established at Simla upon a site which has been presented to the Indian government by the Maharaja of Patiala.

Christian Greece and Living Greek.—Dr. Achilles Rose of New York, who has long been known as an ardent advocate of the use of Modern Greek as a universal medium of medical nomenclature, has in readiness for the press a monograph bearing the above title.

Legacies for Harvard Medical College.—The late Dr. Antoine Ruppaner bequeathed to Harvard Medical College the sum of \$10,000, to be called the Dr. Ruppaner Fund. The sum of \$5000 has been given by Mr. H. H. Hunnewell toward the endowment of the Surgical Laboratory of the same institution.

Quebec Physicians Prohibited from Serving Benefit Societies.—According to the *Times* (London) the Quebec College of Physicians and Surgeons has issued a decree prohibiting medical men from accepting positions as physicians of charitable or benefit societies under pain of withdrawal of the privilege to practice.

Lectures by Sanarelli.—Professor Sanarelli, who is expected soon to arrive in Genoa, Italy, will start on a series of visits to the leading medical schools of Europe, at each of which he will deliver a lecture on his discovery of the bacillus of yellow fever, and present his recommendations for the prophylaxis and treatment of the disease.

Transfer of Dr. James E. Pilcher.—Recent War Department orders transfer Dr. James E. Pilcher of the Army Medical Department from Columbus, Ohio, to Fort

Crook, Neb., a fact which will be of special interest to the members of the Association of Military Surgeons of the United States, of which organization Dr. Pilcher is the secretary and editor.

Diphtheria in Connecticut.—Diphtheria is epidemic in Montville and Greenville, near Norwich, Conn. Twelve deaths have already occurred in the former town, where the disease first made its appearance a month ago, and whence it was carried to Greenville. All schools are closed and the health-officer at Norwich is endeavoring to prevent the disease from spreading to that place.

Officers of the New York County Society for 1898.—At the annual meeting of the New York County Medical Society, held Monday evening, October 25th, the following officers were elected for the ensuing year: President, Dr. A. M. Jacobus; first vice-president, Dr. Nathan E. Brill; second vice-president, Dr. B. Farquhar Curtis; secretary, Dr. Chas. H. Avery; treasurer, Dr. John S. Warren.

A Green Cross Society.—A society having for its object the giving of "first aid" in cases of accident has been organized in St. Petersburg under this name. The need for such an organization is shown by statistics collected by the originator, M. Chernik, by which it appears that during the twelve years, 1881-1893, there were in St. Petersburg alone 46,618 registered accidents, and the number is yearly increasing.

W. K. Van Reyphen Appointed Surgeon-General of the Navy.—President McKinley has appointed Medical Director W. K. Van Reyphen to succeed General Bates, deceased, as Surgeon-General of the Navy. Dr. Van Reyphen was appointed to the navy from New Jersey as assistant-surgeon in 1861, and made an excellent record during the civil war. He has been a member of the Board of Inspection and Survey since 1894, and attained the rank of Medical Director in March, 1895, while stationed in Washington. He was Fleet-Surgeon of the Pacific station for several years.

Decision against the New York Board of Health.—In the Appellate Division of the Supreme Court of New York a decision was handed down by Justice Rumsey to the effect that the condemnation and destruction by the Board of Health of four tenement-houses in the rear of 308 to 314 Mott street, New York, on the ground that they were unfit for habitation, was unlawful in that it was not proved that they could not be made habitable. In the opinion, however, the power of the Board of Health to vacate and destroy unhealthy tenements is expressly upheld, and it only provides for a new trial at which the Health Board may offer further evidence to prove that sanitary evils caused by the condition of the buildings could only be remedied by their destruction. The Board of Health will appeal the case.

Italian Foundling Hospital Scandal.—The first report of the investigation into the condition of foundling asylums in Italy has just made its appearance. It deals with the Brefotrofio of Padua, and is by Dr. Natali, provincial

medical officer, who describes it as being worse than defective in every requirement of hygiene, and calling for prompt and energetic improvement. The women who wet-nurse the babies are never allowed to go beyond its walls, except in cases of urgent necessity, and this confinement has a very bad effect upon their health and that of the foundlings. Artificial feeding and its disastrous results come in for Dr. Natali's most severe censure. The death-rate is 94.20 per cent. The medical service is under the supervision of one physician at a salary of 600 lire (about \$100) per year. His duties also include the responsibility of the prison-service attached to the law-courts.

Health Reports.—The following statistics concerning smallpox, yellow fever, cholera, and plague, have been received in the office of the Supervising Surgeon-General of the United States Marine Hospital Service, during the week ended October 23, 1897:

YELLOW FEVER—UNITED STATES.

A Question of Priority.—In a recent issue of the *Centralblatt für Chirurgie*, 1897, No. 39, there is a notice of a paper by Bloch, presented at the Moscow Congress, in which appears an account of a resection of a portion of a kidney for diagnostic purposes. It is interesting that a similar procedure was conceived by Dr. D. D. Stewart of Philadelphia, at a presumably earlier date, the operation being done for him by Dr. W. W. Keen of Philadelphia. In Dr. Stewart's case a portion of a kidney sufficient for histologic study was excised by Dr. Keen during December, 1896. An account of Dr. Stewart's case appeared in a paper, entitled "A Further Communication on the Occurrence of a Hitherto Undescribed Form of Chronic Nephritis Unassociated with Albuminuria," read before the Association of American Physicians during May, 1897, and also appearing in the transactions of the association, as well as in *The Lancet*, September 4, 1897.

Obituary.—Newton L. Bates, Surgeon-General of the United States Navy, died in Washington on the 18th inst. He was appointed by President McKinley on October 1st, and was so ill at the time that the oath of office was administered to him while in bed. Alarming symptoms developed only two or three days before he died. General Bates was assigned to the Mississippi Squadron in 1863. He served at the New York Naval Laboratory from 1864 to 1867, after which he rendered service at sea. He was Fleet Surgeon of the South Atlantic Station from 1873 to 1876, and subsequently of the European Station. He leaves a widow, who was a Miss Bates, a daughter of Medical Director Bates of the Navy.—Dr. James P. Daly, who was candidate for coroner in the Borough of the Bronx, died suddenly on the 15th inst. of apoplexy brought on apparently by overwork and the excitement incident to the opening of the campaign. He addressed two political meetings on Thursday, became unconscious shortly after reaching home, and died early Friday morning. He was only thirty-six years of age.—Dr. William H. Ford, President of the Philadelphia Board of Health, died suddenly on the 19th inst. at his summer home at Belmar, N. J., aged fifty-eight years. He was an authority on hygiene and sanitation, and well known to physicians throughout the country.

Yellow-Fever Notes.—The continued spread of yellow fever in the South has necessitated many additional employees in the Marine Hospital Service. On the recommendation of Surgeon-General Wyman, the Treasury Department has appointed thirty-four assistant surgeons and fifty-two guards to do duty in the yellow-fever section and on the borders of the States where the disease may spread. More appointments will be made if necessary.

Up to October 21st there have been 110 deaths from yellow fever in New Orleans. The largest number of new cases occurring in a single day is sixty, reported on the 20th inst.

Senator Caffrey of Louisiana has arrived in Washington, where he will confer with Surgeon-General Wyman and endeavor to prepare a bill which will place under Federal control all quarantine regulations and the management of epidemic diseases.

Dr. John Guiteras of the Marine Hospital service, who has been investigating the yellow-fever epidemic, returned to Philadelphia, but has been again ordered to the yellow-fever district. He makes the statement that ninety per cent. of all cases of yellow fever imported into the United States comes from Cuba, and that the disease will be kept out of the country only when there is a complete system of sanitation at Havana.

Five cases of yellow fever were reported to the Board of Health of Montgomery, Alabama, on the 20th inst. Owing to the prevalence of the disease at that place and on account of all the towns and cities in the State being quarantined against it, the seat of government has temporarily been removed to Birmingham.

At a prize-fight recently given in New Orleans for the benefit of yellow-fever sufferers, one of the contestants was so brutally treated that he died soon after being removed from the ring.

On October 22d fifty new cases of yellow fever were reported in New Orleans. Up to that time there have been 1074 cases and 117 deaths in that city.

Dr. Sanarelli does not claim to be able to prevent yellow fever by inoculation with his serum, but asserts that his discovery will reduce yellow-fever mortality to ten per cent. by modifying the disease.

The first case of yellow fever at Memphis appeared on the 22d inst. The patient has been isolated and no spread of the disease is apprehended.

It is estimated that nearly \$1,000,000 has been expended for quarantine purposes by the States, counties, cities, and towns in the infected districts. The belief is also expressed that a national system could be maintained at an annual cost of half a million dollars.

In Texas a combined meeting of the Boards of Health of Houston and Galveston was held, and Dr. Guiteras was denounced to Governor Culberson for having libelled the State by the declaration of the presence of yellow fever. In spite of this, Health-Officer Swearingen admits that yellow fever exists in a mild form in both of the cities mentioned.

It was mentioned in THE MEDICAL NEWS of last week that an epidemic of what was held to be malignant typhoid fever has been raging in the island of Jamaica. When the death-rate rose from thirty to seventy-five per cent. the disease was pronounced yellow fever. Without government assistance or power to enforce restrictive measures, the medical men who responded to all calls for their services were long unable to do much except in individual instances, and a movement was started to compel the governor to put into force by proclamation the clauses of the Public Health Acts providing for isolation and local quarantine in case of epidemics. Finally, acting under pressure from American and other foreign residents, the governor has brought the four parishes of the island in which the disease has appeared under the rule of segregation and other preventive measures. One of the victims of the scourge was W. J. Scanlon, United States Consular Agent at Port Antonio, who died after a few days' illness. Mr. Dent, United States Consul, had a slight attack of the disease from which he recovered. Passenger traffic to

the United States has practically ceased, and shipping agents are refusing to issue tickets.

Fifty-two new cases of yellow fever were reported in New Orleans on the 25th inst., with eleven deaths—the highest mortality yet recorded in one day. Eighteen new cases are reported in Montgomery, Ala., and seven, with four deaths, at Mobile, Ala. The disease appeared for the first time in Selma, Ala., on the 22d inst.

CORRESPONDENCE.

OUR BERLIN LETTER.

[From our Special Correspondent.]

SPECIALIZATION IN WEEKLY MEDICAL JOURNALISM—ACTINOMYCOTIC APPEARANCES OF TUBERCLE BACILLI IN THE TISSUES—PROFESSOR KLEMPERER ON ORGANO-THERAPY—PROFESSOR VIRCHOW AND THE HIGHER EDUCATION OF WOMEN.

BERLIN, October 24, 1897.

THE latest addition to the ranks of medical journalism here in Germany is a *Wochenschrift für Therapie und Hygienie des Auges*, while a weekly journal devoted to consumption alone is also announced. Just how it will be possible to secure every week enough interesting material of really scientific value in specialties so narrow has been the subject of considerable caustic comment in the German medical press.

A very interesting series of observations from the laboratory of Professor Friedrich of Leipzig, appear in the last number of the *Deutsche Medicinische Wochenschrift*. He has been experimenting with miliary tuberculosis as produced by direct injection of the tubercle bacillus into the right ventricle through the jugular veins. He finds in the preparations made from the lungs, kidneys, and iris, within fifteen to thirty days after a successful injection, a series of appearances strikingly like those seen in actinomycosis. Such appearances have been noted by several writers, but only in passing and as a bacteriologic curiosity. Here there is question of their constant occurrence under the circumstance and within the time mentioned. In the sections the bacilli were seen arranged in more or less rosette forms, the radial portions consisting of bacilli with bulbous ends, and the whole picture being almost exactly that which is usually said to be characteristic of actinomycosis. So close was the similarity that for a time the observer thought an accidental contamination of his injections had occurred, but careful precautions precluded such a possibility. The observations are especially interesting in the light of recent developments as to the botanic specificity of microbes and the family relations of various groups. To the infectious granulomata, syphilis, tuberculosis, and leprosy, actinomycosis stands in such an analogous relation as fluorine to the halogen group in chemistry, so that this *rapprochement* of their bacterial causes is suggestive. Professor Friedrich is of the opinion that further investigations may disclose the meaning of the club-shaped ends of the radii of actinomycosis (a disputed point), and throw some light on the appearances in tubercle bacilli, usually considered to be spores.

Professor Klemperer is giving a set of lectures on "Advances in Internal Medicine with Special Reference to Therapeutics." He talked the other day on the practical application of organotherapy, and as he may be considered to fairly represent German practice, his remarks are of special interest.

In Basedow's disease he has seen thyroid extract accomplish a great deal of good, and while the theory that the symptoms of the affection are due to hyperthyroidism, *i.e.*, the presence of too much thyroid secretion in the organism, is not without many supporters, and would seem to contraindicate its use, he considers that thyroid medication should always be given a thorough trial. Where symptoms are made worse its use must be discontinued; but nothing short of a fair trial can decide whether a given case is, or is not, suitable for the treatment. This variety of therapeutics is eminently empiric, and is simply an index of the lack of physiologic knowledge on the subject.

Ordinary goiter in its incipient stage readily yields to treatment with thyroid extract, and even advanced cases, except where there has been actual neoplastic tissue formation or a large overgrowth of connective tissue from irritative processes in the glandular septa, are distinctly benefited by it.

For obesity, thyroid extract in ascending doses, especially when combined with diet and exercise, has given excellent results. It should be remembered, however, that while it causes the disappearance of fat from the tissues, it also causes an increase of nitrogenous waste. It should be used judiciously and with the greatest care. Patients must be constantly under a physician's supervision while taking "the cure." If the dietetic errors which have caused the obesity are continued, the thyroid medication will have very little or, at best, only the most transient effect. A careful dietary must accompany the use of the remedy. In regard to testicular secretion, Brown-Séquard's claims as to its powers have never been substantiated in practice, and the same is true of the spermines. Piperazine, a sort of artificial spermine, which for a time enjoyed quite a therapeutic reputation has fallen into almost absolute disuse. Professor Klemperer has observed good effects from the use of the extract of the prostate gland in cases of prostatic hypertrophy. The theoretic action of the organic extract is not quite clear, but it is supposed to give tone to the prostatic portion of the urethra and vesical fibers which are in connection with the gland, so as to lead to more complete emptying of the bladder. The prostate has been observed to decrease in size in a number of cases in which the extract was employed, and so the real obstacle to urination and the primary causes of urinary retention is removed. Professor Klemperer admits that there is great latitude for opinion as to what may be considered improvement. It seems clear that mental impressions are sometimes the most potent factors in the resulting improvement. The Berlin experience in the matter is interesting. When the principle of the treatment was first announced a certain number of Berlin pharmacists ordered prostatic extract, and quite an amount of the preparation was put up and

sold. A number of instances of improvement were reported after its use, when an inquisitive investigator found that what the butchers had been supplying was not the prostatic tissue of the cattle but their seminal vesicles.

Professor Klemperer considers, however, that the successes so far attained by the use of the prostate gland make it imperative to try a thorough course of the treatment before advising surgical interference; for after all none of the many surgical measures have given the results that have been claimed for them.

Oöphorin, extract of ovarian tissue, has seemed to give good results in a number of cases of climacteric disorder. Here, of course, the chance for mental suggestion is so great that the real efficiency of the preparation is extremely doubtful. In these very bothersome cases, when remedies fail while symptoms multiply, and when the patient must be given something, it is a welcome addition to the physician's armamentarium.

The announcement that fifteen women were about to enter the University of Vienna for the first time in its history has recalled attention to the question of the higher education of women in Germany. At the banquet which closed the meeting of the Society of German Naturalists and Physicians at Braunschweig (Brunswick) last week, Professor Virchow gave expression to his feelings with regard to the question. Despite the deep-seated prejudices which exist among Germans generally in the matter of higher education for women, Professor Virchow was listened to, as he always is, with a great deal of attention, and his remarks occasioned hearty applause.

Though Professor Virchow has generally been considered to be favorable to the higher education of women (in fact his position in the matter made him the subject of a special reception on the part of the women doctors at the Congress at Moscow), this is the first time that he has given public expression to his views. He recalled the suspicions with which the first meeting of The German Society of Naturalists and Physicians had been observed by Church and State. He said: "Our first meetings were of necessity held in secret, and only after much exertion could permission be obtained to hold sessions in public. The strong spirit of the German universities overcame the prejudices of those times. When I conjure you as far as possible to maintain that spirit, let not the lady members construe it into opposition to their academic aspirations. I have never taken a decided position with regard to the movement, but have observed with pleasure how one woman after the other has raised herself intellectually above the majority of her companions in sex and age. I have never been an ardent advocate of women's rights, but neither have I been an enemy to the movement, and have watched its development with the greatest interest. This Society has the merit of first permitting women to enter the sacred circle of science. Before that she could only go to the theater and the concert. The step then taken seems to have been in the right direction, and in accordance with the evolutionary movement in education which marks the latter half of the century."

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

AN ASSOCIATION OF HOSPITAL MANAGERS—COMPLETION OF THE BUILDINGS OF THE PENNSYLVANIA HOSPITAL FOR EPILEPTICS AND COLONY-FARM—COLLEGE OF PHYSICIANS OF PHILADELPHIA—DR. H. F. HARRIS ELECTED ASSOCIATE PROFESSOR OF PATHOLOGY IN THE JEFFERSON MEDICAL COLLEGE.

PHILADELPHIA, October 23, 1897.

A MOVEMENT is gaining progress in this city to bring about the formation of an association of hospital managers, and a concerted effort is being made by several of the more actively interested in this project to call a formal meeting early next month. The exact aims of such an organization are as yet quite veiled to the public, owing to the reticence of those concerned in the movement, but enough has been positively stated to give the impression that the association will have for one of its objects the improvement of the management of hospital affairs, and sufficient has been negatively stated to show decidedly that the projected league does not propose to become a "union" to influence city and State appropriations which could not be obtained single-handed; some have been so unkind as to hint at the latter. As this association aims to regulate the question of medical "charities," particularly of the dispensary type, it cannot be organized too promptly, and it will be earnestly hoped by many medical men of this city that such may be its chief object. Philadelphia, like many another large city, is damned with a large excess of dispensaries, belonging to hospitals, to churches, to "philanthropists," and, until quite recently, to certain physicians, who by such means hoped to compete in the universal scramble for patients. So that, should this hospital association be organized, unlimited work awaits it in the centralization and the direction of medical charities; and its efforts in this direction will receive the hearty endorsement and approval of hundreds of medical men and of the more intelligent of the laity, who understand the dispensary evil, and who desire its correction.

The Pennsylvania Hospital for Epileptics and Colony-farm at Oakbourne has been lately completed, and is now ready for occupancy. The formal opening will take place in a few weeks. The new hospital is made up of three buildings, but it is intended to extend from time to time the field of the work, as funds permit, and to establish cottage after cottage on the grounds of the institution. The idea of the managers of the hospital to colonize on a large scale in this locality as many epileptics as the State can support is an undertaking which, from its humane basis and its eminently practical results, must meet with the sympathy of every one interested in the welfare of this unfortunate class of the community, and that such results outweigh the cost of the monetary outlay is conceded by all students of sociology. The institution has been made a possibility through the generosity of Mr. Henry C. Lea of Philadelphia, who contributed \$50,000 for the erection of the buildings, while the hospital has also received liberal endowments from other individuals and from the

State. The medical staff of the hospital is as follows: Medical director, Dr. S. W. Morton; staff of visiting physicians, Drs. Harvey Shoemaker, G. E. Shoemaker, H. A. Slocum, Wm. C. Posey, A. A. Bliss, Wm. G. Spiller, A. Ferree Witmer, and S. W. Morton. The consulting physicians are Drs. S. Wier Mitchell, J. M. Da Costa, G. E. de Schweinitz, J. William White, and Charles H. Burnett.

At a meeting of the Section on Ophthalmology of the College of Physicians, held on October 19th, Dr. G. E. de Schweinitz presented a note on the occurrence of supposed tobacco blindness in horses, with the exhibition of a number of microscopic specimens illustrative of his remarks; and also read a paper on the blood-vessel formation in the vitreous. Dr. S. D. Risley reported a case of ocular and general disturbance as the consequence of a traumatism of the head. Dr. Edward Jackson read an interesting paper upon autoscopy. Dr. P. N. K. Schwenk exhibited, by invitation, an instance of rupture of the iris resulting from a contusion. Dr. H. F. Hansell exhibited a case of congenital aniridia; a case showing the result of puncture of the sclera in detachment of the retina; and also made some remarks concerning the value of pilocarpin in non-specific central retinal chorioiditis.

At the last meeting of the Section on Gynecology of the College of Physicians on October 21st, Dr. W. Reynolds Wilson read a paper on the anatomic points involved in Emmet's method of operating upon the perineum in instances of laceration of the third degree. Dr. John B. Deaver reported three cases of hysterectomy, two of which were for fibroid growths, and the third for a very extensive parovarian cyst. Dr. J. M. Baldy reported a case of ovarian cancer in a girl sixteen years old, also a case of pelvic inflammatory disease in which the use of Murphy's button was necessary.

Dr. H. A. Hare, who has been convalescent from an attack of enteric fever for several weeks, has gone to Bristol, R. I., for a stay of a month or more. During his absence the chair of therapeutics in the Jefferson Medical College will be filled by Dr. G. E. de Schweinitz, while Dr. E. Q. Thornton will deliver the didactic lectures on materia medica.

Dr. Richard C. Norris' condition is reported by his attending physicians to be improved. It is now hoped that he may recover from the severe septic infection from which he has suffered for the past two weeks.

Dr. W. Frank Haehnlen, who has been seriously ill for several weeks, is reported to be convalescing rapidly, and will shortly be able to resume his lectures on obstetrics at the Medico-Chirurgical College.

Dr. H. F. Harris has been elected associate professor of pathology and bacteriology in the Jefferson Medical College. Professor Harris graduated at the Jefferson Medical College in 1888, since which time he has been largely engaged in the teaching of pathology and chemistry, having occupied for six years the chair of these branches in the Southern Medical College, at Atlanta, and more lately the position of associate in pathology in the Jefferson Medical College.

The mortality in Philadelphia during the week ending October 23d reached a total of 376—a decrease of 16 from the preceding week, and an increase of 2 over the corresponding week of 1896. Of the total number of deaths, 103 occurred in children under five years of age. New cases of contagious diseases numbered 212, or 4 less than last week, with 33 deaths from such causes. There were 118 cases of diphtheria, with 26 deaths; 53 cases of scarlet fever, with 3 deaths, and 41 cases of enteric fever, with 4 deaths.

Paris.

EXCISION OF TUBERCULOUS FOCUS FROM AN EYE—THE ALBUMINURIA OF DYSPEPSIA—NON-TUBERCULOUS FAMILIES—THE ACTION OF DIGESTIVE FERMENTS UPON TOXINS—THE NATURE OF SHOCK.

At the session of the Academy of Medicine held August 10th, VALUDE mentions an instance in which he removed a focus of tuberculosis from the eye of a child aged five years. The disease involved the sclerotic coat. After its removal, the sclerotic wound was sutured. The operation was entirely successful, and ten months later there was no trace of a recurrence.

At the session of August 17th, ROBIN spoke of the albuminuria which occurs in connection with dyspepsia, and which possesses peculiar features. Such patients have hypersthenic stomachs with good appetites, gastric dilatation, an enlarged liver, and constipation. They complain of weakness and vertigo, but do not have edema. The albuminuria is variable, changing according to the diet of the patient. Early in the morning it is usually absent; there are no casts in the urine, but a certain amount of indican and oxalic acid is invariably present.

Most authors attribute this albuminuria to the absorption of toxins formed in the alimentary canal. It seems to Robin, however, that it is due to the absorption into the blood of albumin which has not been perfectly digested, and which acts upon the kidneys as a foreign body. If seen in the beginning and properly treated it is easily cured, but not more than one-third of long-standing cases are curable. The regulation of the diet is the most important part of the treatment. It is best to try the patient for a few days upon exclusively animal diet, and then upon exclusively vegetable diet. In this way it may be ascertained which sort of food produces the albuminuria, and the diet may be regulated accordingly.

DUBOUSQUET-LABORDERIE mentioned a curious instance of freedom from tuberculosis possessed by certain families living in Saint-Ouen. These families are descended from gardeners and have by their thrift become fairly well-to-do. They live at present with good hygienic surroundings, and among them the death-rate does not exceed 15 per 1000. Tuberculosis is almost unknown; while the average mortality of the district is 25 per 1000 and tuberculosis is a common disease.

At the session of the Society of Biology, held July 31st, LEFEVRE spoke of the action of the digestive fluids upon toxins. His experiments have shown that the virulence of a diphtheritic toxin is entirely destroyed by contact for

two or three days at the temperature of the body with a soluble pepsin in the presence of a weak acid.

CHARRIN mentioned similar experiments and called attention to the disadvantage under which chronic dyspeptics labor, as they are unable to nullify the action of certain toxins.

GUIRIAD stated that he had found upon various vegetables numerous colonies of coli bacilli of a deadly character at a time when an epidemic of typhoid fever existed. The most careful tests, however, failed to identify the germ found with Eberth's bacillus.

CHARRIN said that owing to the multitude of germs in the alimentary canal it is puerile to speak of the presence of a few more or less, but in cases in which bacteria present peculiarities such as increased virulence the question is altered. Such variations of virulence explain in a measure the occurrence of an epidemic.

At the session of the Academy of Science, held August 2d, GUINARD and TIXIER described experiments conducted by them to determine the nature of shock and its relation to anesthetics. Healthy and diseased dogs profoundly anesthetized were subjected to complete evisceration for varying lengths of time. The intestines were further subjected to traumatism of one sort and another while arterial tension and respiration were carefully observed. A fall in arterial tension, a slowing of the heart-beat and acceleration of respiration invariably followed. The three functions were differently affected in different dogs. The observers concluded that shock reveals itself by physiologic signs, which correspond exactly to well-known clinical symptoms; that evisceration produces conditions most favorable for the production of shock; that in an individual with a normal peritoneum and a sound heart, evisceration may be performed without danger if it does not continue for more than fifteen minutes; that in an individual whose peritoneum is abnormal evisceration is dangerous on account of the acuteness of the reflex action which follows.

Berlin.

THE GONOCOCCUS AND ITS TOXINS—BOTTINI'S OPERATION FOR PROSTATIC HYPERTROPHY.

WASSERMAN read a paper on the *Gonococcus and its Toxins* before the Medical Society, July 14th, which provoked a long discussion. The author has endeavored to simplify the culture of the gonococcus, and has succeeded in finding a medium in which it will grow, that may be sterilized, without becoming cloudy, by simply boiling it in a test-tube. For this purpose he employs a mixture of 15 c.cm. of pig-serum, 30 c.cm. of water, 2 c.cm. of glycerin, and 0.8 gram. of "nutrose," a sodiophosphate of casein. This mixture is sterilized by boiling two successive days, and is then ready for use upon plates after mixing it with ordinary two-per-cent. pepton-agar in equal proportions.

Experiments conducted by WASSERMAN led him to the conclusion that gonococci produced a most virulent poison, and that to this is due the muscular and rheumatic symptoms which follow an attack of gonorrhea, although no gonococci can be demonstrated in the affected parts. Furthermore, as this poison seems to exist for a long time

after the death of the germs, and as there seems to be no such thing as an acquired immunity for it, the reason is clear why so many women suffer for months or years from retained collections of pus of gonorrheal origin, even though these collections are sterile, as indeed they usually are. So confident was the reader of this, that he thought one justified in classing as gonorrheal, all such sterile pus collections, when it is possible to exclude tuberculosis; for streptococci and staphylococci continue for a much longer time in closed cavities than do gonococci. Indication for operation is none the less strong than it has been considered heretofore, as the lack of immunity and the long duration of the poison make it unwise to await the ultimate absorption of these toxic products.

LANDAU spoke of the fact that pus from a pelvic abscess, bacteriologically found to be sterile, will, if injected under the skin, cause an abscess. It is, therefore, not difficult to understand that, without new infection, a woman may from her old pyosalpinx have from time to time new attacks of pelvic peritonitis. Whether this effect is due to the persistent action of the toxins, or to the dissemination of a few cocci remaining alive in the walls of the tube, is not yet proved, but clinically it can make but little difference.

WERTHEIM said that he had obtained no reaction from the subcutaneous injection of the filtrate of a culture of gonococcus, while the injection of the unfiltered sterilized cultures produced a strong reaction in almost every case. He could not understand, however, how a poison could remain very long in the body without absorption taking place.

BUSCHKE injected a sterile filtered culture of gonococci into the urethra of three patients suffering from chronic gonorrhea, but in whom no cocci could be found. The effect in all was to produce a free purulent discharge, lasting some days, but in it no cocci were to be discovered.

LESSER said that it had been sufficiently proved that the inflammations occurring in joints and tendon-sheaths in connection with gonorrhea were caused by the cocci. He mentioned the remarkable case of Alman, in which for the first time gonococci were demonstrated in the blood of a man with gonorrheal arthritis. They were artificially cultivated, and the fifth generation was injected into the urethra of a man who had never had gonorrhea. This injection acted only too well, as the patient developed acute gonorrhea, and then rheumatism, with both joints and tendons affected, prostatitis and epididymitis, while the exudate from the tendon-sheath yielded a pure culture of the specific germ.

In closing the discussion WASSERMAN said that he did not intend to impart the idea that old gonorrheal abscesses were absolutely sterile, but that the number of germs present was quite out of proportion to the amount of disturbance in the pelvis; and that the germs being in the living walls of the tube could not be easily found in examinations of the contents of the tube.

FREUDENBERG showed a male patient, aged 63, who for over three years had not passed a drop of urine except through the catheter. Three years previously

both testicles were removed, but without beneficial result. On April 27, 1897, Bottini's operation of incision of the prostate by means of a galvanocautery was performed. Spontaneous urination took place within $5\frac{1}{2}$ hours; and in ten days he was able to empty the bladder almost entirely, and in a month he discarded the catheter. The urine, previously cloudy, became absolutely clear.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held October 5, 1897.

The President, B. SACHS, M.D., in the Chair.

DR. C. L. DANA presented a paper, entitled

A CONSIDERATION OF THE PARESTHETIC NEUROSES.

HE said that paresthesia includes nearly all the subjective sensations of the skin except those of pain. When these sensations fasten themselves to a particular part, as a nerve, they develop a definite picture, and are as much entitled to a distinctive name as is neuralgia. Sometimes paresthesia of the head cause sensations of burning, pressure, and cold, which are entirely comparable to headache. They affect the cerebrospinal nerves just as do neuralgias. The cephalic paresthesia are usually indicative of a lithemic condition. The most frequent causes of local paresthesia are those concerned with occupations. Women are affected more frequently than men. The feet and legs are most often the sites of the trouble; next in order the hands alone, and the hands and feet together. The nerves most frequently affected are the brachial and their branches. The most common form of paresthesia is a sensation of tingling or numbness; more rarely there is a sensation of heat. Among the rarest forms of paresthesia are sensations of cold which do not indicate an actual lowering of the temperature of the part, and which occur without any objective vascular changes. This form is not usually very distressing. The term "psychro-esthesia" was first applied by a French physician during 1836. Dr. Dana said that he had observed a number of these cases, of which the following are illustrations:

CASE I.—Female, had suffered from chronic tinnitus for three years, and had disease of both middle ears. She complained especially of a cold sensation which she had felt continually in the forehead for three years. The sensation was bilateral, and involved the upper part of the forehead. The skin was not cold to the touch, nor did it appear in any way abnormal. Examination revealed no anesthesia, and no signs of organic disease.

CASE II.—Male, fifty-six years of age. He was compelled to stand all day at his work. For a year and a half he had had some paresthesia of the lower part of the legs, and had also suffered from a distressing sensation of cold in the feet. The physical examination showed absolutely no anesthesia of the affected parts, and no change in vascularity. The reflexes were slightly exaggerated.

CASE III.—Male, forty-two years of age, whose previous history was negative. He complained of a sensation

of cold over the left thigh, particularly over its anterior surface. This sensation had been continuous during six months, and was increasing in severity. There were absolutely no objective signs over the affected part. The man was a dyspeptic.

None of the cases, the speaker said, was an example of beginning or terminal alcoholic neuritis, in which paresthesiæ are so common. He had noted particularly two classes of cold anesthetics, *viz.*: One, not definitely limited to certain areas, but involving the whole extremity or all four extremities; and the other, to which the name psychro-esthesia proper should be given. The former was associated with pain or vasomotor disturbance, and was due to irritation of the peripheral nerves; it indicated an abortive type of degenerative neuritis. Sensations of cold are very rare when neuritis is marked, as in alcoholic neuritis. Such diffuse sensations of cold also occurred in syringomyelia and in lesions of the central gray matter of the spinal cord. The second class represents a disease in which the patient exclusively suffers from a sensation of cold, there being no associated tingling or prickling. It is usually confined to a small area. These patients feel as though some cold object is lying upon the part. The sensations usually are of traumatic origin, and are associated with lithemia, and with the degenerative changes of middle life. In his experience, they had more often occurred among men than among women. Apparently, the cold paresthesiæ were not produced by lesions of any of the sensory neurons, that is, by any lesions above the spinal cord, nor did they seem to be produced by lesions of the spinal ganglia. The only two conditions in which cold sensations were found were: (1) lesions of the central gray matter, possibly involving the terminals of the first sensory neuron or the beginning of the second (*e.g.*, in beginning syringomyelia); and (2) in lesions of the peripheral sensory nerves. They must be due to lesions of the very terminal portions of the peripheral filaments. The pure types of psychro-esthesia he considers to be always due to irritation of the peripheral filaments, and that the cold paresthesiæ found in tabes and various lesions of the spinal cord are always mixed pains.

DR. WILLIAM H. THOMSON said that he had a case to report which was not in harmony with Dr. Dana's decision with reference to the central relations of psychro-esthesia. On March 7th, a gentleman, fifty-one years of age, had called upon him, stating that he had awakened the night before with a sensation of "universal numbness" over his right side. It involved the face, right arm, and legs, and the numbness was accompanied by a prickling sensation, and by a binding sensation just above the right knee. The pulse was 94 and of high tension; the artery was somewhat thickened; there was no real anesthesia to pain. There was a decided increase in the knee reflex on the right side. There was no aphasia or deviation of the tongue. His special complaint was a sense of coldness distributed over the shoulder and down the arm, involving the fingers and back of the hand, but more particularly the leg and foot. The urine did not show the presence of albumen or casts. The case was kept under observation until June 4th. At that time it

was noted that there was the same distribution of the cold sensation, except in the face. There was also a pronounced redness of the skin extending from the crest of the ilium to the knee, but quite as marked on the other extremity as on the affected side. The speaker said that the lateral distribution, involving the face, seemed to be an exception to the cases reported in the paper.

DR. GEORGE W. JACOBY thought Dr. Dana was right in ascribing many of the one-sided paresthesiæ to neuritic conditions, but he was of the opinion that the symmetric paresthesiæ are due to some general condition—one which exerts an influence upon the central gray matter of the spinal cord. This condition is usually a toxemia of some variety—quite commonly an auto-intoxication from the intestines. He had seen a number of examples of paresthesiæ resulting from the inordinate use of tobacco. In these cases there is a general feeling of heat extending down one or both arms, along the distribution of the ulnar nerve, and such a paresthesia is to him almost symptomatic of tobacco poisoning as the etiologic factor. Another characteristic paresthesia is a sensation of heat or tingling passing along the penis and into the scrotum; and a third is a paresthetic condition distributed along the inner part of the thigh, usually symmetrically. These three paresthesiæ he had very frequently observed in persons using tobacco to excess, and they had disappeared after its discontinuance.

DR. C. A. HERTER said that he had observed several instances of paresthesia of cold sensations in which the distribution was somewhat different from that mentioned in the paper. For example, he had twice met with paresthesia of the abdomen, and also of the chin. He agreed with the reader of the paper in ascribing most of these cases to peripheral irritation of nerves, but whether this irritation depends upon auto-intoxications is a matter about which we cannot speak very certainly as yet. In one of his cases there has been an actual lowering of the surface temperature of about one degree, as compared with the other side. He could not say whether or not this is a common feature.

DR. WILLIAM HIRSCH said that these cases are in all probability due to a peripheral lesion, or are cases which had developed as a result of chronic alcoholism. He had seen four cases (including one he had already presented to the society) in which trauma had acted as an exciting agent. One patient, while traveling, had carried another passenger upon his lap for a long time. Following this, he had developed a paresthesia of the thigh. Another patient, a sufferer from chronic alcoholism, had experienced trauma of the upper portion of the thigh. More than one of them had noticed on taking a hot bath, that the part complained of did not feel heat with the normal acuteness.

DR. FRAENKEL said that he had examined the sensory disturbances in tabetics, paying particular attention to temperature paresthesiæ. Out of thirty-six tabetics, only two had cold paresthesia. One complained constantly of a cold sensation of the back and legs; the other complained of cold paresthesia of the back part of the legs and the extensor surfaces of the upper extremities. The

general appearance of this patient was rather that of cerebrospinal syphilis, and the condition appeared to be the result of some meningitic pressure. There was no disturbance of the temperature sense in these cases. The last case he would explain by simple pressure on the posterior horns.

THE PRESIDENT said that he had seen a number of the special forms of pure paresthesia described in the paper. One case was that of a physician, thirty-five years of age, who had been moderate in his habits, yet ever since his student days had had a sensation of cold on the inner aspect of the left thigh. This was aggravated by severe exercise but not influenced by changes in the weather. The examination was entirely negative, and treatment had no effect. The speaker said that he had been particularly troubled with a class of cases with a persistent burning sensation in the heel. This is not affected by exercise, posture, or by treatment, either surgical or medical. He thought these cases are generally due to some lithemic or gouty condition; he had suspected otitis or periostitis in some instances.

DR. DANA, in closing the discussion, said that the more pure the cold paresthesia, the more sure one might be that it is a lesion of the peripheral nerves and terminal filaments. In some of his cases, similar to those described by the last speaker, there had originally been an eczema or some slight form of trauma, which had ultimately become a mere dermal hallucination. Regarding the case reported by Dr. Thomson, he said that it compelled him to admit that these paresthesiæ might be caused by central brain lesions as well as by peripheral lesions. He could confirm Dr. Jacobi's statements regarding the effect of tobacco, for he had seen obstinate and distressing paresthesiæ of the hand, which disappeared very promptly on giving up the use of tobacco. The authors that he had consulted had not made systematic observations of the temperature of the skin. In reply to Dr. Rockwell he would say that after pneumonia and typhoid fever he had only seen the general anesthetics such as are observed in the mild types of neuritis. He had had some experience with the troublesome cases of "burning heels," and had come to believe that many of them, at least, are due to a certain degree of traumatism, resulting, perhaps, in periostitis.

A CONSIDERATION OF FLECHSIG'S "GEHIRN UND SEELE."

DR. MARY PUTNAM JACOBI read a paper with this title. She said that in 1876 Flechsig had announced several laws—*e.g.*, the law of the organization of central nerve-fibers, and the principle of the systematic assumption of myelin sheaths by all of the nerve-fibers belonging to the same system; but now he claimed another law, *viz.*, that tracts of different functional significance ripen at different times, and that this is the keynote to the entire problem of the relations of brain and mind. The old "statue theory," enunciated as long ago as 1846, is evidently the key to the theory now under consideration. Flechsig divides the sensory system into three parts: (1) That which begins to be medullated at the eighth month;

(2) that which begins at nine months, and (3) that which does not commence until several months after birth. Observation has proved that all sensory tracts do not ripen at the same time—there is an interval of about four months between the period of medullization of the first division and that of the third. If sensory fibers are invariably medullated they must begin to functionate first, but data furnished by Flechsig himself has shown that medullization of many sensory fibers is anticipated by medullization of many motor tracts. We must believe, therefore, that the germ of function begins with the germ of structural growth, and that function does not suddenly make its appearance. The histologic details described by Flechsig lack sufficient support, and his philosophic conclusion is simply amazing. A sensation implies a central excitation of gray matter in the brain cortex; it does not precede consciousness, for it constitutes one of the phenomena of consciousness. There might be many nervous excitations of which the individual remains entirely unconscious, but an unconscious sensation is a contradiction in terms. An afferent neural impulse is not a sensation, but expresses one form of general susceptibility to external excitation. His theory involves the following postulates: (1) that sensations do not involve psychologic phenomena; (2) that the mental act proper always implies generalization from two or more sensations or memory residues of sensations, and (3) that this generalization is affected by propagation to an associative center, along ascending fibers of excitations originating in sensory centers lying on either side. The only plausible basis for Flechsig's theory is the indisputable fact that masses of gray matter in the human brain are intercalated between the cortical areas constituting the expansions of nerve tracts. In concluding, Dr. Jacobi expressed the belief that this theory of Flechsig's is but another futile attempt to demonstrate that the brain is the mirror, rather than the impression of the mind.

MR. MARSHALL said that psychologists looked with some doubt upon the positive statements made by many of the modern neurologists. It seemed rather startling that the neurologist pays little attention to psychology. He was certain if Flechsig had followed the development of modern psychology he could never have written the book under consideration. He agreed most heartily with all the criticisms presented by Dr. Jacobi. It is impossible to hold any such view of sensation as Flechsig apparently does. It cannot be looked upon as though existing alone—it is a part of the whole pulse of consciousness—a sort of "streak" in our conscious life. The whole mass of the consciousness of the moment must be taken into account. Sensation seems like the top of a wave, or a particular kind of increment to this mass of consciousness. Flechsig's position seems certainly to be determined by the old-fashioned view of the separation of the soul from the mind, but modern psychology considered consciousness only—the soul, the *ego*, which is a part of consciousness. Consciousness from a certain standpoint may be regarded as divided into the field of attention and the field of inattention. There is no absolute separation between the two. Stout, a recent author, dis-

tinguishes between moetic and amoetic consciousness, and the soul is a part, if not the whole, of this field of inattention. His own personal view is that the "empiric ego" is nothing more than the field of inattention to which the items of attention are added. Flechsig's view of association, also, is not in accord with modern doctrine, and the whole notion of association, as held in the early part of the century, is fast disappearing. The notion of the addition or summation or semichemic combination of sensations has been entirely dropped. Psychologists also look with some doubt upon the statement of the neurologists regarding a record in the cortex, for nothing in the consciousness gives any reason for believing this. The psychologist believes that it is impossible for any two successive stages of conscious life to be the same. Each addition to our psychic life changes the whole of it, and there is no such thing as the reduplication of any conscious phenomenon, so that the notion of "storage" and psychic residua or record in certain centers is not acceptable to the psychologist. Each added state changes the whole pulse of mental life; apparently the brain itself is altered as a whole.

DR. HIRSCH said that the attacks on Flechsig's theory had become exceedingly numerous. To his mind, the principal theory did not seem at all new; it simply consisted in dividing the psychic functions of the brain as such from the lower functions, *i.e.*, the different sense perceptions from the lower motor functions. The really new thing introduced by Flechsig's theory is the localization of these two functions to special areas of the brain. His reasons for such localization are: (1) the later development (as Flechsig claimed to have proved); and (2) that these purely psychic areas belong exclusively to the association system. If this could be proven, the whole theory will stand. The objections of H. Sachs of Breslau, are based upon some published pathologic cases. Among others, there was a case in which the whole occipital lobe and the part of the cortex which Flechsig claimed to be the entire perception center for vision, were destroyed. According to this theory, there should have been a degeneration of the optic coronary system, yet H. Sachs found this system intact, and he concluded, therefore, that this system must necessarily be in connection with other portions of the brain, and hence, that Flechsig has no right to claim that the parietal convolutions are association centers. The speaker said that he cannot accept this argument of H. Sachs. Any degeneration in the optic coronary system must be centripetal; hence, H. Sachs had no right to expect a centrifugal degeneration.

With regard to the differences of development, the speaker said that every other organ of the body is perfectly developed as regards function immediately at birth—*e.g.*, in the case of the heart or the kidneys—yet the brain of the new-born child is far different from that of an adult. Why should not this well-known gradual development of the brain have the anatomic basis assumed by Flechsig? He thought, with Flechsig, that there is a certain proportion between the time of medullization and the development of function. From a purely psychic point of view it seems that Flechsig's theory could

be sustained. The idea of the different localization of the intellectual power with what Flechsig called the function of the frontal center of localization is in full accord with our psychiatric experience. One portion, it is well known, could be diseased without intellectual impairment. This is seen every day in cases of melancholia. The anatomic part of Flechsig's theory is undoubtedly open to much criticism, but Flechsig had opened a new channel of investigation—a combination of anatomic and clinical research—which should make his theory welcome as an attempt which would, in time, bring great benefit to psychology.

DR. JOSEPH COLLINS said that if time permitted he thought he could show that the reader of the paper had not done Flechsig justice from a historic point of view. For instance, statements made more than twenty years ago should not be cited as reflecting that writer's state of mind to-day, especially when such statements are at variance with recent utterances. The essay "Gehirn und Seele" had been followed by a torrent of criticism, but many of the objections had been satisfactorily controverted in the author's later essay on cerebral localization. When this last essay was read at the congress at Zurich, psychologists in both Europe and America were very much in accord in the admission that it satisfied their ratiocination faculties at that time, and Baldwin of Princeton University, in his report of the paper to an American periodical, had no criticism to make against Flechsig's contentions save that they probably could not be accepted *in toto*. Flechsig's anatomic contentions have been cited in great detail by Van Gehuchten in the recent edition of his admirable work, and although he does not say in so many words that he is partisan to all of Flechsig's claims the space given to them in his book may be taken as an index of their importance in his mind. Other reputable anatomists and psychologists have corroborated many of Flechsig's claims, and it would, therefore, seem that the burden of proof to show the speciousness of Flechsig's contentions is very materially with his critics.

It could be shown that the localization of functions in certain areas of the brain, as stated by Flechsig, coincided exactly with the functions allocated to these parts by clinicians and physiologists the world over. The central visual representation is in the occipital lobes, especially the cuneus, an area to which it had been allotted long years ago by the labors of Seguin, Henschen, Wilbrand, and others. The "körpergefühl" area corresponds with the area which Dana had shown nearly a decade ago to be that in which tactile sensations are interpreted, and so on through the entire list of "centers." The same might be said of the association centers which Flechsig believes are intercalated, as it were, between the specialized areas, or the areas of specialized function.

Mr. Marshall had said that the notion of "storage" and of psychic residua or record, the result of the impingement of sensory stimuli on the brain, is not acceptable to the psychologist. The speaker was glad to hear that they are as critical in this respect as the clinician, for except as a colloquial expression it is not acceptable to the latter. Yet until a word can be found which will ex-

plain that the potentialities of a specialized area of the brain is changed by having given reception to a stimulus, whether the change be chemic, psychophytic, or purely psychic we shall have to make use of this term at its current value. Probably no one is ready to accept Flechsig's contentions *in toto*, but they are too important and too uniformly in accord with the teachings of anatomy, physiology, and psychology to be dismissed after a few minutes of scholastic indulgence.

THE PRESIDENT said that he had discussed this subject in an address delivered at Baltimore last May. He had always had unbounded confidence in anything published by Flechsig, and had gone at the task very seriously; yet he did not think that any one who had had any sort of training in psychology, philosophy, or logic could accept Flechsig's presentation of the subject. First of all, the evidence presented is insufficient. This deficiency has quite recently been acknowledged by one of Flechsig's ablest students. The theory of the coincidence of function with the development of the various medullated tracts seems to have been carried too far. If Flechsig's theory is correct on this point, why should speech-fibers be developed fully (as he said) at the third or fourth month of life? We are all agreed as to the extent of the somesthetic area, but his argument went further: Flechsig has taken almost the entire outlying districts and called them association *centers*, intellectual centers, not tracts. These centers, he said, simply connect the various areas of the brain, and connect sensory with motor areas. If true, the frontal lobe's chief function should be to combine the somesthetic area with the sensory speech area or tactile area. From our knowledge of tumors in the frontal lobe it is evident that there are other more important functions than could be assigned to it on the basis of Flechsig's theory. The latter seemed to him to be open to a number of serious objections which the speaker had stated in detail in the *American Journal of Insanity*.

DR. JACOBI, in closing the discussion, said that no one could doubt the position of Flechsig as an anatomist. It is not necessary to dispute what he has established anatomically; her object had been to show how much that was not anatomic he had added to pure anatomic facts. There is really very little foundation of fact for all his fanciful conclusions.

REVIEWS.

THE INTERNATIONAL MEDICAL ANNUAL AND PRACTITIONER'S INDEX: A Work of Reference for Medical Practitioners. New York: E. B. Treat, 1897.

THIS well-known annual, now in its fifteenth year, scarcely needs any comment at our hands. As in former years, the book is compact and reliable, and gives a careful and complete account of the progress in medicine and surgery. The illustrations, for the most part, are well selected, but we notice a few which might well have been omitted. The alphabetical arrangement makes the book of particular value to the busy physician; a very full index, as usual is added.

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK for the year 1897.

THE present volume contains an extensive discussion on the relation of impure water to disease, participated in by the leading members of the Society. Its special relation to the causation of typhoid fever is thoroughly considered. There is a large array of valuable clinical papers, and the important executive work of this year's session is recorded in detail.

THERAPEUTIC HINTS.

Painless Application of Nitrate of Silver.—To the mucous or granulating surface apply first a solution of azotate of cocain which has an anesthetic effect equal to that of the hydrochlorate, and unlike the latter salt, does not form a precipitate with the silver solution. Following this a solution of nitrate of silver may be applied without giving rise to pain.

For Blepharitis Marginalis.—After the crusts have been completely removed with warm water, apply the following ointment:

R	Ichthyol	.	.	.	.	.	<i>m. v</i>
	Zinci oxid.	.	.	.	.	.	<i>gr. xl</i>
	Vaselin	.	.	.	.	<i>q.s.ad.</i>	<i>3 iv.</i>

M. Sig. Apply at bedtime.

Creosote for Constipation.—For this purpose the drug should be administered in drop doses, twice daily, after breakfast and dinner. It should not be prescribed in capsules or pearls, but should be taken in milk, beer, wine, etc. After a few days the dose should be gradually increased to *m.vii.* twice daily.

Vinegar as an Antidote to Carbolic Acid.—The following method is recommended for the treatment of carbolic-acid poisoning: Wash out the stomach with a solution containing equal parts of vinegar and water, and then with water alone. The patient may then be stimulated by means of a small quantity of whisky and milk, or with hypodermic injections of strychnin.

For Chronic Laryngitis.—

R	Argenti nitratis	.	.	.	<i>gr. ss-v</i>
	Aquæ destillatæ	.	.	.	<i>3 i.</i>

M. Sig. Apply locally by means of an atomizer.—*Ringer.*

For Atrophic Pharyngitis.—

R	Pilocarpinæ muriatis	.	.	.	<i>gr. ii</i>
	Aquæ	} aa	.	.	<i>3 i.</i>
	Glycerini		.	.	

M. Sig. A teaspoonful three times daily.—*Sajous.*

Apenta Water for Constipation.—Apenta water is strongly commended for chronic constipation due to atony of the bowel. It is said to have the advantage that its continued use does not give rise to further constipation. Increased activity of the bowels continues on those days on which Apenta is not taken. A wineglassful should be administered daily before breakfast. Its action is efficient, but not unpleasant.

ORIGINAL ARTICLES.

WATER PURIFICATION HYGIENICALLY CONSIDERED.

By C. G. CURRIER, M.D.,
OF NEW YORK;

ASSOCIATE OF THE AMERICAN SOCIETY OF CIVIL ENGINEERS, ETC.

A FEW years ago the author, in various articles giving the results of experimental investigations on some of the subjects touched upon in these pages, felt bound to offer considerable evidence to prove that pure water is necessary to health, and that thousands of lives are yearly lost because of impure water.¹ Many epidemics due to a bad water supply have been reported at more or less length in the medical journals and in the daily papers, which reach all classes. Thousands or even hundreds of thousands of deaths from cholera have occurred in Asia, in the Orient, in Egypt, and in Europe. The recent epidemic in Hamburg (1892) is still vividly impressed upon the minds of those who give any thought to the question of water-borne diseases.

Fortunately the broad oceans safeguard us to a large extent against cholera and other Asiatic plagues; but here, as well as elsewhere, typhoid fever, not to speak of various lesser diarrheal disorders which are likewise communicated by impure drinking-waters, yearly causes thousands of deaths and many more cases of disease of varying degrees of severity. Even malaria is regarded by numerous intelligent physicians and other acute observers as presumably a water-borne disease, although the evidence offered does not suffice to prove that contention. Yet typhoid fever alone is a sufficiently grave peril to warrant an immense amount of agitation and the expenditure of many millions of money to prevent its occurrence. It is very well known that when the water-supply of any isolated household or of any community is naturally pure or adequately purified by artificial means, typhoid fever does not occur unless water be casually consumed from an impure source, or unless milk or other food, used in an uncooked condition, have come in contact with infected water, or unless the victims have acquired the disease directly from someone suffering from it. For all industrial and domestic purposes it is desirable that water be as pure as possible. Whether for "feeding"

a boiler or quenching thirst, for watering the streets or cleansing a wound, the purest water is the most satisfactory. The enlightened economist and the sanitarian insist upon this, and, even if space permitted, a citation of the volumes of facts and figures available to prove it would not be necessary for those familiar with the rudiments of modern sanitation.

What then is pure water, hygienically speaking? Briefly, it may be said to be clear, palatable, free from bacteria in large numbers, and wholly free from bacteria which can cause disease; it must contain no lead or other poisons, and have only a permissibly small amount of mineral salts. The salts of lime and magnesia, in a supply for general industrial and domestic use, must not be much in excess of 15 parts in 100,000 of water, otherwise it is too hard. The water of the best lakes and rivers may be less than one-half or even one-fourth as "hard" as this. It should be mentioned that the salts present in the water which we drink do not count for much in the total amount needed daily by the human body (nearly two ounces of salts being required), as that amount is abundantly supplied by a mixed diet. The daily amount of water swallowed by a healthy man averages about a gallon. This quantity of good natural water usually does not contain more than ten grains of salts, and a mineral water having one hundred grains of salts to the gallon is altogether too strong for large amounts of it to be tolerated. A slight proportion of lime is hygienically desirable in water-supplies, for it restricts the tendency of the water to act upon metals. A very soft water more readily takes up lead, for instance, from lead pipes in which it is conveyed. A very soft moorland water, especially if acid and well oxygenated, is more apt to cause lead-poisoning to develop than is the case with limy waters.

Clearness, to the uninstructed, seems to be the most important quality of a water, and yet the clearest water, particularly that of wells, often causes typhoid fever, for the causative bacteria of that disease are not detectable by the senses when they have been introduced into a supply. On the other hand, turbidity is not usually due to a dangerous cause, however unpleasant it may appear to the eye. Water may be perfectly wholesome, and yet so colored by harmless vegetable matter as to arouse distrust among those unfamiliar with it. Chemic tests of water are of most importance nowadays as aiding one to determine its mineral constituents. In studying a pro-

¹ During the last few years there has been furnished so much statistic and other testimony to this effect that it would require too much space to reproduce it here.

posed new supply, especially if it be from a peaty source, it is well to know its degree of solvent action upon lead, for it is quite expensive to construct and maintain the plant needed for counteracting such a tendency, by filtration through lime or by the suitable addition of lime or soda carbonates. Of the organic constituents, an undue quantity (more than .015 in 100,000 parts) of albuminoid ammonia is the important practical factor which aids us to determine whether a water is bad or not. Wanklyn, in his latest work on "Water Analysis," does not attach much importance to the presence of nitrates, although they are usually regarded as evidence against the purity of a water. The elaborate organic chemical testing of a sample of water is not of nearly as much hygienic value as a careful local inspection by a skilled hydrologist of the sources whence the water comes and a critical searching for possibilities of present or future contamination.

Chemistry, then, being an inadequate guide, except as regards the presence of metals and salts, can any degree of reliance be placed upon the revelations of the microscope as to whether a water contains or is likely to contain matters or organisms prejudicial to health? Not to any sufficient extent. Of course, if tapeworm eggs or partially digested meat fibers be detected in a sample of water, it evidently is polluted, and must be condemned; but it is hardly probable that such things, even if present, will be found to have come into the exceedingly small field of a microscope. Nor does the recognition of protozoa in water aid us hygienically, according to Neisser, who has made a special study of this subject. While a water rich in organic matter is likely to contain many micro-organisms, it may not have many protozoa. On the other hand, both bacteria and protozoa can thrive in water that is very pure indeed. Wash-water, sewage, privy-vaults, and manure-heaps are rather lacking in protozoa, although affording most unwholesome contaminations of drinking-water. Every leaf or blade of grass that falls into a well introduces more protozoa (*monadines*, *amebæ*, *ciliata*) than would human feces. Protozoa abound in hydrant water at all seasons.

During the last fifteen years an incontrovertible mass of evidence has accumulated to prove that when drinking-water causes cholera, typhoid fever, and other diseases it is because of the presence in the water of the bacteria peculiar to that disease. While heretofore none of the various methods in use have enabled us to always recognize with certainty the disease-producing bacteria which are present among the numerous microbes of harmless character always to be found in ordinary water, it seems as though we are on the threshold of important discoveries in this

direction. Even the familiar gelatin-culture method is of considerable value in the service of an expert, although local inspection is always of paramount importance.

The usual way to make the gelatin test is to add some of the water to strong, specially prepared, sterile bouillon made solid by the addition of gelatin, as explained in THE MEDICAL NEWS by the writer (April 27, 1889). This is done carefully after the gelatin is softened by gentle heat. Then the gelatin is allowed to "set," and in two days, more or less, the isolated bacteria of the original drop or more of water added, being diffused evenly throughout the mass of nutrient gelatin, will have increased enormously in that favorable medium. Accordingly, each separate one of the bacteria ($\frac{1}{10000}$ of an inch in size), although of itself visible only by the aid of high powers of the microscope, has, by multiplying to millions, formed a visible dot, cup, or other peculiar appearance separate from the others.

Without taking the necessary space to explain the many details of bacteriologic work which do not bear directly upon the subject of this paper, it may be briefly stated that, after years of discussion of the value of the mere counting of the number of bacteria present in a cubic centimeter of a carefully taken fresh sample of water, as a rule a water which has few bacteria is better than one which has many. The best waters have usually less than one hundred bacteria in each cubic centimeter (nearly one-fourth of a teaspoonful). Yet a large number of the organisms should not necessarily be considered as indicating that the water is unfit for use; and, on the other hand, disease bacteria entering a water which normally has few bacteria may produce serious infection. Of course, the species of bacteria present must be considered in forming an opinion. Elsner's method, consisting in using "potato gelatin" containing one per cent. of iodid of potash, promises to aid materially in the recognition of typhoid germs in water. For testing the efficacy of filters or other means of rendering an infected water fit to drink, the gelatin-culture test is all-important. It is the bacteria in such a water that the sanitarian regards as the element of danger. If the process removes all of these, it effectually purifies the water; and if it removes or destroys all but a minute proportion of these micro-organisms, it is safe to assume that practically all of the disease-producing germs, if any were present, have been removed. That the water produced is clear or palatable is, of course, readily determined by the senses.

In testing a filter in operation, the original water is examined from time to time by collecting average samples in heat-sterilized bottles. A cubic centi-

meter, or half as much, of a sample is taken in a sterile glass pipette and added to a cotton-plugged test-tube containing ten cubic centimeters of nutrient gelatin which has been softened by gentle warmth. After these are commingled the gelatin is poured upon a cool plate of sterile glass or a flat glass dish, and this is then promptly covered and labeled. Another test-tube of gelatin is treated in the same way, but is plugged with its sterile cotton as soon as the water is added. After mixing this in by gentle agitation, it is marked and laid upon its side so that the fluid gelatin and water reaches almost up to the cotton. Frequent samples of the filtered water are taken with care to prevent the entrance of bacteria from without. These are plated and tubed in the way just indicated, and all the plates and tubes are then kept away from dust and strong light, under identical conditions of free air, light, and moisture. Those in which the water introduced was sterile will show the gelatin unchanged even after a week, while those into which bacteria entered with the water will show a varying number of colonies corresponding to the number of bacteria entering. Usually those from filter-samples are of fewer varieties, even if—as in the case of low-grade or badly cared-for filters—greater in number than with the same amount of water from the raw supply.

Natural purification by slow flow through many feet of fine, porous earth produces water absolutely free from harmful or other bacteria which may have been in the water or on the surface where it fell. The majority of investigators find that, while bacteria abound on and very near the surface, they are greatly lessened a yard beneath the surface of the ground, and five or six feet deeper, in fine soil, none of these have penetrated. Accordingly, such ground-water, whether issuing as uncontaminated natural springs, or even obtained by properly constructed and protected wells, is very pure as regards bacteria, although it may have taken up a considerable amount of mineral matter. Water evaporated from oceans, lakes, and the top of the ground, and precipitated as rain, is then, like distilled water, very soft and pure, although that which first falls takes up some impurities from the air, especially near cities and from the roofs from which it is collected. In very many examinations made in various parts of this country the author, like others, has regularly found that brook-lets in unsettled regions have very few bacteria, and that larger streams and lakes supplied by springs and rainfall from watersheds which are uninhabited and untilled have, as a rule, few bacteria. But as human habitations and industries increase, the number of bacteria present also increases, and a river in an agricultural valley, even without sewage entering the

stream, has many more bacteria than a similar one in an uncultivated district under the same conditions of rainfall.

Communities which derive an abundant supply from the best of such upland sources, and which can preserve the watershed free from all permanent or temporary human contamination, have an ideal water-supply. Unfortunately, such pure supplies are altogether too few and do not increase, while the demand for water increases constantly, and must be met. Furthermore, supplies which were originally pure become contaminated. Thus, the necessity arises of purifying an inferior water so as to make it healthful and yet have an abundance for domestic and industrial purposes. The masses cannot or will not afford the outlay and trouble involved in using bottled waters when the public supply is bad. Neither is it found practicable to have a separate system of hydrants and pipes for a scanty pure supply when the main supply is unfit to drink.

If a water be regularly turbid and contains visible dirt, a general outcry for some process of treatment is much more likely to arise than when it is clear and palatable, yet containing the germs of infectious diseases. It is in the latter case that sanitarians find fault with the water. When turbid and colored with dirt and vegetable matter, there will occur numerous complaints from the users. If inspection of the watershed and the evidence of skilful bacteriologic examinations make it seem likely that dangerous contamination exists and cannot be checked or prevented in the future, then it is well to have recourse to filtration on a large scale. This renders the water more agreeable to the eye and the palate, while the process properly carried out removes nearly all the bacteria.

It is not easy to determine just how much dangerous contamination may be tolerated in a water without manifesting itself in the form of disease and death among those using the unpurified raw water. When a supply is condemned because obviously contaminated, the argument may be brought forward that the germs of cholera, typhoid, and other diseases tend to die out soon after entering a stream or body of water, and that that water purifies itself. It is true that something of the sort takes place. The writer studied this question¹ and found that dilution and sedimentation, the influence of light and oxygen (of the air), and also the antagonistic action of volatile acids in some river, and of the hardy water-bacteria present in all waters, especially in impure ones, contribute to the purification after contamination by the entrance of harmful bacteria with sewage or other filth. Yet if Elsner's test is employed, it is found

¹ *Trans. Amer. Soc. of Civ. Eng.*, February, 1891, and *American Journal of the Medical Sciences*, December, 1890.

that typhoid germs survive much longer and are much more prevalent than was formerly thought.¹ Accordingly, and in view of the seemingly small amount of infection causing some very serious epidemics, it is wisest in case of doubt to regard all filth contamination of water as dangerous. It is not safe to assert that all rivers of this country can "purify themselves" within twelve miles, as is often stated. Each case must be considered by itself, and judged independently. Yet it is difficult to convince municipal authorities of this necessity for pure water, and some of our cities have water supplies which may be classed as dilute sewage. As a consequence, thousands of cases of typhoid fever result among those drinking such impure water, and the disease is much more common among us than in the well-managed cities of Europe.

Recognizing to a certain extent the possible danger in drinking impure water, but also being influenced chiefly by its unpalatability or unpleasant appearance, intelligent people try to do something individually to purify the small amount used by their households. Straining the water through clean flannel or other dense substance, they find it clearer. If boiled, in addition, it is also free from any element of danger to those who drink it. And yet, prepared in this way, it has an unpleasant taste for one not used to it. This is because the two per cent., or less, of air in the natural water has been driven off by the boiling. If we restore this by forcing air through it by a bellows or by pouring the water several times from one pitcher to another, the taste is improved. The addition of a little cold tea, lemon juice, seltzer water, or other chosen savor, disguises the taste. But boiling, though the most generally available and reliable means of artificially purifying water, requires effort, especially when bottles or similar containers are used for holding the sterilized water, since they have to be kept clean. If the water be cooked in the bottles, this involves some breakage. When, therefore, a housekeeper is offered "pure, drinking-water guaranteed," for an outlay of 17 cents, which purchases a "self-cleaning water-filter" which has embossed in large letters upon its nicked metal case the pretentious words, "germ-proof filter," the temptation is strong to employ such a means of improving the domestic supply. These quoted words are from the printed advertisement of one of the large department-stores of this city. The filter, unfortunately, does not purify the water as claimed, although it strains out coarse dirt and makes dirty water somewhat clearer. It is as valuable as any of the ordinary filters, and is perhaps least likely of all of these to become a source of infection by serving

as a breeding-ground for bacteria. It is filled with crushed quartz held in place by two wire screens. Screwed upon a faucet, when clean, it allows a considerable flow of water. Soon, however, the flow is obstructed by the accumulated dirt. If then, such a filter be reversed and the other end be screwed upon the faucet, the coarser dirt is washed out and also much of the finer. Yet considerable fine dirt and, among other things, many bacteria remain attached to the sand. Boiling kills these, but if this be omitted, and the filter allowed to remain unused for some hours, as over night, at ordinary room temperatures, the adherent bacteria will have increased by multiplication in the organic matter present. Accordingly, the first flow of water from the faucet after such disuse of the filter will contain many more bacteria if it flow through the filter than if the filter were not used. The number lessens gradually as the water continues running.

This serves as a type of all ordinary domestic filters, in which class is included for brevity all, whether straining water from a faucet or from a jar, or other receptacle under gentle pressure, and in which the straining substance is not very dense. In THE MEDICAL NEWS for April 27, 1889, the writer reported the results of prolonged experiments upon very many filters made of the various substances used for the purpose, and since that time he has tested every kind on the market. Nearly every permeable substance has been called into requisition by inventors in this line, such as cotton felt, wood felt, wood pulp, wood, cloth, sponge paper, chaff, wire gauze, charcoal, carbon, polarite, spongy iron, porous porcelain, porous stone, and mineral substances of varying composition in a natural or prepared state, asbestos, and simple sand. As a rule, these are the products of wholly untrained minds quite unfamiliar with the principles underlying successful filtration. Now and then there comes a new variation upon, or an independent application, of some previous idea. The study above indicated, showed that except in so far as it is intended to be a mere strainer of more or less of the visible dirt, the essential virtue of a filtering substance is fineness of structure such as will hold back all bacteria under ordinary conditions of usage for a day or more. If not of such dense material, it is merely of service as a strainer through which bacteria can pass, however well the water is cleared up, and in which they can increase to such an extent that the water flowing from them has more bacteria than that which they are supposed to purify.

This element of bacterial contamination from the filter itself varies with the kind used, and of course disappears for a brief time after the filter is sterilized,

¹ *New York Medical Journal*, April 10, 1897.

as by boiling. Accordingly, such imperfect filters should be simple in construction, commodious, easy to cleanse, and not destructible by frequent boiling. As to their capacity for holding back bacteria, that varies with the density of the filtering substance and its strength and durability. If it tears readily and allows holes or fissures to form, bacteria can of course pass through such breaches of continuity. The simplest and most permeable kind—the sand filter or, rather, strainer above described—holds back so few bacteria as to be practically worthless in this respect. A dense, freshly sterilized flannel bag upon a faucet or a folded filter paper (or even a plug of absorbent cotton) in a funnel does rather better work. Carbon blocks and wood pulp hold back a considerably larger percentage, but allow disease bacteria to pass through and also to increase in the porous filtering mass. Porous stone is still more efficient and when of the finest quality will hold back larger and medium-sized bacteria, such as the germs of cholera and typhoid fever, for many hours. It renders some turbid, silty waters very clear. While the best of these, frequently sterilized by chemicals or by boiling, can be employed by an expert with safety, they are not to be recommended for ordinary use in time of epidemics or when the water filtered is regularly infected, unless it has always been cleaned and boiled a few hours after it has first been used after a previous boiling. This is a requirement which the masses will not observe. So long as a filter renders water clearer, they allow it to strain their drinking-water, regardless of the possibility of bacteria passing through. Asbestos, in carefully arranged sheets, is employed for filters, some of which display great mechanical excellence. This can be made to yield better results than any ordinary filter, although inferior to the best; but the weakness of the tissue, the bulkiness or complexity of the efficient filters of this substance, and the difficulty of cleansing them, militate against their adoption, although some may be sterilized by baking. Porous porcelain of coarse texture, such as is used in electric-battery cups, is much like porous stone, holding back bacteria for a brief time, but is quite inferior to finely porous porcelain as used in the most efficient filters.

These second-rate substances are bacterially efficient, in proportion to the minuteness of their largest pores and in inverse ratio to the pressure with which the water is supplied. The densest offer the greatest resistance to bacteria and also to water. A corollary of this is the fact that a thoroughly efficient filter cannot be very rapid, and when a given filter yields water much more rapidly than another having the same surface exposed to the crude water, the former is less capable of separating bacteria. Both being

under the same conditions, the less rapid yields water freer of germs than the other. And yet the slowest filters are not necessarily in all cases the most efficient, as when, for instance, the slowness is due to a thick mass of fibers or granules which cannot altogether prevent bacteria from getting through, and which, in consequence, must allow them to increase prodigiously in the dirty mass. In no case is slowness a merit, but, because of exhausting the patience of those who use a filter, is to be lessened as much as is consistent with practical retention of "germ-proof" quality.

The only filtering substances which can safely be recommended for household or other use on a small scale, is (1) fine, dense, porous porcelain of standard make and uniform quality tested by the maker; and (2) the prepared infusorial earth cylinders which carry the trade name of Berkefeld. The latter remain germ-proof for a shorter time than the best of the former class—of which the "Pasteur" filter cylinders may be taken as a type (Fig. 1), yet they

FIG. 1.

Pasteur-Chamberland filter tubes. Portion of wall of upper one removed.

are within the limit of safety if cleaned and sterilized (by boiling) daily. They have the great merit of comparatively rapid flow, and are less likely to become broken than the French tubes. Both of the two specified are expensive, being patented articles of foreign manufacture. There are several patterns of filters using excellent porcelain material but made in this country at Trenton and elsewhere. Specimens tested by the writer were quite as good in germ-proof quality and flow as the material of the Pasteur filters. This he has proved by the most rigorous tests carried on in one instance for eight weeks of unintermitting flow, during which time no bacteria came through.

The "Pasteur" filter is also, and more properly, designated by the name of Chamberland, who first exploited this valuable material, taking out a Belgian patent (No. 69,095) for the exclusive right of using rebaked porous porcelain for filtration. A German patent, antedating this, and a French one dated eighteen months later, might be interpreted as indicating that Chamberland attached importance to the principle of filling with charcoal the space within the metallic casing outside of the porous cylinder. This idea was not utilized by the producers, although in a less popular competitor (Mallié filter, patented in

February, 1895) are used flat plates of similar porous porcelain outside of which are corresponding plates of carbon to intercept dirt and prevent speedy clogging of the porcelain by turbid water. Before knowing of Mr. Chamberland's idea, the writer had suggested the same expedient for use with muddy water.

For the Chamberland-Pasteur tubes, semivitrified porcelain is ground up and used in the preparation of the finest product, to give greater porosity. Finely ground silica answers the same purpose, yet if any but the smallest sand-grains are used, it is considered by the makers that the resistance to bacteria is likely to prove insufficient. Some of the best porous porcelain produced in this country seems to be composed of from fifty-five to seventy per cent. of finely ground silex, with between forty-five and seventy per cent. of kaolin clay. This porcelain is quite inexpensive, fairly durable, and as germ-proof as the best French product. The German patent, No. 19,589 (January, 1882), covers the preparation of a similar porous filtering material, as is also the case with the English patents of Bagshaw (1834), Roberts (1859), and Joseph (1870). Yet it is doubtful whether the products were fine enough to be germ-proof. It was not until 1871 that it was definitely recognized that porous porcelain of the proper sort could remove all bacteria from liquids. This was discovered and utilized by Tiegel, a Swiss pupil of Klebs. About the same time Zahn employed clay cells for the same purpose. In the same way Hiller (1874 or earlier), Panum, and others, as well as Sanderson (1878), utilized porous porcelain. In France, Arloing, Toussaint, and others achieved the same result as Tiegel by using plaster with or without the admixture of asbestos for strengthening the texture. Pasteur, in 1877, used this also, abandoning it later for rebaked porcelain. The admirably adapted cylinder shape still used in the Pasteur filter is due to Chamberland, although somewhat similar patterns had been illustrated in publications previous to his time. The efficacy of rebaked porcelain was announced by him in 1884, through Bouley.¹ While formerly made of two degrees of porosity, the output sold here is now of only one uniform density.

This substance, thus gradually evolved, has never been improved upon as regards permanency of germ-proof quality. A perfect cylinder will remain impermeable to bacteria for days and even weeks, allowing water to flow through in a slow stream or in drops, until the silt and other things carried by the crude water choke up the interstices on the surface. This extreme slowness, increasing with use, is a serious drawback, which, like the brittleness, renders it less popular than its admirable filtering property

would otherwise make it. A cracked or flawy cylinder should be discarded, like a broken one. The frequency of mishaps with ordinary careless handling and cooking for the purpose of sterilizing make the Pasteur filter too expensive for the masses, since a new cylinder is retailed for three or more times as much here as in France. There the writer has bought them for about thirty cents. A cylinder which has deteriorated by weeks or months of use, but which is not cracked, can be renovated; yet the ordinary cook cannot be trusted to do this. Careful baking of cleaned and dried cylinders at the high temperature of nearly 300° C. (572° F.) will make the porcelain nearly as efficient as when new. This heat, of course, completely sterilizes the cylinders at the same time. They should be allowed to cool gradually. Another method is to use chemicals. The tubes are well cleaned and then inverted to drain out for fifteen minutes or more. Then, outlet upward, they are filled with, and soaked for at least fifteen minutes in, a twenty-per-cent. lukewarm solution of pure chlorid of lime (or Labarraque's solution or *eau de Javelle* with twice its volume of water). Thereby the albuminoid and mineral deposits in the pores are disorganized. Next they are emptied and then filled with, and lie for another quarter of an hour in, hydrochloric acid diluted with four or five times its volume of water. After this they are emptied and rinsed with boiled water. Another means of sterilizing and regenerating them is to employ similarly, and for twice as long a time, a 1-150 solution of permanganate of potash, followed by a five-per-cent. solution of bisulphite of soda. Very dilute hydrochloric acid tends to prevent the deposition of manganic bioxid in the pores. To detect flaws or other imperfections, the manufacturers of good porcelain filters moisten the substance and then apply air-pressure of at least seven pounds. Those which allow air to pass are rejected. The test is very easy for any one to make by means of a small air-pump.

After a few days, or at any rate a week of use, such a filter-cylinder needs to be removed, brushed off, and rinsed. Then it should be boiled gently for half an hour and allowed to cool gradually before replacing in its casing. This is because not even the best filter-substance is germ-proof for an indefinite length of time. Until nearly a decade ago they were regarded as absolutely germ-proof, and even later than that some observers, presumably after inadequate tests, have said that these porous porcelain surfaces allowed no bacteria to get through. In 1888, by a series of thorough tests and checks thereon, made at the Carnegie Laboratory in New York, the author found that, even when the filters were kept cool and when only cold water was used,

¹ *Comptes Rendus. Acad. des Sciences*, August 4, p. 247.

bacteria passed through soon after the end of the second week of constant usage; so that in time many more were in the filtered than in the unfiltered water. Pasteur cylinders used for the purpose were of the pattern sold at present, and of the best quality, having been purchased by the writer in Paris, of the principal agency, and represented by the seller as perfect. The results of those experiments were accepted, and have since been confirmed by other investigators. Disease-bacteria can grow through this substance in laboratory experiments where everything is arranged to favor the growth; but it has not yet been shown that this can occur under ordinary household conditions of usage of tightly fixed, perfect cylinders washed and sterilized by boiling at least once every week.

These filters possess, then, a high degree of efficiency as regards the removal of bacteria, and whatever has been said above regarding the efficacy of

FIG. 2.

Battery of filters of the Berkefeld pattern. *a*, inflow; *b*, outflow.

one well-known pattern applies equally to all filters properly constructed of the best porous porcelain. As already stated, American porcelain stands the severest bacteriologic test as well as does the imported material. There seems no inherent reason why all of these should not be fairly good if only made with proper care. It must be borne in mind, however, that when of small surface they cannot be rapid and at the same time germ-proof for any considerable length of time.

When "batteries" are arranged by connecting a few or many of the separate porcelain tubes, of the Pasteur type, or of similar styles, to an outflow pipe by very tight joints, correspondingly increased quantities of pure drinking-water can be obtained from them. These multiple arrangements do not prove quite so "germ-proof" as the simple tubes securely fixed each in its separate metal casing, yet in an institution where a physician, or other person, trained in simple bacterial methods, constantly su-

pervises the arrangement, the cleansing and necessary renewals, and also regularly tests the yield, very bad water can be rendered wholesome by such means. This is proved from the reports of the French Minister of War, based on the prolonged and systematic use of these filters in French garrisons, resulting in a reduction of the typhoid death-rate from one to ten per cent. of what it formerly was, and the cases occurring are said to be nearly always explainable by the use of the ordinary or some outside supply in an unfiltered state. As a point in favor of these and against inferior filters, it is stated that in the British army in India, where charcoal and sand-filters have been used, the number of deaths from typhoid fever has steadily increased since 1884. Such filters are worse than none. Outside of garrisons, military use of porcelain filters proves, with or without the André cleaner and infusorial earth powder, to be unsatisfactory, notably in campaigns where the foulness and pestilential quality of the only waters obtainable make an adequate purifier absolutely necessary. However brilliant the laboratory and exposition results, the military filters failed under the conditions of practical usage. Barthélémy, and also Molinier,¹ very forcibly pictured the inadequacy of these. The best pattern among military filters is called "*filter de campagne*," has fifteen filtering cylinders, and weighs 110 pounds or more.

For use in households where no hydrant water or other piped supply exists, yet where filtration of the drinking water seems necessary, the writer would suggest that some manufacturer introduce circular plates of this germ-proof porous porcelain, perhaps slightly convex on the lower surface, in order that the water might drop only from the center of the plate. This could be held to the necessary cylinder or section of pipe above, and to which it will form a bottom, by screw-clamps pressing it tightly against an intervening rubber ring on the periphery. Although such a plate would filter very slowly, it could be very easily cleaned and boiled. Porous stone of similar pattern is used, but is unsatisfactory, not being germ-proof, although it clears turbid water. Being cemented into the lower rim of the jar above, it cannot well be sterilized. There are various patterns of non-pressure filter metal jars using several porcelain tubes inserted in holes in the bottom. Siphoning arrangements may also be employed. The yield is often contaminated.

The porcelain tube-filters, as also those of the material about to be mentioned, may be used with a union-joint or two-way water-cock. The cumbrously long Pasteur filter is thus rendered more convenient for ordinary sinks, yet the writer prefers the older

¹ *Archives de Médecine, Navale et Coloniale*, 1893 and 1894.

patterns in which the water flows directly downward out of the porcelain cylinder into jars or other receptacles, even though that necessitates a special faucet reserved for the use of this filter. In the case of a specially introduced piping the water should come through iron instead of lead, or a block-tin pipe could be used at twice the price of lead pipe.

A successful rival to the above filter is presented by the (Nordtmeyer) Berkefeld pattern which is similar in shape and mechanism, but which is many times faster, yielding when clean and freshly boiled nearly a quart of germ-free water in a minute from the smallest domestic model. The porous filtering cylinder is only three inches in length. Closed, like the porcelain cylinders, at one end, the open end is firmly cemented into a flattened, metal funnel having a small central outflow tube, by the outside of which it is screwed tightly inside its metal casing. (See Fig. 3.) No breakable part is exposed when the fil-

Berkefeld filter.

ter is attached to a faucet. The household pattern, illustrated here, is so compact that it can be attached to a kitchen faucet and yet allow a jar or pitcher to be placed beneath to catch the filtered water. Its comparatively rapid yield is due to its extreme porosity. The short porous cylinders or cups have walls more than half an inch thick, and are composed chiefly of infusorial earth appearing under the microscope as compressed diatoms (fossil bone-meal) held together by a secret process. They cost \$1.50 each, and are more durable than porcelain. The general rule above given, that with increased yield the germ-proof quality is lessened, holds good with these as with other filters, yet they hold back bacteria long enough to render them safe if sterilized by boiling every day or two. The writer, who has tested a number of these during the past two years, has not found one that could not hold back all bacteria for one day. In some experiments, under various conditions of practical usage and with a pressure as high as thirty-eight pounds, when the filters were

kept cool (10° - 12° C.) during an intermittent yield of more than five gallons daily, they produced sterile water until the eighth day.

From the results of many tests, it may be stated briefly that the Berkefeld filter will hold back all bacteria from one to three days. We can safely recommend them, therefore, even for use with infected waters, on the condition that the porous filtering cup be taken out daily, and cleaned and then sterilized by boiling for half an hour. The water should not be very warm when they are put into the clean vessel in which they are to be boiled and should be allowed to cool enough to be endurable by the hand when they are taken out. When greatly thinned by repeated brushing or whenever a flaw develops in a porous cup, it should be discarded. It is advisable to have an extra tube on hand, although a single tube can be used for many months. The filtering substance lasts longest if not brushed roughly, but rather cleansed by means of pieces of cloth under a flow of water upon the cup. They do not break by gentle boiling, with little or no ebullition, even if for convenience they be thus sterilized in the same clean vessel in which other things—such as nursing-bottles—are cooked; yet rough handling breaks them. As with porcelain tubes of different makes, when the water is not supplied under pressure, these can be arranged to work with various forms of portable or fixed pumps, singly or in batteries. A single tube thus arranged weighs, with pump and portable stand, eleven pounds, and yields a gallon in two minutes. At least one extra tube should be at hand and also a vessel for the daily boiling, which must not be omitted. For bottling establishments and other users of large amounts of clear waters, batteries of these tubes are successfully used. One of fifteen tubes freshly cleaned and boiled yields seven gallons of sterile water per minute under a hydrant pressure of forty pounds. Testing such a filter under a lower pressure (East 42d St., New York), the writer found the water quite free from bacteria, the very few that were present probably coming from the unsterilized hose pipe used for conducting the outflow. The water was as pure as that from any mechanical filter which the writer has examined. Yet stress must always be laid upon the importance of frequent boiling of such tubes. Reliance must not be put upon the employment of automatic means of cleansing them by the use of powdered infusorial earth to the neglect of boiling several times a week, although bottlers are apt to disregard such injunctions. In a carefully managed hospital or institution under proper scientific medical control these battery filters can produce water entirely free from germs.

All things considered, the simple form of the

short-cylindrical Berkefeld filter is to be recommended as the best for household use when there is a hydrant supply needing filtration, but it must be repeatedly emphasized that frequent boiling of the porous cup is essential to perfect results. While thus commending this filter, the writer would not disparage the best porcelain filters. In his own residence, both kinds are in regular use and both yield sterile, wholesome water.

As compared with the use of these germ-proof filters by the few intelligent people who will regularly give them the requisite amount of care (in itself very trivial, but yet indispensable) any other filtration of drinking-water is inferior. Even the best gravity-filters are not perfect and yet they are in every respect better for a city than the individual use of any ordinary domestic filter; for most every pattern in the market is worse than none and vastly inferior to the employment of boiling for purifying water at the time of an epidemic.

(To be continued.)

THE TREATMENT OF ABORTION.

By HENRY J. GARRIGUES, M.D.,
OF NEW YORK;

CONSULTING OBSTETRIC SURGEON TO THE MATERNITY HOSPITAL;
VISITING GYNECOLOGIST TO ST. MARK'S HOSPITAL, ETC.

THE Century Dictionary says that a somewhat useless distinction has sometimes been drawn between abortion and miscarriage, by which the former is made to refer to a termination of pregnancy during the first four months, and the latter to the following three months. According to the same authority, the terms miscarriage and abortion are applicable to a premature ending of pregnancy at any time before the end of the seventh month. In my opinion this distinction is useless. If employed as a basis for therapeutic indications, it is dangerous and should be abandoned. To place a landmark at the end of the fourth month of uterogestation is probably a relic of olden times, when the theory prevailed that the fetal life did not begin until the mother became conscious of the child's movements, the so-called quickening. Many women regard it as a comparatively slight offense to take measures causing the interruption of pregnancy before the child is supposed to be viable, while possessing the idea that the same act committed at a later period is something akin to infanticide. From a physiologic standpoint, fetal life begins the moment of the junction of the male and the female elements.

Other authorities, *e. g.*, Foster's Medical Dictionary, limit the period during which abortion may occur, in a stricter sense, to three months. This is better, since it has reference to the completion of the placenta. In a general way it may be said that at the

end of three months there is a well-developed placenta, but its formation is gradual, and, like most other vital processes, is to some extent subject to individual variations. Some time between the middle of the third and the middle of the fourth month, the ovum loses the chorionic villi with which it is covered at a previous period and becomes smooth, except over the area where the villi grow into the decidua, and together form the placenta. From this it follows that the treatment which will be advocated in these pages is indicated at any time, not only during the third, but even during the second month. I am, therefore, not in favor of establishing a difference between abortion and miscarriage. Both terms may be used to express an interruption of gestation at any period previous to the viability of the fetus.

In regard to the use of the terms abortion and premature labor, I do not approve of the period of seven months as a landmark to be employed in discriminating between them. Since many infants may be reared when pregnancy terminates as early as at the end of the sixth month, this is the time after which abortion is no longer possible, and indicates the natural and proper use of the terms abortion and premature labor. From the end of the fifth month of pregnancy the child may be born alive, inasmuch as its circulation is maintained independently of the maternal organism, and its muscles evidence contractility; but at this early period it is not viable. If the placenta is expelled spontaneously, or is expressed by Credé's method, as is often possible at this stage, the case should be regarded as one of premature labor, and the treatment for abortion is not indicated.

During an extensive experience in obstetrics and gynecology, I have observed a large number of abortions at every stage, and my clinical notes, which form the exclusive basis of this paper, lead me to think that abortion is most frequently observed during the third month of gestation, and with diminishing frequency during the second, fourth, and fifth months. As to the first and second months, I do not doubt that many abortions occur which do not come under medical observation, and sometimes without the knowledge of the patient. I have thus accidentally observed an abortion at the end of the second week which was entirely deprived of subjective symptoms. On the other hand, I have seen dangerous hemorrhage coincident with abortion at the end of the first month which, without proper treatment, might have ended fatally. Many menstrual irregularities in recently married women are probably due to pregnancy and its untimely interruption.

By far the most common symptom of threatened abortion is hemorrhage from the uterus. When abor-

tion actually occurs, clots are discharged, and in some cases this is all that will be observed. In others the entire ovum, or portions of it, or even the fetus itself, is discharged. The loss of blood may be so considerable that the patient becomes faint, loses consciousness, or even dies. The hemorrhage may be protracted over days, weeks, and even months, and in such cases, even though moderate, it weakens the patient to a greater or less degree.

In most cases there is some pain, which is described as being cramp-like, and indicates painful contractions of the uterus. Backache is also a common symptom. Often there are nausea and vomiting. Among rare symptoms I have observed stiffness of the lower jaw, which means a beginning tetanus.

On vaginal examination the uterus will be found changed in size, consistency, and shape, according to the stage of pregnancy reached before the occurrence of abortion. As a rule, the os is more or less patulous, sometimes to a degree sufficient to admit a finger. Often the ovum may be felt projecting from the os, or if the fetus has been expelled the torn umbilical cord may be found. In other cases the os is closed. If the fetus is macerated, offensive purulent discharge may be observed to come from the interior of the uterus. If general septicemia has developed the pulse will be small and rapid, and sometimes the temperature will be elevated. Under such circumstances there may be present weakness, nausea, vomiting, and a yellowish color of the face. In such a case I have seen repeated epistaxis and the development of a retro-uterine hematocoele, which finally led to a fatal termination.

At the normal end of pregnancy, and even in premature labor, the ovum separates from the uterine wall, leaving only a layer of cells which serve for the reproduction of the endometrium, and therefore interference is not usually indicated. I do not even employ an intra-uterine or vaginal injection. On Braune's¹ beautiful plate representing a section of the frozen body of a woman at the end of the eighth week of pregnancy, the decidua in the lower part of the uterine cavity is a centimeter in thickness, and its cut surface is twice as thick as that of the chorion. Usually the decidua vera is the last portion of the products of conception that is expelled, and the process of discharge may require weeks or even months before it is complete, the uterine contractions being too weak to expel what is now a foreign body; it must remain until disintegrated and removed in small shreds as a constituent of the lochial discharge. During this time the patient is exposed to the dangers of hemorrhage and septicemia.

In very early pregnancy the entire ovum may be expelled at once, and the remaining decidua be so insignificant that it will take care of itself. At best the reflexa may be discharged with the ovum, the vera remaining. In the plate above mentioned may be seen an accumulation of blood between the chorion and the reflexa. During abortion the blood, by increasing in quantity, will gradually separate the ovum from the reflexa, and the former may be expelled, leaving both the vera and torn reflexa behind. Sometimes there may be a fetus in the discharged products; in other cases we find only a deformed mass, even when the ovum is expelled entire. Again, in other instances, only the fetus will be thrown off, and the remaining conception products remain in the uterus.

The prognosis in any case of abortion is doubtful. If rational treatment has been instituted, the prognosis is good. I have never observed a fatal termination when I have been able to direct the treatment from the beginning. If left to itself or improperly treated, abortion is a dangerous accident which often ends fatally, usually from the occurrence of hemorrhage or septicemia. More women die from abortion than from childbirth, even if the bungling operations of professional abortionists are not considered.

The treatment may be prophylactic or curative. The former is especially called for in cases of habitual abortion, in which a history of syphilis is so frequently elicited, and by instituting specific treatment of the husband, the wife, or both, it may be possible for pregnancy to be completed. It may be necessary for the patient to change her occupation or location of residence, especially if the latter should be in a malarious district. Sometimes a uterine displacement exists which may be remedied before pregnancy occurs. If no such indications are found, I have sometimes succeeded in preventing abortion by having the patient remain in bed during the week corresponding to what would be a menstrual period if pregnancy had not occurred. Confinement to the bed should continue from two days before menstruation would be due under non-pregnant circumstances to five days after. At the same time a teaspoonful of fluid extract of *viburnum prunifolium* should be administered three times a day. During the remaining three weeks moderate exercise in the open air is indicated, and at the same time iron, quinin, red bone-marrow, arsenic, and phosphorus may be given with benefit. In my opinion, this is a better plan than forced and complete rest during the whole of pregnancy, which treatment is very weakening and may assist in the causation of abortion or make the patient less fit for the ordeal of childbirth. Coition,

¹ Wilhelm Braune, "Topographisch anatomischer Atlas," Leipzig, 1875; plate No. 11.

dancing, horseback riding, bicycling, gymnastics, and all sorts of sports or fatiguing work must be absolutely forbidden.

If abortion threatens, as indicated by loss of blood from the uterus, it becomes necessary to decide if further prophylactic measures are advisable. Under these circumstances it is often possible to prevent abortion by means of complete rest and the administration of *viburnum prunifolium*, opium suppositories, a saline, and the application of an ice-bag to the hypogastrium. If hemorrhage is considerable or has continued long, if the cervical canal is open, if the ovum is felt projecting into the vagina, abortion is inevitable, and then the sooner the uterus is emptied the better it will be for the patient.

The old treatment, consisting in vaginal injections of ice-water tamponade and removal of the ovum, exposes the patient to great danger, and at best leads to a tedious recovery. I very rarely use a tamponade. The indications for its use are only when there is great weakness, necessitating a better general condition of the patient before having recourse to operative interference, and also when, on account of unfavorable surroundings, it is wise to remove the patient to a hospital.

In many (even new) books the use of tents for producing dilatation of the cervical canal is recommended. I am opposed to the employment of any kind of tent except that, if it is deemed necessary for other reasons to tampon, I use iodoform gauze in the upper part of the vagina, and introduce a portion of the gauze into the cervical canal. If immediate dilatation is necessary it is, in my opinion, much better to use either the expanding or coniform dilators. If a tampon is used, only the portion which is placed in the upper part of the vagina should be composed of iodoform gauze. The portion of the tampon in the lower part of the vagina should be made of pledgets of absorbent cotton wrung out of a one-per-cent. creolin emulsion, and should be inserted with the aid of a Sims' speculum, and so tightly packed that it effectively prevents any loss of blood.

In most cases it is my practice to dilate the cervical canal instrumentally. For abortion occurring during the first three months of pregnancy, all that is required for this purpose is a set of conical, hard-rubber dilators, or a dilator embodying the principle of a glove-stretcher. During the fourth and fifth months a higher degree of dilatation is required, and for this purpose I employ a set of olive-shaped hard-rubber dilators. The set consists of ten olives, ranging in circumference from 33 to 68 mm. At a later date of pregnancy Hanks' large dilators, ranging from 73 to 137 mm., are very useful. When

the necessary degree of dilatation has been effected, the uterine cavity may be emptied. Much less violence is required in introducing dilators than in forcing a finger through a closed os, as has been recommended.

For the purpose of emptying the uterus, Thomas' small dull wire-curette is useless, and may lead the operator into an erroneous belief that the cavity is empty. On the other hand, his large dull wire curette, with an opening admitting the tip of a forefinger, is an admirable instrument for the purpose of both loosening the ovum from the walls of the uterus and removing it by seizing it between the instrument and the index-finger, as well as for scraping off the decidua vera. Formidable as the instrument appears, I have used it many times with the greatest satisfaction. Before the end of the second month of pregnancy it is too bulky, and in such cases I employ the old Récamier curette, which also is dull, but much smaller and better adapted for this period. At a very early stage, say at the end of the first month, it is even necessary to use Simon's sharp spoon or Sims' curette. For the removal of the fetus, a blunt forceps with heart-shaped or oval rings is required, and the same instrument may, in rare cases, be necessary to assist in removing the placenta; but in nearly all cases I prefer the combined use of the finger and the large, dull, wire curette. By using moderate force one can safely scrape as long as anything comes away. When the uterus has been emptied and is small, it is only necessary to pack the vagina as described above. If it is larger, say corresponding to three-months' gestation, it is my practice to pack the uterine cavity with iodoform gauze before tamponing the vagina. The tamponade is removed the following day, and after that a vaginal douche of one-per-cent. carbolyzed water is given twice daily. The patient should remain in bed at least one week.

Immediately before and after curettage the uterine cavity should be flushed with two pints of a one-per-cent. creolin emulsion, which is both antiseptic and hemostatic. For this purpose I use a single-current metal tube. There is no advantage in combining the curette and irrigation-tube in one instrument. I prefer, on the contrary, to distinctly see what is scraped away. To use the finger as a curette is in most cases unsatisfactory, even when one hand is used for pressing the fundus down. The finger is often arrested at the internal os or does not reach the uppermost part of the cavity, and at all events, it can only be used to separate the ovum from the uterus, and cannot remove the decidua vera.

When the uterus is empty and the tampon has been applied, ergot may be administered to the best advantage, and it should be continued in doses of one

teaspoonful three times daily until an ounce has been taken.

Should pain be an element, which is exceptional after the uterus is empty, there is no objection to the administration of an opiate. In most cases it is certainly advisable to employ anesthesia. It is hardly necessary to say that the rules of clean midwifery should be carefully observed.

Should pregnancy be terminated after the fifth month, and the placenta not be expelled, either by the uterine contractions or by Credé's method, it is better to tampon the uterus and vagina as described before, and await further developments. If the placenta does not come away within twenty-four hours the dressing should be renewed and left in place a day longer, and then if the placenta yet remains within the uterus, its mechanical removal is positively indicated. The intra-uterine use of steam has of late been recommended, but it has been found in cases in which hysterectomy has subsequently been performed that it requires four weeks before the cauterized tissue is regenerated. Experience in other conditions in which I have used steam after curettage has shown that its use is often followed by a protracted purulent discharge. Consequently, its employment does not seem advisable.

That the treatment advocated in this paper may be used even when the os is closed, follows from its applicability to cases of induced abortion. I have had but four such cases, which were described in a paper read before the American Gynecological Society.¹ The operation was performed at the end of the first, the second, and the fourth months, and at the end of the seventh week of pregnancy. All the patients made good recoveries within a week, and at no time were seriously ill.

Our resources are limited for the treatment of septic cases, and the prognosis should be very guarded. If the fetus, ovum, or placenta are retained, or should there be hemorrhage, the cervix must be dilated and the uterus curetted and washed out. In doubtful cases it is often better to refrain from curetting, for by this operation the protective wall which Nature throws out may be destroyed, and infectious germs given a ready means of penetrating to the deeper tissues. Under all circumstances great attention must be paid to the general treatment in septic cases. The patient should be given as much whisky or brandy as she can tolerate—twelve ounces or more during the twenty-four hours. Salophen given in 5-grain doses every three hours has seemed beneficial. It is needless to say that the bowels should be kept open.

In localized septic cases a treatment similar to that recommended for simple abortion is indicated. In septicemia whether or not local treatment is necessary will depend upon the obtaining circumstances.

THE CONTRIBUTIONS OF BACTERIOLOGY TO THERAPEUTICS.¹

BY WILLIAM HALLOCK PARK, M.D.,
OF NEW YORK;

ASSISTANT DIRECTOR OF THE RESEARCH LABORATORIES OF THE
HEALTH DEPARTMENT OF THE CITY OF NEW YORK.

It is now a matter of familiar knowledge that bacteria cause disease chiefly by means of the poisons which are elaborated during their growth. The abstraction of food from the body and the mechanical interference with functions which are caused by their presence are also deleterious, but in a minor degree. Bacterial activity outside the animal organism produces fermentation or putrefaction, inside the body it produces what is termed disease.

Although many complex factors influence the degree of susceptibility of the body to infection from any pathogenic germ, the most important and perhaps all-embracing one is whether or not the animal organism at the time and place of infection is in proper condition for the growth and activity of the invading germ. The living body certainly is not a good soil for most bacteria, even after they have penetrated the outer protecting wall of skin and mucous membrane. The reasons for this are, however, only partially discovered.

While it is true, that the animal temperature and the concentration of food in the blood and tissues militates against the growth of many forms of saprophytic bacteria, on the other hand, these conditions are not unfavorable to the vital processes of most pathogenic organisms, and can hardly be thought to explain the great variation in virulence between different varieties of the same species. Thus, if a single virulent streptococcus be introduced into the tissues of a rabbit, it reproduces itself a million fold within a few hours, and the resulting septicemia proves fatal within a short time, while a million streptococci from another and less virulent culture injected at one time will die instead of developing in the body of the inoculated animal. Both these cultures will, however, grow equally well in the blood-serum after its removal from the body. Consequently, to the other factors influencing bacterial growth must be added qualities only possessed by the living tissues. This protection against infection exists in different degrees in the same individual toward different bacteria, and among different individuals toward the same bacteria.

¹ "Transactions American Gynecological Society," 1875, vol. xx, p. 469.

¹ Original abstract by the author of the Wesley M. Carpenter Lecture, delivered at a meeting of the New York Academy of Medicine, October 21, 1897.

The causes of immunity, either natural or acquired, are still only partially understood. If a few virulent anthrax bacilli are injected into a susceptible animal, the results of inoculation are soon manifest, and death of the animal follows. If an animal of the same species, which has previously been immunized, be inoculated with the same germ, the bacilli not only do not increase but soon die. In seeking the reasons for this varying action of bacteria, it was found that in non-immunized animals they develop unhindered by the vital activity of the cells or fluid substances of the body, while in the immunized animals certain cells are attracted by the bacteria, and eventually destroy them. Mennes' recent investigation of the pneumococcus infections would seem to show that the attraction of the leucocytes for bacteria is not wholly due to any inherent property of the leucocytes, but rather to the effect upon the leucocytes of substances in the serum. He found that when pneumococci are added to non-immunized serum containing leucocytes from immunized blood, no phagocytic action occurs; but that when leucocytes from either immunized or non-immunized blood are added to immunized serum, they attack the bacteria. Besides this action of the cells, the blood probably possesses direct bactericidal properties. As to the nature of the action of toxic and antitoxic substances upon each other, there has been much curious speculation. The following slight modification of the theory of Knorr is presented as a working hypothesis:

It may be considered that a toxin is a substance which is directly poisonous according to the intensity of its affinity for the cells of the living body. Thus, the cells of a chicken which can tolerate enough tetanus toxin to kill thirty horses, but which can be affected by still larger doses, may be considered to have 10,000 times less attraction for the toxin than those of a horse. If we further consider that the toxin even has a stronger affinity for the antitoxin than for the cells, it may be understood how, this affinity being satisfied, the poisonous power is neutralized, and it can no longer injure the cells. An antitoxin may, in my opinion, be best conceived as a toxin which has been changed by contact with the living cell, either within the cell or outside of it. The antitoxin may have been changed by uniting with some constituent of the cell, or may have simply been acted upon by it. For the specific nature of the antitoxin it must, I believe, be considered to be a part, however little, of the toxin; for it seems improbable that the cells can produce a specific antidote for every variety of bacterial poison. Others consider that the antitoxin is secreted by the cells, the toxin simply acting as an irritant, and that the antitoxin also acts upon the cells, rendering them in-

susceptible to the poison. As neither toxins nor antitoxins have ever been obtained in a chemically pure state, and as an antitoxin cannot be separated from a toxin, nor differentiated from it by chemical means, we will be obliged to remain satisfied with theoretic explanations for some time to come.

An important characteristic of antitoxins is the fact that they are gradually eliminated from the blood by the urine, saliva, etc., so that after a few weeks they may have entirely disappeared. As we do not know the nature of the micro-organisms which cause smallpox, syphilis, etc., the immunity which follows their occurrence is naturally not clearly understood. Some days after the infection the blood contains immunizing substances, but they are very weak, and it is difficult to attribute to them the long duration of the immunity. However, when the long duration of the infectious period of syphilis is remembered, it is not impossible to imagine that the tissues in the other diseases in which protection is most lasting contain substances, perhaps in encysted form, which directly or indirectly cause the production of future immunity.

Bacteria differ greatly as to the particular tissues in which they can develop, and, therefore, in the manner in which they produce infection. Thus, a few tetanus bacilli are introduced by a splinter into the foot, they multiply but slightly, but find the soil suitable for the production of sufficient toxin to kill within a few days. The same bacilli introduced into the body by way of the alimentary canal, although readily developing in the intestines, find no lodgment in the mucous membrane, and are, therefore, harmless. On the other hand, the cholera spirillum introduced in the same way develops in the intestine and causes disease; carried by a splinter under the skin it is harmless. The bacillus of diphtheria requires still different conditions for its growth. It is practically harmless in the intestines, under the skin, or in the blood, but lodged on the throat or mucous membranes it causes diphtheria. Bacteria differ markedly in the rapidity with which they produce disease. Thus, the tetanus bacillus kills quickly by its toxin, while the tubercle bacillus slowly invades the tissues, and month after month destroys portions of one or more organs before finally causing death.

There are certain general factors which temporarily affect the susceptibility or resistance of the living tissues to all micro-organisms. Thus, clinically, as well as bacteriologically, it is known that lack of food, exposure to heat and cold, over-exertion, extreme youth, old age, and many other influences predispose to disease, while opposite conditions assist the body to protect itself.

In order to determine whether curative agents are produced for any individual disease, it is necessary to examine in each, by means of the toxins, or by means of living cultures, whether immunity may be produced in an animal, and whether in such an animal the blood contains at any time sufficient antitoxic, or bactericidal properties, to confer immunity when introduced into the bodies of other animals. Further, it must be decided in each individual disease what length of time may elapse from the date of the infection in which the serum or toxin will still be able to prevent the development or arrest the progress of the disease.

Tetanus antitoxin has been applied on a large scale in immunizing animals against possible infection. Thus, horses which are used for the production of antitoxic serums run a considerable risk of tetanus infection from the large number of hypodermic injections which are necessary. During 1895 the Health Department lost several very valuable animals in this way. Since then the experimental animals are immunized from time to time with 30 c.cm. of tetanus antitoxin, with the result that tetanus does not occur. The power of tetanus antitoxin to neutralize the poison before it has affected the cells is marvelous and certain, but after the cells have been injured the opposite is true. The results of treatment are not as brilliant as are those of immunization. By the time the symptoms of tetanus are manifested the cells are frequently too profoundly affected to receive any assistance from the antitoxin. The symptoms of this disease develop from one to five days after infection. Usually until the symptoms appear the animal may be saved by an injection of antitoxin, but after the appearance of the first symptoms the antitoxin is, as a rule, useless. Sometimes, however, it will save when given a few hours after the first symptoms have developed.

When the symptoms develop within six to eight days, and the disease runs an acute course of forty-eight to seventy-two hours, the antitoxin usually gives negative results. When, however, there is a longer incubation period, and the disease tends to run a more subacute course, the antitoxic treatment is very beneficial. Dr. Lambert, in a study of statistics, found that in thirty-one acute cases developing within eight days from the date of infection there was a mortality of sixty-one and one-third per cent., while among similar untreated cases the mortality is considered to be as high as eighty per cent. In forty cases of long incubation and slow onset of symptoms the mortality under antitoxic treatment was but five per cent., while in similar cases without the antitoxin, it usually is as high as forty per cent. Judged by these statistics, made it is true from a small num-

ber of cases, antitoxin seems to have positive curative effect in the less acute cases of tetanus. As it is impossible to tell at the outset which cases will be benefited, it seems wise in conjunction with the usual treatment to administer the antitoxin in doses of 20 to 50 c.cm., twice daily, in all cases of tetanus, and to begin the treatment at the very earliest possible moment.

The antitoxic treatment of diphtheria has so frequently and fully been treated, that I will only mention a few points which seem to me to be of special interest. Diphtheria antitoxin is singled out among antitoxins by the success which has attended its employment in the treatment of diphtheria, as vaccine is among immunizing procedures in the prevention of smallpox. The great mass of physicians, especially those having had the greatest experience, are convinced that diphtheria antitoxin in doses of 200 to 300 units will confer immunity against diphtheria during from two to four weeks, and that the period may be lengthened at will by repeated doses. By this means many children's asylums are now kept free from diphtheria. They are further convinced that when cases are seen early, that is at a period when the disease may be readily diagnosticated, but before general poisoning has occurred, antitoxin may be relied upon to arrest, with but very few exceptions, the progress of the disease.

Why is it, may be asked; that two substances such as tetanus and diphtheria antitoxin, so nearly identical in their efficacy as agents for immunization, differ so greatly in curative value? The secret is in the manner in which the two infections begin and progress. The tetanus infection progresses from five to ten days undetected in the wound, the toxins develop unnoticed, cause their deleterious effect, and only after general poisoning has occurred is the disease manifested to the observer. The diphtheria infection starts on the surface, and before its toxins are fully developed and absorbed it is diagnosticated. At such a period the tetanus infection could also be arrested. In diphtheria as in tetanus, if the favorable time is allowed to pass and the constitutional poisoning has occurred, the antitoxin is usually of no avail.

No other bacterial toxins produce such powerful antitoxin as do those of tetanus and diphtheria. The nearest approach is in the case of the plague bacillus. This with its toxins produces in immunized horses a serum which is distinctly antitoxic and bactericidal, so that from one-tenth to one-fortieth of a cubic centimeter will protect a mouse from ten times the fatal dose of toxin or living bacilli. This serum, prepared by Roux and Yersin, has proved to be capable of arresting the plague in monkeys in which the dis-

ease runs a course very similar to that in man. In man the serum has been used in several hundred cases, and given beneficial results both for purposes of immunization and cure, the mortality having been lowered from an average of eighty to fifty per cent.

The serum of animals immunized to streptococcus and pneumococcus toxins and cultures possess bactericidal and antitoxic properties, but of much less power than the plague serums. The streptococcus serum has been most experimented with, and has been obtained in sufficient strength so that a dose of one-fifth cubic centimeter would protect rabbits from one hundred times the fatal dose of streptococci. After infection has developed to any considerable extent the serum is useless. In spite of the many favorable reports of its use in septicemia, erysipelas, and other streptococcus inflammations, there is no doubt that its curative value is limited, and the discovery that it rapidly deteriorates accounts for the fact that practically all of the preparations on the market are valueless.

The serum of animals immunized to tuberculosis is also extremely weak in bactericidal and antitoxic substances. Most preparations show absolutely no immunizing effect. The apparently good results from any serum now on the market are probably due to other measures employed in the treatment.

The new tuberculin of Koch requires improvement before it can be advised for practical application. The experiments of Trudeau and Baldwin as reported in *THE MEDICAL NEWS* have shown that, as at present prepared, the new serum is not only frequently contaminated, but that most of the vials contain living tubercle bacilli. That these bacilli are capable of causing tuberculosis has been proved by Dr. Baldwin by experiments upon animals, when, in spite of continued tuberculin injections, the animals became infected and died of tuberculosis. It is too early to judge of the therapeutic value of the new tuberculin. It will probably be shown to possess slight curative value in beginning tuberculosis and in lupus. With an improved technic it should be furnished free from bacilli.

Typhoid fever and cholera may be classed together. Animals may be immunized to both, and their serum will be found to contain feeble antitoxic and moderate bactericidal properties. From the results of experiments upon animals, it may be said that injections of the serums or of the dead bacteria into man will produce a fair degree of immunity, which will continue some weeks. The treatment of typhoid fever with serum has not given any marked results, although a few observers have claimed that the attack is shortened.

Although no form of micro-organism has yet been

discovered in the brain or spinal cord of men or animals attacked by hydrophobia, nevertheless it is certain that one exists, for the disease is so readily transmitted from animal to animal in characteristic form that skepticism is impossible. The preventive treatment instituted by Pasteur has been subjected to an immense amount of criticism, but I believe its efficacy is to-day finally established. Two objections have been made to the treatment: (1) The proportions of cases developing after the bite is as large in those treated as in those not treated; and (2) that some who would not have developed hydrophobia from the bite developed it from the injection of the virus. As the Health Department intends soon to offer the Pasteur treatment to all who desire it, these criticisms have naturally been very interesting. During a visit at the Pasteur Institute in Paris this summer I carefully inquired concerning these points. It was stated that the apparent diminution in the percentage of those developing hydrophobia after bites by rabid animals is so great, that it is impossible to believe it to be due to misinformation as to the extent the disease formerly occurred. They stated that from time to time a person infected developed rabies two weeks or more after having passed through the whole course of treatment, which is a time when the patient should have been fully immunized. As to the possibility of producing hydrophobia by means of the injections, they believed it had never occurred in the thousands of cases treated at the Institute. Similar testimony comes from all the other institutes.

In order to test experimentally the immunizing value of the Pasteur treatment, numerous experiments have been carried out in the Research Laboratory of the Health Department of New York City by Drs. Wilson and Cabot. These, though not as yet complete, present striking evidence that the injections do produce immunity, and that when properly carried out they are without danger even in very susceptible animals.

The results of the use of vaccine virus in the prevention of smallpox are so nearly universally accepted that they will not be touched upon here. The serum of vaccinated animals contains very feeble curative properties, too feeble for practical use.

As to the future: The outlook is bright for obtaining through serums, or through the toxic substances of the micro-organisms themselves, means for immunizing against most if not all of the bacterial diseases.

This immunity in most instances will not be of long duration. This drawback may be overcome, however, by repeating the immunizing injection. When we have discovered the micro-organisms causing scarlet fever, measles, and the other diseases, in

which a prolonged immunity follows recovery from infection, we may hope to obtain vaccines as efficient as that now used in smallpox. The prospect of obtaining serums which will promptly arrest the further development of a disease by the destruction of the micro-organisms and their poisons already in the body, is rather less encouraging than it appeared to be shortly after the discovery by Behring of the diphtheria antitoxin.

The serum procured from animals immunized by the pneumococcus has only slight curative power, but sufficient has been accomplished to make further investigation imperative. The serum is practically harmless, and physicians who desire to test it would be justified, by the results of experiments already published, in using it in the treatment of cases of pneumococcus infection.

We must remember that all we can hope for is to stop all growth of the micro-organisms and prevent further action of the bacterial poisons at the moment the treatment begins. We cannot hope to benefit the tissue-cells or the activity of organs except by neutralizing certain deleterious products, and thus allow the vital processes and other therapeutic aids a better chance of success.

CLINICAL MEMORANDUM.

A CASE OF LYMPHATIC LEUKEMIA.

By JULIUS FRIEDENWALD, M.D.,
OF BALTIMORE;

CLINICAL PROFESSOR OF DISEASES OF THE STOMACH;
AND

STANDISH McCLEARY, M.D.,
OF BALTIMORE;

ASSOCIATE PROFESSOR OF PHYSIOLOGY, COLLEGE OF PHYSICIANS
AND SURGEONS.

CASES of pure lymphatic leukemia are very rare. We therefore report this case, although an autopsy was not permitted. The clinical features, however, were so characteristic that there can be no doubt as to the correctness of the diagnosis.

Tillie R., aged eleven years, of Russian parentage, was first seen by Dr. A. Friedenwald at the Hebrew Orphan Asylum about April 20, 1896. Finding the patient suffering from a profound anemia he ordered her sent to the Hebrew Hospital. She was admitted to the hospital April 27th, and through the courtesy of Drs. Rosenthal and Wolf we were allowed to observe the case.

We learned that the patient had been in ill health for five or six months previous to admission. She had frequently suffered from nose bleeding, had emaciated markedly, and was constantly languid and tired. She had complained frequently of palpitation of the heart and difficulty in breathing. The family history was negative. On examination the child was found to be very anemic and emaciated. The mucous membranes were extremely pale. Both legs showed signs of ecchymoses. There was no edema and no jaundice. The pulse was feeble, regular,

but accelerated (110 beats per minute). There was marked visible pulsation of the veins of the neck. The subaxillary, suboccipital, axillary and inguinal glands were much enlarged, the several glands of each set being distinctly separated from each other. The glands were all very tender to the touch. The respirations were increased in frequency (34 per minute), the lungs were everywhere resonant, the breathing puerile. The apex beat was weak, accelerated and found in the fourth intercostal space just within the mammary line. The heart-sounds were weak, though clear. The abdomen was markedly distended, though the presence of fluid could not be detected. The spleen was much enlarged, extending to within one-finger's breadth above the crest of the ilium and two-fingers' breadth to the right of the umbilicus. It was very tender to the touch. The liver was enlarged, extending to two-fingers' breadth below the costal carti-

Blood examination in a case of lymphatic leukemia. A. Small mononuclear lymphocyte. B. Large mononuclear lymphocyte. C. Red blood-cell. D. Nucleated red blood-cell. E. Eosinophile. F. Neutrophile. G. Myelocyte. (Objective, one-twelfth oil-immersion lens; eye-piece No. 4.)

lages. Its upper boundary in the mammary line was the sixth rib.

The urine was normal. The specific gravity was 1018. Upon microscopic examination crystals of uric acid were found. The ophthalmoscopic examination, made by Dr. Harry Friedenwald, May 3, 1896, was as follows: Papillæ pale and margins blurred. The vessels, both arteries and veins, very tortuous, their color being distinctly lighter than normal. There were dark hemorrhages scattered throughout the posterior portions of both retinae. For the most part these were small, the largest being half the size of the papillæ; many were but faint reddish discolorations. No white spots were to be seen anywhere in the retinae. The patient did not seem to be conscious of any impairment of vision.

The patient complained of severe headaches during the next few days, especially marked in the back of the head, and more pronounced in the evening. The appetite was

variable, there being a craving for acid foods. The temperature would rise each evening, reaching its highest point on the evening of May 1st,—104° F.

On May 6th, the patient feeling stronger, she was allowed to sit up for two hours, but at the end of this time she complained of severe pains in both legs and feet, which on examination were found to be markedly edematous. This was the first time this condition was noted. On the following day she became very irritable, there was a total loss of appetite, and nausea developed. She then began to vomit, and diarrhea set in. On May 9th she became very restless and had dyspnea. There was marked edema of the legs, arms, and hands. She died the next morning. Unfortunately no autopsy was allowed.

The examination of the blood was most important and interesting. These examinations were made on a number of different days, but as the results were identical they may be embodied in one report. The drop of blood obtained from the ear was strikingly characteristic of the condition which afterward was made apparent. It resembled sanious pus, rather than blood. Cover-slips were prepared in the usual manner for staining purposes, and differential counts were made in two ways from the fresh blood with the Thoma-Zeiss apparatus: first, Toisson's fluid was used to dilute the blood, and at the same time to stain the leucocytes, and with the special tube which accompanies the instrument the leucocytes were counted; second, a count of the red and white corpuscles was made from the stained specimens with the use of Ehrlich's stops—metal discs with a graduated square perforation in the center which fit into the eye-piece of the microscope. The results from these procedures were the same. The red blood-corpuscles numbered 800,000 per cubic millimeter, a marked oligocythemia, and the white corpuscles, an almost incredible number of 1,200,000, or the phenomenal ratio of two red blood-corpuscles to three whites. The hemoglobin, as estimated with the hemometer of Von Fleischel, registered twenty per cent., which was proportionate to the decrease in the red cells. The blood-slides were stained with a slight modification of Ehrlich's triple stain. Examination revealed that the increase in the white elements was confined exclusively to the small mononuclear lymphocytes, all other varieties of leucocytes being markedly diminished. In the red blood-cells few abnormalities other than the pronounced oligocythemia and the proportionate oligochromemia were observed. Nucleated red blood-corpuscles were present in small numbers, also a few megalocytes, and there was a slight poikilocytosis. In making the differential counts of the white cells, the Ehrlich stops were used and one hundred fields counted. A table giving the proportion of the different elements and the proportion of the different white elements in normal blood is appended.

	Tillie R.	Normal Blood.
Small mononuclear lymphocytes....	97.1	20
Large " " " and		
transitorial forms.....	.5	6
Polynuclear neutrophiles.....	2.	70
Eosinophiles.....	.1	1 to 5
Myelocytes.....	.3	

The great increase in the small mononuclear lymphocytes and a proportionate decrease in the polynuclear neutrophiles is striking. The eosinophiles are decreased, the myelocytes rare, which is in marked contrast to splenic myelogenous leukemia in which there is a great abundance of these elements. The presence of an inconsiderable number of myelocytes would not warrant the assumption that we were dealing with a case of mixed leukemia. Myelocytes are occasionally met with in like numbers in various other conditions.

This case is remarkable not only on account of the infrequency of this form of leukemia, but also from the fact that in no other recorded case, which we have been able to discover, has the number of white elements exceeded the red by such a majority.

MEDICAL PROGRESS.

Prognosis in Hemiplegia.—LÓDOR (*Medicine*, October, 1897) says there are three points which, when taken together, give a fair indication of the permanency of the paralysis in hemiplegia. They are the voluntary motor power of the patient, the spastic rigidity, and the increased reflexes. To reduce the problem to almost a mathematic level, let it be supposed that the fibers composing the pyramidal tract of one side number one hundred. Suppose that ten of the fibers are destroyed by degeneration subsequent to hemorrhage. If such be the case, after a lapse of three to six months, the patient should have recovered nine-tenths of his original power, with the increase in reflex represented by one-tenth and the rigidity or spastic condition scarcely noticeable. On the other hand, suppose that the reflexes are exaggerated one-tenth, the voluntary power reduced to zero, and no rigidity. With such a condition it is fair to suppose that nine-tenths of the fibers are intact and out of the reach of the patient's will, either from former pressure of the clot, or from long disuse, and that recovery may take place to the extent of nine-tenths of the former power. Again, suppose the patient presents the following points: Motor force reduced to one-tenth, reflex markedly increased, and rigidity great. With such symptoms it is fair to presume that approximately nine-tenths of the fibers have been destroyed, and that further recovery cannot take place. Experience has shown that these points are to be relied upon with almost mathematic precision.

Galvanocautery in Procidentia.—MACEVITT (*Brooklyn Med. Jour.*, October, 1897) has had excellent results from the use of the galvanocautery in procidentia. The operation, which is extremely simple, consists in cutting out with the cautery a conical piece of the uterus, including the cervix. The relief of the strain on the uterine ligaments, and the beneficial action of the heat, which extends far beyond the cauterized area, are the means of restoring to the ligaments their natural tone. In order to facilitate this, a large firm tamponade is inserted into the vagina, the cotton used for this purpose being saturated with glycerite of tannin. A new tampon should be inserted every day, preceded by a hot-water douche. This

treatment should be continued for about three weeks, the patient meanwhile remaining in bed with the hips elevated. Tonic treatment should also be administered. In a few months' time there will be a surprising diminution in the size of the remaining portion of the uterus. The only accidents which can happen in the performance of this operation, are the opening of the peritoneum, and the division of the uterine arteries. The former has no significance, as long as the bowel is not injured, and the latter simply means the application of a ligature. The shank of the cautery knife should be covered with cotton to protect the vagina from being scorched.

Prescribe Alcohol, not Whisky.—In the *Jour. of the Amer. Med. Assoc.*, August 21, 1897, is an article by DAVIS on the therapeutic properties of alcohol, and the reasons why the fermented and distilled liquors used as beverages should not be recognized in the pharmacopeia as medicinal agents. All the possible beneficial affects to be obtained from them may be derived from a suitably diluted alcohol, and by prescribing this, instead of wine, beer, whisky, and brandy, the doctor knows exactly how much alcohol he is administering—something which is impossible if the beverages are employed, as the percentage of alcohol in them is subject to such wide variations. Besides, all of these liquors contain other substances, many of which are injurious, and which may be excluded, if the plan advocated is adopted. Moreover, there is considerable saving of expense to the patient. Consequently, it is far more economic, as well as more accurate, for every physician to prescribe pure alcohol and water, to be administered with such quantity of sugar, milk, or meat broth, as in his judgment is required. It would be a very great step in advance, if in the next revision of the Pharmacopeia, only alcohol of standard strength should be retained, to the exclusion of all fermented and distilled liquors. If these changes were adopted and carried into general practice, the result would be a more complete separation of both pharmacist and physician from connection with, or responsibility for, the sale or use of the various popular alcoholic beverages.

THERAPEUTIC NOTES.

Saline Solutions in Obstetrics.—In the October number of *Medicine*, BACON makes a plea for a more general use of injections of saline solutions in obstetrics. Many physicians are forgetful of the value of this method of treatment, and few realize how very simple is the technic necessary for its employment. The good results attending its use in severe hemorrhage are well known. Although it is difficult to estimate the amount of blood lost during delivery, it is not far out of the way to say that a completely saturated sheet will contain two pounds. A deduction must be made for the amniotic fluid. In cases of hemorrhage of the "second degree," that is when from one-fourth to one-half of the blood in the body is lost (2.5 to 5 pounds), the importance of prompt thera-

peutic aid is very great. Absorption from the rectum of an injection though slow and rather uncertain, does well enough in the less severe cases, but when a patient has lost from two to five pounds of blood, it is necessary to use some quicker method to supply the required fluid in the vessels. This can best be accomplished by hypodermic injection, and the following simple rules are sufficiently accurate: A teaspoon of medium size is filled level-full of fine table salt, which is put into a pint of water and boiled. A hypodermic needle fitted to the end of three feet of rubber tubing and then filled with the solution is thrust into the inner side of the thigh; or by using a glass Y-tube, two needles may be used at the same time, one in each thigh. The saline solution is allowed to flow through the tube, no force but that of gravity being necessary. Constant massage is made about the point of the needle to assist in disposing of the fluid. In this manner from twenty-four to thirty-two ounces may be introduced in fifteen minutes, if the irrigator is raised three feet. Not more than a quart of fluid should be given at one time; if necessary, the injection may be repeated in an hour or two.

It is well understood that in eclampsia the toxicity of the blood-serum is increased. Whatever their nature, the poisons are not excreted by the kidneys fast enough. To increase the rapidity of excretion has been the rule of treatment. Formerly, venesection was employed to remove a part of the poisoned blood, while transudation from the lymph spaces, diluted that which remained. This dilution may also be obtained by the injection of saline solution. If a patient be plethoric, from twenty to forty ounces of blood should be withdrawn, and its place taken by the injected saline solution. In anemic patients it is better to make the injection without venesection. The salt solution is a valuable diuretic, diaphoretic, and purgative, as well as a diluent of the blood.

The treatment of puerperal fever by saline injections has been tried on the supposition that by dilution of the bacterial toxins and hastening their elimination, the condition of the patient will be improved. The successes are too few to permit an advocacy of the procedure in these cases. In fact the treatment of this dire affection has made practically no progress for three decades.

The Proper Method of Preparing Yellow Oxid of Mercury Ointment.—KEIPER (*Ophth. Record*, September, 1897) says that carelessness in the preparation of the ointment of the yellow oxid of mercury deprives this excellent application of much of its value. As in making a flour paste it is a matter of common sense not to dump all of the flour at once into the water, so in the preparation of this ointment the mortar and pestle should first be smeared with a little vaselin, and the mercury added in minute quantities, and thoroughly incorporated, adding then a little vaselin and again a little mercury until the whole is made into a smooth paste. This requires a considerable expenditure of time, but the result warrants it. The mixing may be somewhat facilitated by warming the mortar. When finished, the ointment must be kept in glass or porcelain.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SEWAGE FARMS AND THE PUBLIC HEALTH.

GREAT progress has recently been made by a number of American cities in the methods of disposing of garbage, but few, if any, have yet attempted to deal rationally with the question of sewage disposal. As a rule, the easiest and apparently most economic method has been adopted, with the result that beautiful streams and waterways are contaminated to a degree which renders them a menace to the health of the communities along their banks. The system of "sewage farms" which utilizes to the best advantage the vast wealth of fertilizing material contained in the refuse of urban life, returning it, as it were, to the soil from whence it came, and preventing it from ultimately being lost in the depths of the sea, is the most practical method of dealing with the question.

Theoretically, many objections may be raised against this system which would be sufficient to condemn it, were it not for the fact that it has been tried, has proved to be unobjectionable, and is now in use in a surprisingly large number of transatlantic cities. For instance, England has fifty large sewage farms, and more than one hundred smaller ones. France and Germany have not adopted the system to

the same extent, but it is rapidly growing in favor. Berlin, Danzig, Breslau, and Freiburg are the most important cities of Germany that have adopted the system. From an article read by Dr. Theodore Weyl before the Berlin Medical Society, we learn that Breslau has had a sewage farm in operation since 1559, while the city of Edinburgh has used one farm for the disposal of all its organic refuse during one hundred and fifty years.

The most salient objections raised to the system are: that the sewage farms will cause an intolerable stench; that the earth will become saturated after a short time, and necessitate the employment of constantly widening areas appropriated to this purpose; and that sewage farms are likely to be an excellent culture-ground for the germs of infectious diseases. Dr. Weyl discusses these various objections, and answers them in a most convincing manner. Practically, the odors emitted are of no consequence. An English Parliamentary Commission, appointed to investigate the subject, reported through its expert, Dr. Carpenter, that the sewage farm of Norwood, in the vicinity of London, is so free from objections of this nature that a favorite promenade leads directly across its fields. Colin investigated a complaint about a sewage farm on the Seine, and found that the odor was due, not to the sewage, but to chemical works located near by. Incidentally the fact was brought out by this investigator, that schools had been established on the sewage farms, and that there was not an unusual amount of sickness among the pupils in consequence. In regard to the saturation of the soil and the failure of the mineral constituents to neutralize the organic substances, the fact that the city of Edinburgh has used one sewage farm continuously for so long, and that neither experience there or at Danzig, or Berlin, supports the assumption, is sufficient answer to this objection. The famous English hygienist, Corfield, confirms the observations made at Berlin and Paris, that only the soil of badly managed sewage farms can possibly become saturated. The character of the country which it is proposed to devote to one of these farms must be carefully considered in order that efficient drainage may be obtained.

The fear that these farms may become a source of disease seems absolutely unfounded. The medical officers of the English Commission above referred to,

through Dr. Littlejohn, deposed that in the year 1865-'66, when cholera raged in Edinburgh and London, the inhabitants of the respective sewage farms remained free from the disease. When Paris undertook the first sewage reform, the owners of villas in the vicinity of the proposed farms opposed their establishment, whereupon the French government appointed a commission of investigation, which published very elaborate reports. One of these was compiled by Bertillon, and in it was compared the mortality of the *arrondissement* in which the sewage fields were located with the neighboring *arrondissements*. On the sewage farms, taking the average for several years, six or seven persons per thousand died annually of typhoid fever. The same ratio, seven per thousand, held good for the other localities. The same was true in regard to deaths from diphtheria. The French military surgeon, Vallin, found that the mortality from typhoid among the garrisons of Southern France, namely, at Marseilles and Montpellier, was respectively fifty-six and fifty-seven per thousand. For the same number of soldiers in Northern France, namely, in Arras and Douai, it was five and thirteen per thousand. In Northern France sewage is disposed of by spreading it upon the fields as in the time of the Celts, and in spite of this rather barbaric method no unfavorable effect has been observed.

The sewage farms of Berlin are the largest in the world. Statistics have been preserved relative to their sanitary condition, extending over a period of fifteen years according to a system elaborated by Virchow. These statistics show that the inhabitants of sewage farms and their neighborhood maintain an average health in advance of that of Berlin. Moreover, mortality among children living upon these farms has been less than that among children in the city. As to dysentery, intermittent fever, measles, and scarlatina, the percentage of sickness and of death has also been lower on the sewage farms. Moreover, Professor Virchow affirms that in no instance could cases of typhoid fever be ascribed to infection from these farms except in instances in which the patients had drunk the sewage water.

The vegetables and various products of these farms are not only used for food by the people who inhabit them, but are sold in the markets of the neighboring villages and towns. Even lettuce and celery have not been charged with having conveyed disease.

OUR QUARANTINE AS IT IS AND AS IT SHOULD BE.

THE first step toward the inauguration of a National Department of Public Health necessitates a complete reorganization of our present system of quarantine. Let us examine for a moment this important branch of National sanitation. There are at present sixty-eight quarantine stations on our seaboard. These are divided according to their purpose into simple inspection stations, of which there are forty-four, and quarantine stations proper, of which there are twenty-four. Of the latter, eleven are National, conducted by the Marine Hospital Service, and thirteen are under the jurisdiction of State or local authority. Of the inspection stations six are National and thirty-six, State or local. This division of administrative authority is responsible for most of the abuses and shortcomings which mark the system. It gives rise to unnecessary stations and to the overlapping which frequently occurs. For instance, in addition to a National Quarantine Station at the Delaware Breakwater and another at Reedy Island, further up the Bay, there is a local quarantine and boarding station at Marcus Hook, eighteen miles below Philadelphia. That the last-named is unnecessary is evident to anyone; for all ports on Delaware Bay are fully protected by the Government stations.

Should it be asked what is the actual *raison d'être* of the supernumerary station, it would be difficult to answer, unless it is to give employment to the necessary officials. That this statement may not appear unwarranted, let us inquire into the work which has been accomplished at this station. A year and one-half ago it did not possess an apparatus for the disinfection of vessels and baggage, and had no facilities for the removal and detention of suspected individuals. Quarantine was maintained under United States Treasury laws and the laws of Pennsylvania; but the quarantine procedures were those of the Treasury Department. Any vessel having on board a case of cholera, yellow fever, or smallpox was (or would be) returned to the Federal quarantine at Reedy Island.¹

Such is the local quarantine station of a port where 1379 vessels arrive during a year.

To make a long story short, when nothing is re-

¹ "Report of Inspection," by Surgeon George Purviance, M. H. S. "Annual Report of the Supervising Surgeon-General of the Marine Hospital Service of the United States for the Fiscal Year 1896."

quired but perfunctory inspections and the collection of fees, the Marcus Hook Station is amply sufficient; but should an emergency arise, calling for the exercise of genuine quarantine functions, it would be necessary to call upon the National Quarantine Station at Reedy Island conducted by the Marine Hospital Service, where vessels and baggage can be disinfected and suspects removed and detained.

This is not an isolated instance as is proved by the fact that the same condition exists at the local quarantine stations of Charleston, S. C., Savannah, Ga., Fernandina, Fla., Mobile, Ala., Sabine Pass, and Galveston, Texas. The palpable absurdity of a system so conducted that a pest-ship must go from Texas ports to Ship Island, Miss., or from Charleston or Savannah to Sapel's Island, Ga., for quarantine is manifest to the most casual observer. Such a system is inefficacious, onerous, and inhuman.

While, of course, the function of quarantine is the protection of the public from an invading disease, its enforcement should be as free from harsh exactions as is compatible with efficiency, and the expense to commerce should be reduced to a minimum. That a pest-ship should be obliged to go out of its course a hundred miles or more to be disinfected is a sufficient evil in itself; but that the sick, often without medical care, and the well, in constant danger of infection, should be penned up in the same vessel, perhaps for several days, is barbarous.

A system of quarantine which is just and humane, at the same time that it is efficient, should at once remove the sick to a hospital, should have means for comfortably caring for the well, but possibly infected, should possess the necessary apparatus for the speedy disinfection of vessels, baggage, merchandize, and clothing.

Another strong argument in favor of a uniform and National control of quarantine is the great benefit which would accrue to ports of entry by the abolishment of the sometimes onerous taxes and fees. It is enough for shipping to be obliged to pay pilotage, custom's fines, harbor dues, towage, and lighterage, one or all, as it must in many ports, without having to pay inspection and other fees to local quarantine officers. Ships entering ports protected by National quarantine stations do not pay inspection fees, and when occasion arises are disinfected free of charge, and their sick are likewise gratuitously cared for. In the

very next port, perhaps protected by a local or State quarantine station, all these compulsory attentions must be well paid for. Such discrimination militates in favor of the free port, and has induced commercial organizations in many instances to advocate a National quarantine. As Surgeon-General Wyman has said, "there are quarantines for protection and quarantines for revenue." The latter, all State or local affairs, should be promptly abolished in the interests of commerce, economy, science, and humanity. By lack of uniformity, they are a constant menace. By reason of local and political character, their personnel is often unscientific and is always changing. In fact, from no standpoint except perhaps a selfish one can the present dual system be defended.

The Marine Hospital Service has proved itself capable of conducting quarantine affairs scientifically, economically, and uniformly. Let us, therefore, place under its jurisdiction a quarantine service which of necessity will be uniformly and justly administered and supported, as an efficient quarantine must be, by Federal authority.

ECHOES AND NEWS.

Gum-Chewing.—The *British Medical Journal* deplors the fact that the habit of gum-chewing, "so prevalent in the United States," is on the increase in England.

Bequests to Charity.—By the will of the late Caroline Talman of New York City, \$135,000 is left to New York charitable institutions and societies, of which the Home for Incurables receives \$5000; Free Church House for Incurables, \$3000; St. Luke's Hospital, \$5000.

Changes at Bellevue Hospital.—By order of the Commissioners of Charities, fifteen employees at Bellevue Hospital have been discharged on account of lack of funds to meet the running expenses. The salaries of the places made vacant vary from \$240 to \$600 a year.

Diphtheria on Staten Island.—Within the past two weeks twenty-seven cases of diphtheria, with four deaths, have occurred at Stapleton, Staten Island. The local physicians claim that they have the disease under control and no apprehension is felt in regard to a spread of the infection.

Winter Gardens for the Poor.—The recreation-piers which have been constructed in New York during the past season will be enclosed with glass and fitted up as winter gardens. They will be heated, lighted with electricity, decorated with plants, flowers, fountains, etc. Three of them will be ready for occupancy before the new year.

Obstetrical Society Elections.—At the last meeting of the New York Obstetrical Society the following were elected

officers for the ensuing year: President, Dr. W. Gill Wylie; first vice-president, Dr. J. C. Edgar; second vice-president, Dr. A. M. Jacobus; recording secretary, Dr. Le Roy Broun; assistant recording secretary, Dr. Geo. W. Jarman; corresponding secretary, Dr. E. B. Cragin; treasurer, Dr. J. Lee Morrill; pathologist, Dr. Geo. C. Freeborn.

The Pathogenic Role of Dust.—According to a communication recently read before the Paris Academy of Medicine, the floors of dwellings are as fruitful and dangerous a cause of infection as drinking-water. It is stated that, with the exception of typhoid fever and cholera, which are almost always spread by means of water, by far the greater part of other infectious maladies, such as the eruptive fevers, diphtheria, pneumonia, and, above all, tuberculosis, almost always arise from germs preserved in dust, except when direct infection takes place.

Verdict for a Hospital.—A suit for \$30,000 was recently brought by a woman against St. Vincent's Hospital, New York, for injuries received while in the hospital as a private patient. The woman was operated upon and was badly burned by an unprotected hot-water bag which was placed in her bed. The facts in the case were not disputed, but counsel for the hospital asked that a verdict be given for the defendants on the ground that all reasonable precautions had been taken by the management, and that the negligence was the fault of the nurse alone. A verdict was rendered in favor of the hospital.

Serum Diagnosis of Typhoid Fever.—Surgeon-major Smith of the Army Medical School at Netley, England, has been applying the serum test in groups of cases of diarrhea which have accompanied the typhoid epidemic at Maidstone. The results of his tests show that it is unsafe without a controlling bacteriologic examination, to infer that cases of diarrhea which occur before or in the course of epidemics of typhoid fever are in any way the cause or consequence of the prevailing epidemic. In other words, his experiments failed to show the presence of the typhoid reaction in cases characterized by diarrhea only.

Dangers Attending Bacteriologic Work.—Surgeon-major Semple, attached to the Army Medical School at Netley, England, recently scratched his hand with a hypodermic needle when immunizing a horse for the preparation of serum against Malta fever. Shortly after this he developed the symptoms of the fever, and his blood when examined gave a typical reaction of the micrococcus of Malta fever when diluted 1-1000. As an act of poetic justice, the horse which he was immunizing has been bled, and has supplied two injections of its serum to his immunizer. The patient is responding to the treatment and gives promise of speedy recovery.

Bubonic Plague in India and China.—It is officially announced in Bombay that an outbreak of plague has occurred in the Jalandhar district of the Punjab, and the village where the disease has made its appearance has been

cordoned. There are 294 cases in the hospitals at Poonah, and 115 cases are being cared for at Bombay. The United States consul at Amoy, China, in his report to Washington, says that the plague has died out at that place after running for three months. Nearly 90 per cent. of the persons attacked succumbed to the disease, but no foreigner contracted it. In Amoy and four adjoining towns there were 250 deaths from the plague daily during June, 400 daily during July, 200 daily during the first fifteen days of August, and 100 during the latter part of that month.

Starvation in Cuba.—Sanitary Inspector Brunner, in his last report to Surgeon-General Wyman of the Marine Hospital Service, reports seven deaths from starvation in Havana for the week ending October 7th, and twenty-one for the week ending October 14th. He also reports an increase in intestinal diseases due to the diminished food-supply, and estimates that two-fifths of the total deaths of the city are due to this cause. He calls attention to Los Fosos, a place set aside for the country people sent to Havana, and which he describes as a pest-hole. It is a large wooden building, 60x50 feet, situated in an inclosure which is used for storing the carts of the municipality. Of the 500 persons in this building, which is not a hospital, over 200 were found lying on the floor, sick and dying. All the children under ten years of age are suffering from enteritis or dysentery, and their emaciation is startling. About ten die every day. The civil hospitals are full to overflowing and are refusing patients, one—the Mercedes—capable of properly caring for 200 patients, now has nearly 500.

Lodge Doctors Not Allowed in Quebec.—The resolution passed by the College of Physicians and Surgeons of the Province of Quebec prohibiting medical men from accepting the position of lodge doctor was moved by Dr. J. B. McConnell, and seconded by Dr. S. Gauthier. It is as follows: "In view of the extent to which the members of the medical profession are defrauded of proper remuneration for professional services, owing to the acceptance by many of positions as medical officers to various benefit societies, lodges, etc., where remuneration is arranged for by contract, it be considered beneath the dignity of our profession to accept and hold such positions. In order that all professional services shall be awarded remuneration not less than the tariff adopted by this board, it is hereby enacted that members of the College of Physicians and Surgeons of the Province of Quebec shall be prohibited from accepting or retaining the position of lodge doctor where a stipulated amount is paid annually or otherwise for professional services amounting to less than the minimum tariff adopted by this board, or from attendance upon families, groups of families, or other associations, at contract prices, which name a stated amount for a certain term, usually an annual fee, and that no physician shall be permitted to retain membership in this college or practice in this Province who accepts such positions." The College of Physicians and Surgeons has the power to revoke all licenses to practice medicine or surgery in the Province.

Health Reports.—The following statistics, concerning smallpox, yellow fever, cholera, and plague, have been received in the office of the Supervising Surgeon-General of the United States Marine Hospital Service during the week ended October 30, 1897:

The "Massage-Treatment."—It is well-known that massage, an excellent thing when medically prescribed and

scientifically applied, is not only hazardous but positively injurious when an individual puts himself in the hands of the average "masseur," who is usually ignorant of anatomy and physiology. In cases where there is a gouty diathesis, ignorantly applied massage of muscles infiltrated with uric-acid poison creates as much histolytic waste as a brisk six-mile walk, and calls upon the kidneys for an excretory effort quite beyond their powers. Repeated day after day and unmodified by circumstances, this process is destructive to the already damaged kidney, and the patient finds he is rid of a certain amount of pain at the expense of a chronic renal incompetency and eventual uremia. In England and on the Continent this history is so commonly elicited that the condition is known as "massage-kidney."—*London Lancet*.

Progress at Craig Colony During the Past Year.—The Craig Colony for epileptics at Sonyea, Livingston County, N. Y., closed its fourth fiscal year September 30, 1897. There were at that time 214 patients in the colony, the majority of whom had been transferred from the various county houses throughout the State. New buildings are in course of construction which, when completed, will enable the colony to accommodate 140 additional patients, making the total number about 350. It is estimated by State charity officials that this number represents about one-third of the total number of epileptics now a public charge throughout the State. The medical superintendent, Dr. William P. Spratling, reports a great increase in the value of agricultural and industrial products of the colony over last year, so that the ratio of earnings of the patients to the cost of their maintenance is even larger than that of last year, which was a little over 50 per cent. A laboratory for the use of a pathologist and pathologic chemist is being constructed. Dr. Christian A. Herter of New York has been appointed pathologic chemist, and Dr. Ira Van Giesen of New York, consulting pathologist to the colony. Dr. Frederick Peterson of New York was re-elected president of the board of managers. The managers, at their annual meeting, decided to ask the coming legislature for \$200,000 for dormitory buildings in order that they may increase the residence capacity of the colony for patients.

ANNOUNCEMENT.

THE SEPARATION FOR DIAGNOSTIC PURPOSES OF THE TYPHOID BACILLI FROM THE STOOLS AND URINE IN CASES OF TYPHOID FEVER—A NEW METHOD.

BY THE NEW YORK BOARD OF HEALTH.

THE examination of specimens of blood from cases of suspected typhoid fever for the Widal reaction has been of great assistance in diagnosis. Occasionally, however, the agglutinating substances do not develop in the blood at any time, or only very late in the course of the disease, or an earlier infection cannot be excluded, owing to the lack of a reliable previous history. In these instances the Widal test fails to give the information desired.

Bacteriologists have long sought for a rapid and certain

method of obtaining and identifying in pure culture the typhoid bacillus from the stools and urine in cases of typhoid fever; but hitherto without satisfactory results. Dr. Hiss, Assistant Bacteriologist to the Health Department, has devised a method, by which it is believed it will now be possible to recover and identify the typhoid bacilli within less than forty-eight hours, from specimens of feces and urine containing them. The Health Department desires to thoroughly test this method and is prepared to undertake these examinations, if proper specimens are furnished.

While definite knowledge is lacking as to the number of typhoid bacilli usually present in the stools of typhoid patients, and as to the time of their appearance and disappearance, it is believed that they are generally present in the discharges, not only during the height of the disease, but also, though to a less extent, at its commencement and for a considerable time during convalescence. The appearance of the bacilli in the urine is usually later than in the feces. The experience thus far obtained seems to indicate, that the bacilli may be obtained from about fifty per cent. of all cases on the first examination, and from about ninety per cent. after repeated examinations. The Health Board hopes that these examinations will prove of value, not only for diagnostic purposes, but also in solving important sanitary questions relating to the presence in and time of disappearance of the bacilli from the stools during convalescence.

Physicians are requested to send specimens of intestinal discharges and urine from well-defined cases of typhoid fever, and also from all doubtful cases in which the Widal test has failed to give definite information.

It must be understood that, as yet, these investigations are largely experimental; but that when the typhoid bacilli are isolated in culture an absolute diagnosis of typhoid infection is obtained.

DIRECTIONS FOR PREPARING SPECIMENS OF FECES OR URINE FOR EXAMINATION.

Care should be taken to send, if possible, a specimen obtained from a natural movement, or one following a simple enema. No disinfectants, of course, should be employed. If the movement is formed, the portion from the part last passed, that is, the portion coming from highest up in the intestine, should be selected. In cases complicated by colitis, care should be observed to avoid, if possible, the selection of a specimen largely composed of mucus.

The specimen is collected by seizing a small portion of the discharges between the two slips of wood accompanying the outfit, and placing this in a bottle. The top of the bottle is replaced and the specimen returned to a culture-station or to the laboratory.

Specimens of urine should be received directly into the bottle accompanying the outfit, or should be collected in an absolutely clean vessel and immediately transferred to this bottle, which is then returned to a culture-station, or to the laboratory.

The necessary outfits, with directions and blanks, may be obtained at the various Health Department Depots, where diphtheria culture-tubes, antitoxin, and other prod-

ucts are supplied. The accompanying blank should be fully filled out in every case.

DIRECTIONS FOR PREPARING SPECIMENS OF BLOOD.

The skin covering the tip of the finger is thoroughly cleansed and then pricked with a clean needle deeply enough to cause several drops of blood to exude. Two large drops are then placed on the glass slide, one near either end, and allowed to dry without being spread out on the surface of the slide. After they have dried, the slide is placed in the holder and returned in the addressed envelope to a culture-station, or mailed to the laboratory. The blank giving the history of the case must be filled out in full and forwarded with each specimen. The data thus obtained are for record.

DIRECTIONS FOR OBTAINING SPECIMENS OF SERUM FROM BLISTERS.

The shield (designed to protect the blister from rupture), is stripped from its protecting gauze and applied to the skin somewhere on the anterior portion of the body. The piece of canthos plaster is then fixed within its center. After ten to twelve hours, the shield is removed and one of the ends of the small glass tube accompanying the outfit is introduced into the blister. The tube, both ends of which should be open, should be held so that the end inserted is higher than the other, to allow the serum to run into it. After the tube has been nearly filled, it is removed and the ends sealed by holding them a moment in a gas flame. Care must be observed not to heat the middle portion of the tube, and thus coagulate the serum. The tube so prepared is then placed in the wooden box and returned in the addressed envelope to a culture-station, or mailed to the laboratory.

A report on the result of the examination will be mailed to the attending physician on the following day.

CHARLES G. WILSON, *President.*

GEORGE B. FOWLER, M.D., *Commissioner of Health.*

EMMONS CLARK, *Secretary.*

CORRESPONDENCE.

THE CHARITIES COMMISSIONERS' FATAL PRECEDENT.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: THE MEDICAL NEWS of October 30, 1897, in an editorial on this subject, reflects so severely upon the manner of my recent appointment as visiting physician to Bellevue Hospital that I am forced to conclude that the article was based upon misinformation or misapprehension of the actual facts, and to ask you, as a matter of fairness and justice, to publish the other side of the story. As little autobiography as possible will be inflicted upon the patience of your readers.

For some years prior to October, 1895, the writer had been visiting physician to Gouverneur Hospital, but in the reorganization of the Charities Department at that time, he was one of those summarily removed without cause. The different nominating bodies, however, expressed regret at his removal, and one of them—the Bel-

levue Hospital Medical College faculty—reinstated him as their medical representative in Gouverneur Hospital. Another nominating body—the fourth or non-collegiate division of Bellevue Hospital—tendered him the unsolicited position of assistant visiting physician to Bellevue Hospital for the year 1896. At the end of 1896 this appointment was renewed for the year 1897 with many assurances of satisfaction with the work of the assistant visiting physician.

This commendation of his work and evidence of confidence on the part of his principals encouraged the assistant physician to ask for a nomination for the post of visiting physician when a vacancy occurred during the summer of 1897. He adhered strictly to the "time-consecrated method of procedure," and sought this professional honor, as he has sought and obtained other professional honors—entirely at the hands of his colleagues in medicine; in this instance at the hands of men whose absences from duty he had been covering for eighteen months. To his amazement he was informed by four of the six members of the division that no applications for the position could be considered, as the appointment had been promised to one man three years before the vacancy occurred, and that this man's name, and no other, would be sent to the Commissioners for appointment. He thereupon appealed to the Commissioners against the injustice of this discrimination, and the Commissioners, believing with him that the fourth division had no reason for official existence, except in the claim that they represented the whole of that portion of the medical profession not engaged in teaching in the three prominent colleges, decided that this restriction of the appointment practically to one man in the whole profession was an example of that "hasty and nepotistic action" which is so much deplored in the editorial referred to.

The Commissioners returned the nomination, but they *did* assign their reasons and they *did* ask that more than one name be submitted to them, unless the nominating body were prepared to show cause why the other candidates (and the writer of this communication had very good company to whom a nomination was also denied) were unworthy to be considered.

The fourth division responded to this by submitting a plan by which more than one appointment could be made, but the plan was so outrageous an invasion of the rights of others, that the writer preferred to sacrifice his chance of appointment under it than to be a party to such a scheme.

The Commissioners then grew tired of waiting to see a simple act of justice done, and took away from the fourth division the power to make the nominations at all, leaving to the colleges, however, all their previous privileges. Hereafter, any reputable member of the medical profession may apply for a vacant position in that one-quarter of the hospital service which is not already assigned to the three undergraduate medical schools, with the certainty that neither nepotism, nor lack of social connections, nor absence of financial stability, nor lack of college affiliations, can prevent his claim from at least being considered.

It may be possible to demonstrate that a man who has

spent the best years of his life laboring among the poor will not be the man to use a position in the hospitals of the poor "to advance personal interests and emoluments at the sacrifice of science and of the patients whom circumstances confide to his care," even though his appointment may have been made "in a manner entirely at variance with traditional methods."

Respectfully yours,

CHAS. E. NAMMACK, M.D.,

Visiting Physician to Bellevue and Gouverneur Hospitals.

42 EAST TWENTY-NINTH STREET,

NEW YORK, November 1, 1897.

[It appears that it would be in order for the majority of the fourth division to rise and explain.—ED.]

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

TYPHOID FEVER AND MUNICIPAL WATER-SUPPLIES—
THE PURE FOOD LAW—POLICE AND FIRE DEPARTMENTS AND FIRST AID TO THE INJURED—ADDITIONS TO THE GERMANTOWN HOSPITAL—DR. FORD'S SUCCESSOR.

PHILADELPHIA, October 30, 1897.

AN elaborate and interesting report of the death-rate from enteric fever in different cities in relation to the character of their water-supplies has been recently issued by the Director of Public Works of this city, and this comprehensive review of the question has shown, as has been done in the past by other inquiries on this topic, the great difference in mortality in favor of the cities using filtration over those cities in which the water-supply is unfiltered. The statistics of sixty-six different cities have been compared, according to their death-rate from typhoid during a period of five years, and the results of this classification have been anything but complimentary to Philadelphia, which in comparative immunity from typhoid ranks forty-fifth in the list. Of the more important cities in the group, according to their relative immunity, are the following: Dresden, 4; Berlin, 8; Amsterdam, 10; London, 13; Edinburgh, 14; Brooklyn, 16; New York, 17; New Orleans, 18; Hamburg, 21; Paris, 25; Boston, 30; San Francisco, 38; Baltimore, 41; St. Louis, 43; and Philadelphia, 45. Looking at the matter from another standpoint, it will be found that during the five years covered by these statistics the death-rate from typhoid fever per 100,000 people in Philadelphia was 243, while in the Hague, where sand-dune filtration is employed, the rate was but 24, and in Rotterdam, another city using thorough filtration, the mortality was only 26. This argument for the filtration of the water-supply of Philadelphia, which has been for many years earnestly desired by all who understand its value, should be effective in hastening the passage of an ordinance for the establishment of filtration-plants on a large scale; and it is to be hoped that the experimental filtration-station lately authorized by the city authorities will pave the way to its universal application in this city.

The "Pure Food Law" which was passed by the State Legislature early last summer and which was technically in force at that time, has in reality not been put into practi-

cal use until within the past two weeks, when the public were first acquainted with the act by the issuance of an official pamphlet by the State printer. *Apropos* of the discussion at present going on in Philadelphia concerning milk adulteration, it may be of interest to note the provisions of the new law regarding this important food-stuff. One section says: "That the sale or offering for sale of milk or cream for human consumption to which has been added boric-acid salt, boric acid, salicylic acid, salicylate of soda, or any injurious compound or substance for artificially coloring the same, shall be punished by a fine of not less than \$50 or more than \$100, or by imprisonment not exceeding sixty days, or both, at the discretion of the court." Similar fines are imposed by the act for the sale of cheese not the legitimate product of pure unadulterated milk, or any cheese to which have been added foreign fats or substances. Other laws of a similar character forbid the employment in bake-shops of persons affected with tuberculosis or any other infectious or contagious disease, and forbid the importation into this State of dairy cows, except upon a certificate of freedom from tuberculosis issued by an official inspector.

In compliance with an order recently issued by the Director of Public Safety in the matter of instructing the city police and fire departments in methods of rendering first aid to injured persons, a regular course of instruction on this subject is to be given to the policemen and firemen of the various districts. This course includes simple methods of controlling hemorrhage, the treatment of different varieties of wounds, and directions for rendering first aid in cases of drowning, strangulation, unconsciousness, insolation, heat-exhaustion, and poisoning. The previous lectures in past years are said to have borne good results, and it is thought that this systematic instruction will be effectual in many instances in relieving pain and in saving life by prompt and proper action before the arrival of regular medical aid.

The new annex to St. Timothy's Hospital is almost completed, and will be open early during November. The new building is two and one-half stories in height, and is connected with the main hospital building by a covered passageway. The annex will be chiefly used as a receiving-ward, and in addition contains a large women's ward on one of the upper floors.

Important additions necessitated by the large increase in number of its patients are being made to the German-town Hospital. The improvement consists in the erection of two large wings adjoining the hospital proper, one of which is to serve as a children's ward, and the other to be used for an operating-room, and for dispensary purposes. It is intended that the new buildings shall be open for patients before the close of the year.

At a special meeting of the Board of Health A. A. Hirst, who has been a member of the board for twenty-two years, was elected President, *pro. tem.*, in place of Dr. William H. Ford, deceased, and J. Lewis Good was elected Secretary, the place held for many years by Mr. Hirst.

At the request of Director Riter, the New York city authorities will be asked to take precautions against the

escape of certain lepers now living in a tent near Bellevue Hospital.

The deaths occurring in Philadelphia during the week ending October 30th, reached a total of 349, a decrease of 57 from the preceding week, and a decrease of 13 over the corresponding week of last year. Of the whole number of deaths, 97 occurred in children under five years of age. The new cases of contagious diseases numbered 234, or 22 more than the week before. There were 5 deaths from enteric fever, with 26 new cases; 3 deaths from scarlet fever, with 54 cases; and 24 deaths from diphtheria, with 154 new cases.

THE INTERNATIONAL LEPRO CONFERENCE.

[From our Special Correspondent.]

BERLIN, October 30, 1897.

THE International Leprosy Conference held its last session the morning of the 16th of October, and the members left the city thoroughly persuaded that Berlin is the place in which to hold a medical meeting. The reception accorded them on all sides has been most cordial. The Kaiser himself and the Imperial Government clearly manifested interest in the conference. The Chancellor of the Empire gave a reception to the members on Tuesday, and the Emperor and Empress received them in the "New Palace" at Potsdam on Friday. All the foreign delegates were given a personal introduction to the Emperor, who evidenced considerable information on the subject of leprosy, and showed that he is able to appreciate the work of the Conference. The new Public Health Building was placed at the disposal of the Conference, and proved eminently suited to the purpose. The feeling expressed on all sides was one of hearty appreciation of the efforts of the Berlin Dermatological Society, and especially of Professor Lassar, the chairman of the Committee on Organization.

The proceedings of the first day consisted of addresses by distinguished leprologists, introductory to the proper work of the Congress, which largely consisted of the discussion of mooted points.

Professor Besnier of Paris insisted upon the possibility of an early diagnosis of leprosy by means of a bacteriologic examination. He emphasized the importance of such a diagnosis in the protection of others from chances of infection.

Professor Hansen's address was brief, and was mainly concerned with the lack of lasting results from all forms of treatment. He denied that the disease is self-limited, though this has been strongly asserted. There are periods of latency when, though the patient is perhaps atrociously mutilated, the progress of the disease seems to have been arrested; but a cure, in the proper sense of the term, does not take place.

Professor Hutchinson, on account of indisposition, was unable to be present, and so his paper was read for him. It consisted of a reassertion of his favorite theory, that leprosy is due to the consumption of fish, especially salt fish, in certain stages of decomposition.

Professor Neisser spoke of the recent work in his clinic

at Breslau, by which it had been demonstrated that thousands of bacilli are given off from the bodies of lepers; that they are discharged in the breath, and exist in large numbers in all the secretions, and in the scrapings of the skin.

Professor Neumann of Vienna considered that the seeming spread of leprosy in certain countries during recent years is really due to the fact that atypical or abortive cases are better and more easily recognized, owing to a more accurate knowledge of the disease, and so are reported more faithfully.

Professor Petersen of St. Petersburg mentioned the spread of leprosy among the poorer classes of Russia, and considered it practically demonstrated that the spread of the disease is due to contagion, although it often requires a long time after exposure before the symptoms are manifested.

The third day was devoted to a discussion of the following questions: (1) "How Far Are We Justified in Considering the *Lepra Bacillus* as the Cause of the Disease?" and (2) "What Are the Ways of Inoculation?"

The reading of papers was not allowed, any one having had the opportunity to send communications before the meeting. These were placed in the hands of the members in the form of a volume of preliminary transactions. This excellent rule (eminently commendable to other medical societies) secured two noteworthy results: (1) The presence of the members at the sessions in order to follow the discussions of questions in which they were interested; (2) lively discussions replaced the dreary reading of long-winded papers, which often make medical meetings such a bore.

Practically all the authorities were agreed as to the specificity of the bacillus of Hansen. Professor Neisser has found almost invariably, in cases of anesthetic leprosy which had been examined thoroughly, that the bacilli are to be found in the nerves. As to whether the neuritis thus caused is centripetal or centrifugal, ascending or descending, is not so easy to decide. Great care is required in distinguishing anesthetic leprosy from the macular, erythematous patches of tuberculous leprosy before the surface elevation occurs. In these latter the demonstration of the bacilli is comparatively easy. As to whether the demonstration of the bacillus is necessary for assured diagnosis, authorities seem to be divided. Kaposi considered the finding of the bacillus an assistance rather than a criterion. He showed colored plates of three cases of papular leprosy in which, though he had been unable, even with the assistance of so skilled a pathologic anatomist as Professor Paltauf of Vienna, to find bacilli in excised portions of tissue, he considered the clinical characteristics sufficiently typical to justify the diagnosis. Hansen, Ehlers, and Arning, after a careful examination of the pictures, said they did not consider the cases to have been leprosy. The French leprologists seemed to be of the same opinion, and Von Dühring of Constantinople considered them very doubtful. Unna said that he thought the pictures were representations of true leprosy, and that it is in the variety of the disease illustrated that the demonstration of the bacillus is most difficult. With

his new technic—*careful* discoloration in nitric acid and counterstaining with one-per-cent. orcein solution, most of the difficulties vanished. Doutrelepon insisted that in such cases a large number of sections must be examined. Generally the conclusion seemed to be that in beginning cases and in atypical abortive forms of the disease the finding of the bacilli is almost absolutely necessary to justify a diagnosis.

As to the conveyance of the infection, some startling observations were detailed in regard to the number of bacilli given off from a single leper. These communications formed the most striking addition to the present knowledge of leprosy. Sticker of Giessen had found an abundance of lepra bacilli in the nasal secretion of 140 out of 153 lepers examined. They occurred even at times when there did not seem to be any leprosy lesions in the nose. Weber of Halle had found an enormous number of bacilli in scales scraped from the skin of lepers, many of which were about ready to drop off. He had found them in the saliva, in the sweat, in the tears, and in the hair.

From Neisser's clinic, Schæffer reported that he had calculated that a leper gave off 150,000 bacilli per hour. A cover-glass held before the patient while he read aloud would be covered with bacilli, and they extended to a distance of $1\frac{1}{2}$ meters from the patient. The most careful antiseptics of the mucous membranes, the use of bichlorid of mercury and nitrate of silver, did not cause them to completely disappear, though it greatly lessened their number. Professor Petersen considered that an examination of the nasal secretion for bacilli often made a positive diagnosis possible at an early stage of the disease. Jeanselme considered the nasal secretion diagnostic in most cases.

The third day was devoted to the following subjects: (1) "Pathologic Anatomy and Histology of Leprosy." (2) "The Rôle of Heredity in the Etiology of the Disease." (3) "Emigration and Immigration in their Relation to the Spread of the Disease."

Before the regular discussion began Professor Virchow, who acted as President of the conference, talked on "Pre-Columbian Leprosy in America." He considers that the mutilations seen in certain ornamental figures, found on what is evidently pre-Columbian pottery, point to the existence of leprosy on the American continent before the Spanish discoveries. There is no other disease which could produce the mutilations of the feet observed in the figures. The nasal mutilations point to lupus rather than to leprosy, but Professor Virchow called attention to certain faces in Professor Lassar's collection of wax models of Norwegian lepers which very closely resemble those found on the pottery.

As to the gross pathologic anatomy, Professor Glück showed some skulls which make it clear that changes in bones may be induced by leprosy, though this is usually denied. The lesions are commonly those of a rarefying osteitis, though some signs of inflammatory neoplastic changes may also be noted.

The anatomy of anesthetic leprosy, and the existence of nodular nerve enlargements growing fewer centripetally

seem to point, in Professor Babes' (Bucharest), opinion to a neuritis ascendens, and such he considered leprous neuritis to be. Of the bacilli themselves, Professor Babes showed a number of specimens which exhibited the rosette form, the radii with clubbed ends, which is considered so characteristic of actinomycosis. He also exhibited some specimens of tubercle bacilli with the same peculiarities, and considered such appearances characteristic of all the infectious granulomata with whose causative agent we are familiar.

In discussing the place of the bacilli with regard to the cells, Babes precipitated the old controversy as to whether the bacilli are only extracellular or may also be found within the cells. Almost alone, Unna insisted that the bacilli are never intracellular. As to the specimens exhibited, in which it was claimed that the bacilli could be seen within the cells, he considered it an optical delusion, and that the cells really occupy the extracellular lymph space above the cell. The discussion became very warm, but no admissions were made on either side. Neisser insisted that it is sheer obstinacy to maintain the extracellular opinion in view of the specimens to be seen around the room. Unna said that when others had examined lepra specimens as long as he had they too would find his position easier to understand, and that in this, as in other things when he had stood almost alone, further investigation would show, he felt sure, that his opinion was correct. During the recess the specimens were examined very carefully by a number of experts, Professor Virchow being among the number, and all seemed to agree that the bacillus might be intra- as well as extracellular.

As to the Rôle of Heredity, there was practical unanimity of opinion that it counted for nothing in the spread of the disease. There was a complete reversal of the formal decision of the Royal College of Physicians of London, which just thirty years ago absolutely pronounced against the contagiousness of the disease. There were a few non-contagionists from the East. Zambaca Pacha's (Constantinople) paper, published in the preliminary transactions, insisted that heredity is the only etiologic factor in the causation of the disease, and Sachs of Beyrout supported this opinion at the Congress, but every one else opposed it. Alvarez, from Honolulu, had never seen a leper under 3½ years of age, and Dyer's (New Orleans) statistics showed that leprosy in Louisiana, instead of remaining among the French and the descendants of the Acadians, as it would have done if hereditary, had spread to immigrants, and now there are more German than French lepers in the State. As to emigration and immigration, all were agreed that these are the usual media for the spread of the disease. Hansen told of his trip to our American Northwest where lepers from Norway had gone. He had not found any leprosy which could be considered hereditary, though he had seen some cases which seemed to be due to contagion.

The fourth day the conference discussed "The Place of Leprosy among the Infectious Diseases and Its Relation to Syringomyelia, Morvan's Disease, and Ainhum," and "The Therapy, Especially the Serum-therapy, of Leprosy."

Professor Zambaca Pacha of Constantinople, in a long

communication printed in the preliminary transactions of the conference, maintained that not only are syringomyelia and Morvan's disease abortive types of leprosy, but that scleroderma, sclerodactyle, Raynaud's disease, ainhum, morphia, and progressive muscular atrophy are also often of leprous origin. Very few, even those from the East where the frequency of lepra makes every trophic cutaneous change a subject of suspicion, went as far as this. Von Düring of Constantinople found under treatment at the Charité, in the out-patient department of Professor Jolly's service, two cases which had been diagnosed as syringomyelia, and he exhibited the patients before the conference. Many of the leprologists were inclined to pronounce the disease leprosy. In general, the trend of thought seemed to be that such cases should be regarded with suspicion, and the bacillus carefully searched for. The finding of the bacillus makes an immediate positive diagnosis possible, but only further observation of the course of the disease could assure a negative diagnosis.

Jeanselme's position as regards Morvan's disease was generally accepted. He had been unable to find bacilli in the original cases of Morvan's disease in Brittany after most careful search, and believed there was question of its being a nervous, trophic affection, not a contagious or hereditary disease. In general, it was considered possible, however, that sporadic cases of leprosy could be found in the midst of otherwise healthy communities where leprosy had never occurred. The cause is to be found in some contact with lepers on the part of the patient. As the contagion only reveals itself after years, physicians must be ever on their guard in suspicious cases.

As to serum-therapy, very little that was encouraging came from Europe. Carrasquilla's serum had been used in Paris, Dorpath, Berlin, and in Denmark, always without success, and in some cases with the production of dangerous symptoms. Dr. Carrasquilla attributes the non-success of his serum in Europe to some chemic change which occurs in it during the long voyage. Serums prepared according to his method here in Europe, in at least one case, seem to have given no better results. The novelty of Professor Dyer's (New Orleans) method of treatment and the promising results of the preliminary report attracted considerable attention. He uses Calmette's antivenin, the antidote for snake-bite, obtained by inoculation of the virus into animals.

Hansen, Doutrelepont, and Peterson insisted on the rôle of suggestion in the improvement of lepers at the beginning of a new treatment, and warned against the acceptance of therapeutic results which had not stood the test, not of months or even a year, but at least of four or five years.

As regards other therapeutic measures, Besnier considers oil of chaulmoogra almost a specific when combined with electrolysis of the tuberculous lepra patches; it has effected some striking cures in his hands. Neisser has seen iodine do good for a time, but recurrences are noted. In Unna's experience, iodine preparations have also accomplished something. Both believe in cauterization of the local lesions, Neisser with nitric acid.

In Norway injections of the soluble salts of mercury is

the favorite treatment, but the symptoms recur with this as with other treatments. The general opinion seemed to be that some combination of iodine and mercury used intermittently, as for syphilis, constitutes the best treatment known.

Professor Hallopeau read a paper on leprosy in Paris. There have always been a number of lepers under treatment in Paris, and of late years this number has largely increased. There has never been a case of contagion observed, though isolation is practically *nil*, and immense numbers of lepra bacilli have been demonstrated by Janssens to be given off in the secretions of the lepers. He considers that in the climate of Paris the vital resistance is such that contagion is practically out of the question, and that lepers may be treated freely in hospitals in temperate climates without danger of contagion.

The last two days of the conference were taken up with the discussion of the following subjects:

(1) "The Isolation of Lepers and the Best Regulations for the Purpose." (2) "The Best Manner of Establishing Lazarettoes." (3) "The Founding of Leper (Philanthropic) Societies." (4) "The Establishment of a Permanent International Committee." (Resolution of Dr. Ashmead of New York.)

All were agreed that isolation is the ideal means to eradicate the disease. Hansen's resolution, "that isolation is the best means of preventing the spread of the disease, and that the system in vogue in Norway is recommended to all nations," was unanimously adopted.

By this system those who are sufficiently well-to-do to be able to segregate themselves in their own houses according to law, are allowed to do so. All others must go to a lazaretto. Dr. Ashmead's resolution was considered inopportune. Professor Neisser's resolution for the appointment of a permanent committee with power to form a lepra society was adopted.

SOCIETY PROCEEDINGS.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Twenty-fifth Annual Meeting, Held at Philadelphia, October 26, 27, 28, and 29, 1897.

FIRST DAY—OCTOBER 26TH.

MORNING SESSION.

THE meeting was called to order by the President, DR. HENRY B. HORLBECK of Charleston, S. C., after which a business session was held. Sixty new members were elected, and the reports of the various committees were read. A new special committee on "Demography in its Sanitary Relations" was appointed, and a resolution adopted to the effect that the supervision of city water supplies should be vested in properly constituted boards composed of sanitarians.

DR. FREDERICK MONTIZAMBERT, General Superintendent of Quarantine of the Dominion of Canada, read the report of the "Committee on Steamship and Steamboat Sanitation," in which special attention was called to the necessity of freely exposing unlaundried bedding—

mattresses, pillows, and blankets—to the sun and air after each trip. Reference was also made to the danger incurred by the traveling public of contracting pulmonary tuberculosis from fellow-passengers, who, in their expectorations, scatter broadcast infectious material, and it was suggested that all steamboat saloons be supplied with proper receptacles containing a disinfection solution, and, furthermore, that expectorating upon the decks of vessels carrying passengers be strictly prohibited.

A paper, entitled

A CONTRIBUTION TO THE STUDY OF YELLOW FEVER FROM A MEDICO-GEOGRAPHICAL POINT OF VIEW

was read by DR. EDUARDO LICEAGA, President of the Supreme Board of Health of Mexico, and DR. JOSÉ RAMÍREZ, Secretary of the same board. The intention of the authors evidently was to combat the idea that yellow fever is epidemic along the whole Gulf Coast, and the statement was made that at the port of Vera Cruz only three cases occurred during last summer. It was also shown that special care is taken by the Mexican Board of Health to prevent the importation of the disease from the countries of Central America, where it is endemic. The paper asserted that no source of yellow fever exists on the Pacific Coast of the Mexican Republic, and that whenever a suspicious case is reported the Board sends an expert to make a thorough investigation. In this way many supposed cases of yellow fever had been proved to be a variety of fever which assumed a typhus form, and, moreover, that no new cases of this disease have appeared since the first of October. Reference was also made to the difficulty which exists in establishing a positive diagnosis between genuine yellow fever and certain forms of paludic infections which in hot climates often assume the serious characteristics of the former disorder. The paper closed with the statement that Vera Cruz, which has not suffered from yellow fever, is now quarantining against the United States, and has at the present time in the lazaretto of Sacrificio a steamer which recently arrived there from Mobile, Ala., with three cases of the disease on board.

DR. WILLIAM BAILEY of Louisville, Ky., remarked that it is indeed a reversal of the usual order of things to have Mexico guarding against the introduction of yellow fever from the United States. He also spoke of the doubt which exists in New Orleans as to the correctness of the diagnosis in many cases on account of the low mortality (eleven per cent.) which has marked the course of the present epidemic. He said that the first case which occurred in Louisville was imported from Ocean Springs, Miss. The patient referred to displayed unmistakable symptoms of yellow fever, and the disease was diagnosed as such by the physicians in attendance. He was removed from his hotel to a private sanatorium where he died, and was quietly buried without alarming the people. Notice was at once sent to the health authorities of New Orleans, and they were advised to investigate the disease at Ocean Springs. Subsequently, Dr. Oliver and his staff went from New Orleans to the former place and decided that the disease was not yellow fever in spite of the very positive diagnosis which had been made in Louisville.

Later new cases developed at Ocean Springs, and the true nature of the disease was recognized. Meanwhile precious time had been lost, and the disease had been scattered in all directions.

DR. SAMUEL H. DURGIN of Boston said that the lesson to be learned from the present epidemic is the importance of studying all suspicious cases coming from the Gulf Coast, and added that the United States Government could save money in no better way than by assisting the medical profession to discover a means by which a correct diagnosis of yellow fever may be made.

DR. P. H. BAILBACHE of Stapleton, Staten Island, N. Y., remarked that if Sanarelli's investigations are correct, a basis has been formed upon which a correct diagnosis may be made.

DR. BAILEY expressed the opinion that the bacillus for whose discovery Saranelli is receiving the credit is in reality the identical one which was isolated by Dr. Sternberg, and that too much could not be said in praise of the latter's work in this line.

As the topic is one of so much general interest it was decided to devote more time to its discussion than the morning session allowed, and it was made the special order of business for Friday afternoon when it was expected that Dr. Sternberg would be present. After the adjournment of the morning session many of the members visited an exhibition of disinfecting-agents which was held in Horticultural Hall. The principal feature of this exhibition was the new disinfectant formaldehyde, which is claimed to be more penetrating and more powerful than corrosive sublimate, or any other antiseptic. Six generators were shown which will produce the formaldehyde gas either from a solution or from the drug in solid form. A number of disinfectants and disinfecting-machines were on exhibition, and the Boards of Health of all the large cities of the country were represented by apparatus showing the methods of disinfection employed by each.

The evening session was devoted to the President's annual address.

SECOND DAY—OCTOBER 27TH.

MORNING SESSION.

A resolution was adopted authorizing the appointment of a committee of five to carry out the recommendations made by the President in his address, with reference to the investigation of the causes of yellow fever.

The report of the Committee on Pollution of Water-supplies was then read by Assistant Surgeon-General CHARLES SMART, U. S. A., of Washington, D. C., who said that the work of the committee had chiefly been in the direction of perfecting methods of bacteriologic research. He referred to the difficulty of securing a sufficient number of men to do the work, for the reason that the students of bacteriology in America are so busy keeping up with the advances of this branch of science that they have no time to devote to the work of the committee. Furthermore, he asked that the committee be discharged from its duties and a new committee appointed which shall consist of two men who are familiar with municipal water-sup-

plies, two who have a knowledge of the chemic aspect of the subject, and two who are well versed in its bacteriology.

The report of the Committee on Disinfectants was then read by DR. FRANKLIN C. ROBINSON of Brunswick, Me. The report spoke most highly of formaldehyde as a disinfectant, and referred to the fact that only a year ago it was practically unknown in this country, while now it is in general use. He expressed the opinion that there is still much to be learned about this agent, and predicted that as great and even greater progress would be noted in the coming year as had been seen in the one just past.

DR. FRANK W. WRIGHT of New Haven, Conn., then read a paper, entitled

DIAGNOSIS OF SMALLPOX.

The author emphasized the great importance of making an early diagnosis, which next to vaccination is the most essential factor in preventing the spread of the disease. This is not always easy, because in these days of general vaccination, a typical case of smallpox is rarely seen, the vast majority of these cases being modified by former vaccina are really cases of varioloid; in other words, modified smallpox. This modification, unfortunately, is not uniform in all cases and the responsibility of making an official diagnosis is very great, and is felt by all health officers. As many practitioners of medicine have never seen a case of smallpox, and few have seen a sufficient number to be familiar with the appearance of the disease, whenever a physician sees a patient with a suspicious eruption he immediately informs the health authorities, upon whom he shifts the responsibility of making the diagnosis. The health officer is thus placed in a very trying position; to err on either side is fatal to future success. If he fails to recognize a case of smallpox and the disease is spread, he is subjected to most severe criticism, and most likely loses his position. While, on the other hand, if he should be unfortunate enough to pronounce as smallpox some disease which resembles the modified form of that disorder, he is just as severely criticized, and may have to defend himself in a suit for damages.

AFTERNOON SESSION.

DR. A. WALTER SUITER of Herkimer, N. Y., read a paper, entitled

THE BARBER-SHOP AS A MENACE TO THE PUBLIC HEALTH.

The author said that the time has now arrived when the attention of the Association and, through it, that of the public health authorities in general should be called to that part of hygiene which applies to the barber-shop. That this common mode of infection should have for so long a time escaped attention in these days of asepsis and antiseptics, may be noted as one of the most contradictory circumstances of a time in which the sanitary relations of most, if not all, public occupations are carefully investigated and restricted. The first attempt of modern times to sanitarily regulate the barber-shop was made only recently in Paris, where an order was issued requiring that specific rules of asepsis and disinfection shall be observed. Only combs of metal, which can be sterilized, are per-

mitted, and all other instruments, as far as possible, must be of metal. These must be subjected to a temperature of $100^{\circ}\text{C}.$ — $212^{\circ}\text{F}.$ —before and after use. Shaving brushes must be washed before and after use in boiling water, and the hands of the barbers thoroughly cleansed before passing from one patron to another. Sterilized towels are also to be used, pulverizers are to replace the powder puffs, and hair which is removed is to be immediately disinfected and taken out of the shop.

DR. LEONARD PEARSON of the Veterinary Department of the University of Pennsylvania, then read a paper on

METHODS OF MEAT INSPECTION.

In many of the countries of Europe during the last century laws were passed to provide for the inspection of meat, but it is only within recent years, since the bacterial origin of many diseases has been demonstrated, and the relation existing between many of the diseases of man and animals has been established, that the importance of rational meat inspection has been recognized. At the present time all the countries of Continental Europe and the British Isles have a system of meat inspection, which, although incomplete in some places and in some details, is sufficient to protect the consumer from the numerous maladies which may be contracted by eating the flesh of diseased animals. The system which has proven most satisfactory in Europe includes the establishment of a municipal abattoir under the direction of a veterinarian trained in meat inspection, and provides that all animals shall be slaughtered in this establishment. These animals are examined while living and after they are killed. Both inspections are necessary because certain conditions, such as fever, fatigue, exhaustion, starvation, and excitement, which would have an effect upon the meat can only be detected during life. After the animal is slaughtered its organs are examined for evidences of diseases which are directly transmissible to the consumer, parasites which may be injurious, and other conditions which render the meat indigestible or toxic. Germany has more than six hundred of these municipal slaughter-houses, the facilities of which the butchers enjoy by paying a reasonable rental.

The author said that in some American cities, meat inspection is carried out upon good principles; in many, however, of which Philadelphia is one, the inspection of meat is based upon entirely different lines. The meat trade is governed by laws which forbids the sale of any meat which is diseased or unwholesome, it being assumed that the butcher is capable of determining this point. Detectives and police officers are appointed to visit the slaughter-houses, markets, and butcher-shops, to look for diseased meat. If any is found, a veterinary officer is called in to condemn it. This system is complicated and objectionable; if the supervision were properly carried out it would require as many inspectors as there are slaughter-houses. A large municipal establishment, with the cooperation of the butchers, can be conducted on a paying basis; for the rentals received from the butchers cover the running expenses. It is also an advantage to the butcher for it costs him less than it would have his own slaughter-house.

DR. EDWARD JACKSON of Philadelphia then read a paper, entitled

EYE-STRAIN FROM POOR WINDOW-GLASS.

The author referred to the eye-strain caused by astigmatism and the resulting headache and nervous symptoms, and pointing out that the same effect may be produced in normal eyes by defective window-glass. Glass in which there are irregularities of thickness acts like a lens, and its bad influence is intensified by the eye having to look through different parts thus causing different degrees of strain and making it impossible for the eye to properly adjust itself. Even comparatively slight defeats in glass will cause eye-strain similar to that of astigmatism. The use of plate-glass which is entirely free from these defects should be required. This is one of the few luxuries whose effects are entirely beneficial instead of being harmful. Its use in all public conveyances is especially to be desired, as defective window-glass is one of the principal causes of "car-sickness" from which so many people suffer.

REVIEWS.

THE SEQUELS OF DISEASE, BEING THE LUMLEIAN LECTURES (1896), TOGETHER WITH OBSERVATIONS ON PROGNOSIS IN DISEASE. By SIR DYCE DUCKWORTH, M.D., LL.D., Fellow and Treasurer of the Royal College of Physicians; Physician and Lecturer on Medicine, St. Bartholomew's Hospital. London, New York, and Bombay: Longmans, Green & Co., 1896.

THE eminent clinician, the author of these essays, rich in observation and study, begins with a consideration of the sequels of the "Specific Contagious Diseases," and points out that, paradoxical as it may appear, persons rarely die of the disease from which they suffer. Considering these diseases then, he tells in the choicest of words the well-known after-results of the infectious and contagious diseases. He mentions three forms of sequelæ which may follow influenza, the thoracic, the gastrointestinal, and the nervous. Almost an entire lecture is occupied by a consideration of the effects of syphilis. The volume closes with a most readable chapter on "Prognosis in Disease," in which the author dwells upon the desirability and necessity of cultivating the art of prophecy in the treatment of diseases.

The work is charmingly written, abounds in evidence of scholarship and learning, and is a valuable addition, in every sense, to medical literature. A copious index is appended to the book, which is very handsomely printed on heavy paper.

A COURSE OF PRACTICAL HISTOLOGY. By EDWARD ALBERT SCHAFER, LL.D., F.R.S., Jodrell Professor of Physiology in University College, London. Second edition. Philadelphia and New York: Lea Brothers & Co., 1897.

THIS book fulfills its aim. The author tells us in his preface that it is his intention neither to give an exhaustive

account of all modern histologic methods, nor to describe in detail the appearance of histologic specimens. He aims rather to furnish the student the means of conducting histologic research without the constant presence of a teacher. In carrying out this line of thought, he has recorded in simple, admirable English, the recognized methods of fixing, staining, cutting, and mounting. Although some of the methods employed in special research are not found here, the work contains all that a student or a general practitioner can desire in the way of histologic technic. The histologic elements of the human body are taken up in order, beginning with the blood, considering next the visceral and peripheral organs and their ultimate divisions and ending with the organs of special sense. A clear and concise introduction deals with instruments and general histologic methods.

We know of few books which compare with this for thorough usefulness. The former edition has long been a laboratory favorite, and we hope that the present one will soon be exhausted. The book is handsomely printed and profusely illustrated.

INJURIES AND DISEASES OF THE EAR, BEING REPRINTS OF PAPERS ON OTOTOLOGY. By MACLEOD YEARSLEY, F.R.C.S., Fellow of the British Laryngological, Rhinological, and Otological Associations; Surgeon in Charge of the Department for Diseases of the Throat, Nose, and Ear at the Farringdon Dispensary. London: The Rebman Publishing Co., Limited, 1897.

THIS little collection of reprints contains a number of interesting papers on special subjects of otology, ranging from "An Artificial Membrana Tympani" and "The Use of the Pneumatic Aural Speculum," to the "Care of the Ear in Children" and "Aural Reflexes." The first-mentioned paper, treating of the improvement of hearing by the support of an "artificial drum" in cases of old, nonpurulent catarrh with a lax membrane, deals attractively with the history of this subject.

The chapter on "Foreign Bodies in the Ear and Their Treatment," and that advising "What Not to Do in Diseases of the Ear," are of value from a practical standpoint, and while they contain nothing original, sum up in a concise and lucid way the precepts best worth following. The volume, which appears in attractive guise, is marred by inferior presswork, blurred print, and inadequate spacing being particularly noticeable.

THE MIDDLESEX HOSPITAL, W. Reports of the Medical, Surgical, and Pathological Registrars for the Year 1895. London: H. K. Lewis, 1896.

THE Middlesex Hospital reports are well-known for their scientific value. The present volume is no exception. It embraces, aside from necessary statistics, special articles on exceptional and interesting cases, and a full reference to fatal issues of disease. The report of the pathologist is scientific, interesting, and complete. It is a pity that this example cannot be imitated in this country, so that instead of learning annually how many cakes of soap or flat-irons Mrs. X. has presented, we might learn some-

thing of what our hospitals are actually accomplishing in the treatment and cure of disease.

SURGICAL HINTS FOR THE SURGEON AND GENERAL PRACTITIONER. By HOWARD LILIENTHAL, M.D., Assistant Attending Surgeon to Mt. Sinai Hospital, New York City. New York: International Journal of Surgery Co., 1897.

THE author of this book has compressed into a few pages facts and suggestions which only the experience of years can teach. It is a work which can be perused with profit by those who perform minor, as well as major surgical operations. It is concise, capably written, and full of valuable suggestions. Dr. Lilienthal has done the profession a service by giving it the results of his experience in such attractive style.

THERAPEUTIC HINTS.

Iceland Moss as an Anti-emetic.—For this purpose the dose is *m. x* to *3 i* of the tincture, three times daily before meals. It is chiefly recommended for the persistent vomiting which occurs in uremia, polyneuritis, chlorosis, the dyspepsias, cancer of the stomach, and during the gastric crisis of tabes. It is believed that it will prove useful in the vomiting of pregnancy.

For Chlorosis the following combination is highly recommended:

℞ Tinct. ferri. perchlor.		3 ii
Spts. ætheris sulph.		3 ii
Tinct. nucis vom.		3 ii
Tinct. quassiae		3 vi.

M. Sig. A teaspoonful in half a glass of water, twice daily, before meals.

For Subinvolution of the Uterus.—

℞ Strychninæ sulphatis		gr. ½
Quininæ sulphatis		gr. xx
Ext. ergotæ		gr. x.

M. et. ft. pil. No. x. Sig. One pill three times daily.

For Uremia.—

℞ Ext. pilocarpi alc.	} aa	gr. xv.
Ext. scillæ		
Res. jalapæ		
Res. scammonii		

M. et. ft. pil. No. xx. Sig. Four or five pills daily during as many days.

For Simple Tonsillitis.—

℞ Creolin		gr. xv
Aquæ destillatæ		O i
Aquæ menth. pip.		3 iii.

M. Sig. Use as a gargle.

For Tinea scycosis.—

℞ Naphthol		3 i
Saponis viridis	} aa	3 vi.
Cretæ præp.		
Sulphuris loti		
Lanolini		

M. Sig. Apply locally at bed-time.

No. 20.

ORIGINAL ARTICLES.

RECENT RESEARCHES RELATING TO THE ETIOLOGY AND SPECIFIC TREATMENT OF YELLOW FEVER.¹

By GEORGE M. STERNBERG, M.D.,
SURGEON-GENERAL, UNITED STATES ARMY.

In a paper read at the Twelfth International Medical Congress at Moscow during August of the present year, and published in the September number of *The American Journal of the Medical Sciences*, I have given my reasons for believing that the bacillus icteroides of Sanarelli, and a bacillus obtained by me from yellow-fever cadavers at Havana, provisionally named "bacillus x ," are identical. If the identity is not established, the claim of Sanarelli that his bacillus icteroides is the specific infectious agent in yellow fever cannot, in my opinion, be admitted. For this specific infectious agent must be the same in yellow fever occurring at Havana as for that occurring at Rio de Janeiro. My extended and painstaking bacteriologic researches in a series of forty fatal cases occurring in the city of Havana during 1888 and 1889, and three occurring in Decatur, Ala., during the epidemic of 1888, show that no micro-organism, other than my bacillus x , develops in the culture media usually employed by bacteriologists, except the colon bacillus and a few other species exceptionally found and excluded from consideration for reasons stated in my report on "The Etiology and Prevention of Yellow Fever," published during 1890. In summing up the results of my investigations I refer to the bacillus x as follows:

"Among the facultative anaerobics is one—bacillus x —which has been isolated by the culture method in a considerable number of cases of yellow fever, and may have been present in all. This bacillus has not been encountered in the comparative experiments made. It is very pathogenic for rabbits when injected into the abdominal cavity. It is possible that this bacillus is concerned in the etiology of yellow fever, but no satisfactory evidence that such is the case has been obtained by experiments upon the lower animals, and it has not been found in such numbers as to warrant the inference that it is the specific infectious agent. All other micro-organisms obtained in pure cultures from yellow-fever cadavers appear to be excluded, either by having been

identified with known species, or by having been found in comparative researches made outside of the area of yellow-fever prevalence, or by the fact that they have been found only in small numbers and in a limited number of cases."

The bacillus of Sanarelli readily grows in the culture-media which I employed in my researches, and if present in the blood or tissues of the yellow-fever cadavers examined by me at Havana, I could not have failed to find it. In stating conclusions in my official report I say: "The specific infectious agent in yellow fever has not been demonstrated." It will be observed that I say "has not been demonstrated." I do not say that it has not been discovered, for I suspected at that time that my bacillus x was possibly the specific yellow-fever germ.

The name of Eberth is commonly associated with the typhoid bacillus, but Eberth was only successful in finding this bacillus in the lymphatic glands or in the spleen in eighteen out of forty cases in which he searched for it, and it was not until four years later (1884) that Gaffky obtained it from the spleen of typhoid cadavers in twenty-six out of twenty-eight cases examined by him. The demonstration that this is the specific infectious agent of typhoid fever was evidently not made by Eberth, but depends upon the researches of Gaffky, Fränkel, Simmonds, and other more recent investigators.

Klebs is supposed to have first observed or discovered the diphtheria bacillus, but Löffler demonstrated it to be the specific infectious agent in this disease, and this bacillus is spoken of as the Klebs-Löffler bacillus.

Continental bacteriologists have not been so particular in recognizing the discoverer of the micrococcus of pneumonia, which was isolated and described by me in 1880, and was observed in pneumonic sputa by Talamon in 1883, by Salvioli during 1884, and by the author in 1885, before the publication of Fränkel's first paper detailing the results of his investigations. As a matter of fact, the demonstration that this micrococcus is concerned in the etiology of pneumonia depends upon the investigations of Talamon, Salvioli, Sternberg, Fränkel, Weichselbaum, Gameleia, and others, and the common practice of referring to it as Fränkel's pneumococcus is an injustice to the discoverer, and to others who have had a share in demonstrating its rôle in the etiology of croupous pneumonia.

¹ Read at the Annual Meeting of the American Public Health Association, Held at Philadelphia, October 28, 1897.

Neisser discovered the gonococcus, and named it, but he did not present any satisfactory experimental evidence that it is the specific germ of gonorrhea. This demonstration was made by Bumm and others. However, Neisser's name, alone, is usually mentioned in connection with this germ.

If my bacillus *x* and the bacillus *icteroides* of Sanarelli are proved to be identical by the experiments of Sanarelli and this bacillus is demonstrated to be the cause of yellow fever, Sanarelli will deserve full credit for the demonstration, and I shall not be disposed to detract in the least from the praise due him for the success achieved as a result of his investigations. If, as he claims, he has obtained the final proof that this is the yellow-fever germ by producing the disease in man (five cases), as a result of the subcutaneous or intravenous injection of filtered cultures, I think we must accept these results as demonstrating the specific character of the bacillus in question. But without this final proof the demonstration would not be satisfactory, notwithstanding the pathogenic virulence of the bacillus when injected into several species of the lower animals. If it were constantly found in the blood and tissues of yellow-fever cadavers there would be little reason to doubt its specific character. But both my researches and those of Sanarelli show that, notwithstanding the most painstaking investigations, this bacillus has not been found in a considerable proportion of the typical fatal cases of yellow fever examined.

Sanarelli says: "According to the results of my researches, the isolation of the microbes of yellow fever is only possible in 58 per cent. of the cases;" and his paper, published in the *Annales de l'Institut Pasteur*, shows that his investigations were limited to eleven fatal cases. After having differentiated bacillus *x* from the colon bacillus, which it greatly resembles, I obtained it in about one-half of the cases studied by me in Havana during 1889. Sanarelli says, with reference to his failure to find his bacillus in a considerable proportion of the typical cases: "Its isolation often presents almost insuperable difficulties, due in part to the constant occurrence of secondary infections, and in part to its relative scarcity in the organism."

In the series of cases studied by me secondary infections were extremely rare. The colon bacillus was found in a considerable number of cases, but usually in comparatively small numbers, and there is no good reason for believing that the fatal result depended upon its presence. But for the fact that in the second case studied by Sanarelli, his bacillus was present in considerable numbers in blood extracted from the finger of the patient the evening before his

death, and also, after death, in the blood, spleen, liver, and other organs, it is quite probable that his attention would not have been attracted to this particular bacillus. In this regard this case is unique, both in the series of cases investigated by Sanarelli and in those studied by me; and if this is indeed the bacillus of yellow fever, it is evident that it is usually present in the blood or tissues of yellow-fever patients in very small numbers, or not at all.

In my report I suggest the possibility that the yellow-fever germ may multiply in the intestine, as is the case with cholera, and I say: "Finally we remark that many facts relating to the origin and extension of yellow-fever epidemics give support to the inference that the specific infectious agent is present in the dejecta of those suffering from the disease, and that accumulations of fecal matter and of other organic material of animal origin furnish a suitable nidus for the development of the "germ" when climatic conditions are favorable for its growth.

"There is no evidence that yellow fever is propagated by contamination of the supply of drinking-water, as frequently, and probably usually, occurs in the case of typhoid fever and cholera. Moreover, epidemics extend in a more deliberate manner and are restricted within a more definite area than is the case with cholera and typhoid fever. It is usually at least ten days or two weeks after the arrival of a vessel with the disease on board, before cases of local origin occur; and these cases occur in the immediate vicinity of the imported case or vessel carrying the contagion. When the disease has effected a lodgment, the area of infection extends slowly and usually has well-defined boundaries. In towns and cities having a common water-supply one portion remains healthy, while another, usually the most filthy, may be decimated by the scourge."

This hypothesis led me to make the following recommendation: "The experimental evidence recorded and the facts just stated seem to justify the recommendation that the dejecta of yellow-fever patients should be regarded as infectious material, and that such material should never be thrown into the privy-vaults or upon the soil until it has been disinfected."

Sanarelli reports his failure to find his bacillus *icteroides* in the contents of the intestine; but all bacteriologists will recognize the fact that the demonstration of a non-liquefying bacillus which resembles, both in its morphology and in its colonies, the colon bacillus, and which is present in comparatively small numbers in the contents of the intestines, might easily be overlooked even by one skilled in bacteriologic technic, and I cannot admit that Sanarelli's failure to find the bacillus in the contents of the in-

testine is satisfactory evidence that it was not present.

I obtained bacillus *x* in a certain number of cases from the contents of the intestines of yellow-fever cadavers; but it was present in comparatively small numbers, and I was more successful in obtaining it by inoculation experiments in guinea-pigs than in cultures made directly from material from the intestine. I suggest in my report that possibly yellow fever results from the absorption of a toxin produced during the multiplication of the specific germ in the alimentary canal. This, however, is only advanced as a hypothesis, which has some facts in its favor. If, as stated by Sanarelli, comparatively small quantities of a filtered culture of this bacillus will give rise to yellow fever in man when injected beneath the skin or directly into the circulation, this fact would appear to give additional value to the hypothesis. At all events, I think it would be very unfortunate if, upon the strength of Sanarelli's negative researches, sanitarians should neglect to disinfect the excreta of yellow-fever patients.

The fact that both Sanarelli and myself have failed in a majority of the cases studied to obtain this bacillus in cultures from the liver, the spleen, and other organs, or in thin sections made from portions of these organs preserved in alcohol, does not absolutely prove that the bacillus was not present in these cases. A few scattered colonies might easily escape observation, even in the most painstaking research, just as a few bacilli present in the intestinal contents might not be discovered by a competent bacteriologist after a protracted investigation by the plate method. The isolation of a non-liquefying bacillus is especially difficult on account of the presence of the colon bacillus in large numbers. If, for example, bacillus *x* was present in the proportion of 1-1000 of other non-liquefying bacilli, there would be but little chance of finding it by the use of plate-cultures.

All bacteriologists recognize the difficulty of isolating the typhoid bacillus from the dejecta of typhoid patients, and Gaffky has shown that in fatal cases in which the presence of colonies was not detected in the sections of the spleen, or in which such colonies were extremely rare, the bacillus could always be obtained by means of cultures. I had this fact in view in my researches made at Havana, and habitually introduced a considerable amount of material from the interior of the liver and of blood from one of the cavities of the heart into the various culture-media used in my investigations. I admit that a negative result does not prove the absence of bacteria capable of developing in these culture-media. Indeed, I obtained proof that the contrary is the case; for I invariably obtained various bacteria from cultures made from portions of liver or kidney pre-

served forty-eight hours in an antiseptic wrapping. Some of these were well-known bacilli, such as the colon bacillus, bacillus proteus vulgaris, and large anaerobic bacilli. Associated with these was bacillus *x*.

It is evident, then, that notwithstanding the negative results usually attending culture-experiments with blood from the heart or material from the interior of one of the organs principally affected, bacteria of different species were present in the liver and kidney in small numbers, and that they developed abundantly *post-mortem* when portions of these organs enveloped in an antiseptic wrapping were placed in an incubating-oven. This method was followed by Sanarelli, but he neglects to make any reference to the fact that I had employed it in an extended series of cases, or to my bacillus *x*, which is fully described in my official report, to which he apparently had access, although he makes serious mistakes in referring to my work. Thus, he says: "Dr. Sternberg of Baltimore, author of the most recent, the most rich, and the most methodical contribution to this disease known up to present time, declares that the specific microbe of yellow fever is yet to be found, and he affirms that the whole question is to be taken up *ab initio*."

This was not exactly my position, as witness the following quotation from the introduction to my report: "I have now commenced writing a report because I feel that an account of what I have been doing during the past two years is due, and not because I have brought my investigation to a successful termination, or because I feel that there is nothing more to be done."

"No one can regret more than I do that the question of the etiology of yellow fever is not yet solved in a definite manner, but I at least have not to reproach myself with want of diligence or failure to embrace every opportunity for pursuing the research. The difficulties have proved to be much greater than I anticipated at the outset. If the task before me had been to find an organism in the blood, like that of relapsing fever, or of anthrax, or an organism in the organs principally involved, as in typhoid fever, or leprosy, or glanders, or in the intestine, as in cholera, the researches I have made could scarcely have failed to be crowned with success. But this has not proved to be the case, and among the micro-organisms encountered there is not one which by its constant presence and special pathogenic power can be indisputably shown to be the specific agent in this disease."

Note that I say "among the micro-organisms encountered there is not one which by its constant presence and special pathogenic power can be shown

indisputably to be the specific infectious agent in this disease." But, as heretofore stated, I carefully described one particular bacillus, and in summarizing my results said: "It is possible that this bacillus is concerned in the etiology of yellow fever." Evidently it was my intention that subsequent investigators should consider this possibility, and if my work was well done, by approved methods, no one has a right to ignore it, and continued investigations by the same method cannot be considered as taking up the question *ab initio*.

Again, Sanarelli says: "Sternberg thinks that there is probably a localized infection having its principal seat in the *stomach*." This is a mistake. I have advanced the hypothesis that the germ of yellow fever may perhaps be located in the alimentary canal, as is the case in cholera, and that the symptoms result from the absorption of a very potent toxin produced by it. But this is only a suggestion, and I know of no evidence indicating that there is a localized infection of the stomach. I have carefully studied many stained sections of the walls of the stomach, and have never found any evidence of a localized infectious process, although "in a certain proportion of the cases there is evidence of inflammation, as shown by the presence of an unusual number of leucocytes in the submucous coat."

I say in my report: "The mucous membrane of the stomach is always found to be more or less hyperemic; the congestion commonly is not general, but is confined to smaller or larger spots or districts, in which it is observed to proceed from one or more centers. From these centers it extends or radiates in a lesser degree, either gradually to be lost or to pass over to another congested district. It is owing to this peculiarity of the congestion that it presents no uniformity of character, but is observed to spread irregularly over larger or smaller portions of the membrane (Schmidt)."

"The small intestine commonly contains more or less black matter, either fluid and resembling that found in the stomach, or mixed with mucus and smeared over the mucous coating, especially of the ileum. This, no doubt, comes partly from the stomach, but in other cases is due to passive hemorrhage from the mucous membrane of the intestine itself. This membrane presents arborescent patches of congestion, or portions of the canal may be uniformly red from hyperemia of the mucous coat; the color varies from pale red to a reddish brown, and is usually more marked in the lower portion of the ileum than elsewhere. The large intestine occasionally presents similar arborescent patches of congestion, but it usually has a normal appearance. Finally, we may say that the attention of pathologists has hereto-

fore been so largely taken up with the pathologic histology of the organs which present the most notable changes—liver and kidney—that the histology of the alimentary canal has been somewhat neglected, and further researches in this direction are desirable upon material obtained at the earliest possible moment after death."

If we admit the specific character of the bacillus under consideration, I think we must await further investigations before the question can be considered as definitely settled as to the locality in which it establishes itself in the body of an infected individual—whether in the organs involved, as claimed by Sanarelli, or in the alimentary canal, as suggested by me. But the most important question at present relates to the supposed specific character of this bacillus.

Experiments are now being made under my direction both with bacillus *x* and with cultures of the bacillus of Sanarelli, which I obtained through the courtesy of Dr. Roux during a recent visit to Paris. While I am not likely to have an opportunity to make experiments on man, I hope to make a careful comparative study of the pathogenic action upon dogs and guinea-pigs of bacillus *x* and the bacillus *icteroides* of Sanarelli. If identity is established and Sanarelli's results are confirmed, I shall be ready to accept this as the specific infectious agent in the disease under consideration. I desire to express my obligations to Dr. Ezra B. Wilson of the Hoagland Laboratory, Brooklyn, N. Y., for having renewed at regular intervals the cultures of bacillus *x* which I left in that laboratory more than four years ago. I myself maintained the cultures after leaving Baltimore for duty at San Francisco during 1890, until they were placed in the Hoagland Laboratory in 1892.

Serum Therapy.—The writer has long been of the opinion that the discovery of the germ of yellow fever would be likely to be followed by important practical results in prophylaxis and in the treatment of the disease. There was nothing irrational in Freire's method of inoculation but, unfortunately, he did not have at his command cultures of the specific infectious agent, and his statistics are entirely unreliable, as shown in my published report.

It is possible that the bacillus of Sternberg and Sanarelli may have been present in some of his impure cultures, before his visit to France, where these cultures were "plated" by Gibier (1887); but the micrococcus which he declared to be his "*cryptococcus xanthogenicus*" and upon his return from Paris presented to me as his yellow-fever germ, was the well-known and very common *staphylococcus albus*. Inoculations made by him in my presence in four in-

dividuals resulted only in a slight tumefaction and redness at the point of inoculation without any noticeable febrile reaction.

My own researches and those of Sanarelli show that yellow fever is not an acute septicemia, as might perhaps be inferred from the symptoms and course of the disease, and the inference, therefore, is suggested that the clinical phenomena and pathologic changes in the organs involved are due to the action of some potent toxin, produced by a specific micro-organism which has a more or less localized habitat in the body of an infected individual. This is now known to be the case in diphtheria and in cholera, and the deadly effects of the toxins produced by the diphtheria bacillus and the cholera spirillum may fairly be compared with the specific toxemia which we call yellow fever.

The recent experiments of Sanarelli appear to give substantial support to the inference that yellow fever is in fact a toxemia. Time and space will only permit a brief summary of the experimental results reported. In *Il Policlinico* of August 15, 1897, details are given of the experiments made upon man (five individuals) with filtered cultures of Sanarelli's bacillus icteroides. The amounts injected varied from 2 to 10 c.cm.

CASE I.—A subcutaneous injection of 2 c.cm. of a filtered culture gave rise to a slight febrile reaction, and to some tumefaction at the point of injection.

CASE II.—A subcutaneous injection of 5 c.cm. of a filtered culture caused a painful swelling at the point of injection, loss of appetite, an elevation of temperature reaching 38.6° C. (101.5° F.). A trace of albumin was found in the urine during several successive days. A second injection of 5 c.cm. after an interval of ten days caused an elevation of temperature and a slight tumefaction at the point of inoculation, which quickly disappeared.

CASE III.—The subject received an intravenous injection of 10 c.cm. of a filtered culture. This was followed within fifteen minutes by nausea and vomiting, general agitation, and pain in the lumbar region. Gradually the abdominal region became painful and the slightest pressure with the hands over the abdomen or in the lumbar region caused severe pain. The temperature, which before the injection was 37.1° C. (98.7° F.), rose within two hours to 101.3° F., and within four hours to 104.5° F. The patient complained of severe headache during the night, and continued to vomit. The following morning the temperature was normal; at 4 P.M. it rose to 101.3° F., and there was slight delirium; there was complete gastric intolerance and anuria. The liquid vomit had a pale coffee color, and upon microscopic examination was found to contain red blood-corpuses and leucocytes; it had an acid reaction. The anuria continued for two days, when a little turbid urine was obtained from the bladder; this was completely coagulated by heat. Delirium, interrupted by brief periods of coma, continued during the second day, after which the patient's condition improved and recovery took place. On the second day the sclerotics had an evident subicteric tint. On the second day an explorative puncture of the liver and kidney was made and some "juice" was obtained through the aspirating-needle. Under the microscope this was found to contain,

from the liver, hepatic cells in a profound state of fatty degeneration and, from the kidney, epithelial cells in a state of intense tumefaction and granular degeneration.

CASE IV.—Five cubic centimeters of a filtered culture was injected into the median cephalic vein. In this case also there resulted persistent vomiting, headache, fever, reaching 106.1° F., cephalalgia, muscular pains, diminished urinary secretion containing an abundance of albumin, and afterwards complete anuria, delirium, a subicteric discoloration of the skin and, on the second day, a condition of collapse developed, the pulse being imperceptible. However, the patient gradually rallied from this grave condition and made a good recovery. "Hepatic juice," obtained as in the previous case by aspiration, contained hepatic cells in a condition of "profound fatty degeneration."

CASE V.—An intravenous injection of 2 c.cm. of a filtered culture was made, November 26th, and two days later was followed by a second injection of 7 c.cm. A third dose of 15 c.cm. was given November 30th, and a fourth of 20 c.cm. December 3d. Each injection was followed by a febrile reaction, but this was greater after the first dose of 2 c.cm. than after the last dose of 20 c.cm.; this was also true as regards the other symptoms, thus showing the immunizing effects of the doses first administered. The initial dose gave rise to general malaise, cephalalgia, and a trace of albumin in the urine. After the second dose (7 c.cm.) there was a decided chill followed by fever, cephalalgia, and severe pains in the back and of the joints of the lower extremities. The third dose was also followed by a violent chill and general prostration and by a febrile movement less intense than after the second dose (7 c.cm.). In this patient a subicteric color of the skin, and especially of the conjunctivæ, was also developed. Blood taken from this patient December 9th, thirteen days after the first intravenous injection, gave a transparent serum having a lemon-yellow color. This serum mixed with a recent culture of bacillus icteroides in the proportion of 1:10 caused an arrest of movement and agglutination of the bacilli.

In a subsequent number (September 15th) of *Il Policlinico*, Sanarelli gives a detailed account of his experiments relating to immunity and serotherapy in the disease under consideration. In this paper the statement is made that blood-serum obtained from a yellow-fever cadaver produces, *in vitro*, when added to a culture of bacillus icteroides, the phenomena of arrest of motion and agglutination ("phenomenon of Grüber-Durham"), but the intensity of the reaction varies considerably. This serum injected into animals did not manifest any preventive power as regards the pathogenic action of the bacillus.

Serum obtained by venesection from a yellow-fever convalescent produced "very slowly" the same reaction. The simultaneous injection of this serum and of a culture of the bacillus did not preserve guinea-pigs from death, but when the same dose (2 c.cm.) was injected twenty-four hours before the injection of the culture, death did not result in most of the animals experimented upon—numbers not given. Antidiphtheritic serum, prepared in Dr. Sanarelli's laboratory, very promptly produced the "Grüber-Durham" reaction with bacillus icteroides

and "antityphoid serum" produced it in a partial manner, but normal human blood-serum had no effect. Attempts to immunize guinea-pigs by the injection of filtered cultures were not successful, and rabbits were immunized with great difficulty. Dogs were immunized by a series of inoculations with filtered cultures, first subcutaneously and later intravenously. At the end of two months they were able to withstand small doses of unfiltered cultures injected beneath the skin, and later intravenous injections, but at first these gave rise to vomiting, fever, and debility. It was only at the end of seven to eight months that they were able to withstand full doses of unfiltered cultures.

Horses could not be immunized by subcutaneous injections of cultures of the bacillus because these caused enormous tumefaction followed by ulceration at the point of injection. For the immunization of horses the following method was adopted: Doses of 5 to 10 c.cm. of a filtered culture were first given. These gave rise to a febrile reaction often lasting several days. Small doses of a filtered culture were then injected into a vein. After about two-months' treatment filtered cultures sterilized by ether were employed, and it was only at the end of five to six months that a small dose of an unfiltered culture could be given. The first dose of a living culture caused loss of appetite and a febrile reaction lasting from eight to ten days. The dose was increased by from 5 to 10 c.cm., and repeated at intervals. These experiments show that the immunization of the lower animals against the pathogenic action of this bacillus is attended with great difficulties, and is a tedious process.

At the time of the publication of his paper, Sanarelli had in his possession three dogs which were very well immunized. One of these had received 300 c.cm. of virulent culture in the space of eight months. Blood-serum from this dog caused arrest of motion and agglutination of the bacilli in a fresh culture when added to it in very small quantity. This serum saved eight out of ten rabbits inoculated with lethal doses of an unfiltered culture; but was not successful in saving the lives of inoculated guinea-pigs.

A horse subjected to the experiment received in the course of five months 29 c.cm. of filtered culture, 2640 c.cm. of culture sterilized by ether, and 35 c.cm. of living (unfiltered) culture. Serum from this horse had a "good preventive power for rabbits." To save a rabbit from a lethal dose of a culture of the bacillus it was necessary to administer twenty-four hours in advance of the inoculation about 5 c.cm. of the serum. Subsequently a serum was obtained which was effective in the amount of 0.5

c.cm., and which in the dose of 2 c.cm. injected forty-eight hours after inoculation, was successful in saving rabbits from the lethal effects of a full dose of a recent culture.

The painstaking experiments detailed by Sanarelli are most important and interesting, but it is evident that they must be followed by carefully conducted experiments upon man before we can be assured that his immunizing serum can be used with success in the prevention and treatment of yellow fever. If it proves to have specific therapeutic power we can scarcely doubt that the bacillus used in immunizing the animals from which the serum was obtained is in truth the yellow-fever germ.

Note.—Comparative experiments already made at the Army Medical Museum, by Major Walter Reed, Surgeon United States Army, show certain cultural differences between the bacillus *icteroides* of Sanarelli and my bacillus *x*. Whether these are simply due to the fact that bacillus *x* has been cultivated for eight years in artificial media, or are to be considered as evidence that we are dealing with two more or less permanent varieties of a single species, or are to be taken as evidence that the bacillus of Sanarelli is specifically distinct from my bacillus *x* can only be determined by further investigations, and especially by comparative experiments relating to the pathogenic power of the cultures obtained by me from yellow-fever cadavers in Cuba, and by Sanarelli from yellow-fever cadavers in Brazil. At present bacillus *x* is non-motile, while Sanarelli's bacillus is actively motile. But in my original cultures, as stated in my published report, bacillus *x* was motile. At present Dr. Reed informs me that the presence of flagellæ may be demonstrated by proper staining methods.

THE ETIOLOGY AND PATHOLOGY OF YELLOW FEVER.¹

BY RUDOLPH MATAS, M.D.,
OF NEW ORLEANS, LA.;

PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF TULANE UNIVERSITY OF LOUISIANA, ETC.

THE unfortunate circumstances that have called for the present gathering and have revived so much interest and attention in regard to an old enemy—whose existence the present generation had well nigh forgotten, or at least only remembered with indifference—evokes memories which bring us back to a similar occasion during the summer of 1878, when this identical organization called for a general meeting of the profession of this city, with the view of eliciting the opinions of the leading men of that memorable period as to the most effective means of

¹ Abstract of a paper read before the Orleans Parish Medical Society, September 11, 1897, and published in the *New Orleans Med. and Surg. Jour.*, October, 1897.

stifling the pestilence which confronted our people—a visitation which I most fervently pray will not find its parallel in the present outbreak. There are many veterans still among us who were witnesses to that fearful struggle which cost our devoted people over 4600 lives, and some of these are now recognized as Fellows whom we rejoice to welcome and honor in our councils.

I cannot refrain from making an allusion that the present crisis amply justifies. This is related to the fact that since 1879 the germ of yellow fever has never taken root in the city of New Orleans, and this simply because it was never allowed to reach our levees. Not only has the notion that yellow fever is endemic in this country been forever exploded by the immunity we have enjoyed during the past eighteen years, but the evidence furnished by the present outbreak at Ocean Springs is a demonstration in itself of the soundness of the sanitary principles applied at the mouth of the Mississippi River by the authorities for the exclusion of foreign pestilence since 1883.

I have always remembered the pregnant warning uttered long ago by the distinguished Griessinger, to the effect that “a series of years often pass during which yellow fever is scarcely observable in the very places it especially frequents; and this, though there may be no difference in the going and coming of unacclimated strangers. Then there is rejoicing over the presumed disappearance and destruction of the disease, and a triumph of sanitary police over it is claimed.” But the experience of New Orleans since 1879, with its total immunity and continuously increasing prosperity, tells us that this is no ephemeral or fictitious triumph, and that the protection which we have enjoyed has not been due to fortuitous circumstances and accidentally favorable conditions, but that it is entirely the result of the efficiency of the preventive measures employed. Therefore, if the modern generation of medical men in this city has been deprived of the opportunity of acquiring a *de visu* experience with the dread *typhus icteroides*, and has not been granted the doubtful honor of an introduction to “Yellow Jack,” it is due to the system of maritime sanitation established by the Louisiana State Board of Health at the mouth of the Mississippi; and I mean by this more distinctly the “Holt system” of maritime sanitation. As I mention the name of our honored Fellow, Joseph Holt, I feel that you will all agree with me that at no time is the praise of his splendid work more worthy of repetition than at this moment, when, in the very disaster which threatens us, we are compelled to recognize the triumph of his principles and methods.

I remember very distinctly that during 1877, 1878, 1879, and 1880 the lamented Bemiss taught us that

yellow fever was distinctly a microbic disease, and his manner of stating this etiology of yellow fever and the reasons for accepting it from simple *a priori* reasoning was so lucid and impressive that I believe it could not be better stated to-day. His teaching on this subject, which has been preserved in his most interesting contribution on yellow fever in “Pepper’s System of Medicine,” vol. i (1885), reproduces his presentation of the subject as we were familiar with it in his lectures. In my notes taken after the epidemic of 1878, more fully stated in the article referred to, which appeared during 1885, I find that he said: “The study of the yellow-fever poison after the *objective* method (microscopic, bacteriologic, etc.) has hitherto been unproductive of definite results. But when we turn to a *subjective* method of investigating that toxic agent which causes yellow fever, it is found to possess sufficiently well-marked characteristics to justify practically valuable conclusions.” Some of these characteristics or modes of behavior merit notice.

1. The human system is a field of reproduction and multiplication of the yellow-fever poison, and this is sufficiently established by two facts:

- a.* A person in the incubation stage of yellow-fever intoxication may be divested of all fomites and yet originate other cases after a developed attack.

- b.* The infection is intensified by the aggregation of the sick.

These propositions are indisputably true.

2. The poison or infection undergoes some change after leaving the human system.

This appears to be susceptible of proof, because communication from person to person is not a common event. When this does apparently occur, there is often very strong reason for belief that the contagion was resident in some fomites connected with the patient’s bed or clothing.

3. There are no sustained observations which prove that the yellow-fever poison is ever created *de novo*.

The autochthonous birthplace of the poison is unknown. The suggestion that yellow fever may have been one of the causes of death during the plague of Athens cannot be authoritatively denied.

This is not at all likely to be true, and, furthermore, the most recent investigations by learned Mexican and Spanish scholars prove that, according to Maya manuscripts, a fatal epidemic disease characterized by black vomit and other symptoms of yellow fever ravaged Yucatan and the regions of the Gulf Coast long before invasion of the Spaniards. Thus the American origin of yellow fever, which has been discussed since the days of Humboldt, is fully sustained.¹

4. Some of those conditions and circumstances which favor or retard the maturation of the yellow-fever poison outside of the human body are quite well understood. Hot, damp weather is most prominent among the cli-

¹ Dr. Carlos Finlay, *Cronica-Medico-Quirurgica* of Havana, May 15, 1897, and *Revista de Ciencias Medicas* of Barcelona, August 10, 1897.

matic conditions which are favorable to the growth of yellow-fever epidemics.

5. A freezing temperature ordinarily destroys the contagion of yellow fever; a high degree of artificial heat produces a similar result. It is highly probable that certain chemic results would also effect its destruction if brought into contact with it.

6. If yellow-fever fomites are hermetically inclosed in situations protected from cold or other agents which are destructive to their infection, vitality may be preserved for an undetermined length of time, and toxic qualities again made manifest when unacclimated persons (*i. e.*, those who have never had the disease) are exposed to it.

7. Yellow-fever poison possesses ponderability. This characteristic is so distinctly marked that it has been frequently termed a "groveling, low-lying poison."

8. It is incapable of being air-borne through any great distance, at least without being deprived of its toxic effect.

9. It is transportable in fomites through great distances, either on sea or land, but as often as its toxic effects are manifested after these transportations they are so uniform as to be promptly recognizable. A great number of different materials in common use may act as carriers of fomites, such as loose wool, cotton, hair, textile fabrics, ship ballast, and merchandise of various descriptions.

10. The preceding facts explain how the disease is spread, and why it is that it follows the lines of travel and commerce, and thus primarily attacks the seaports and towns situated on navigable streams and then follows the railroads to the inland towns.

11. These qualities of the yellow-fever infection taken collectively, and especially its faculty of reproduction (which only living organisms possess) furnish almost conclusive evidence that yellow fever is a germ disease produced by a specific *contagium vivum*.

Professor Bemiss shared in the general belief still sustained by the latest investigations—that "in the dissemination of yellow fever, atmospheric air is the usual medium through which the infection is received in the human system." That the poison gains its entrance chiefly through the respiratory passages is sustained by almost all the evidence which has accumulated to this day. Dr. Bemiss would very effectively impress this upon his classes by the following striking illustration, which I will quote, as it is pertinent to this occasion. The facts were furnished by Dr. Shannon of Ocean Springs, Miss., in a letter to Dr. Bemiss:

On the 14th of October, 1883, Major J. B. D. died of yellow fever at Ocean Springs. I moved the family at once to a healthy locality, where you saw Miss B., not allowing them to take any article from the room where the husband and father had died. The children applied to me for a lock of their father's hair, which I refused. But the older daughter, now dead, prevailed upon the nurse to give it to her. She placed it in an old envelope which had been torn open at the end, and carefully folded the torn end down, thus practically sealing it, and laid it away among other old letters. Sunday, the 4th of November, at 12.30 P.M., she brought this envelope out upon the gallery and opened it for the first time to examine the lock of hair and show it to her aunt, Miss S., who was visiting her, and upon inhaling the concentrated poison confined in the envelope and emanating from the hair, exclaimed: "Oh, what a peculiar smell." She then handed the envelope to her aunt, Miss S., who, un-

conscious of danger, also inhaled "the messenger of death" with a similar exclamation, when Mrs. B., who was standing near, reached out her hand for the envelope, but was prevented from getting it by the entreaties of a fretful child to be taken up in arms. This gave time for sufficient reflection, and she admonished the young ladies of the possible danger. The envelope was then carefully folded, and with its fatal contents replaced in the drawer where it had been since the 14th of October. This drawer had been almost daily opened. The following Saturday night, November 10th, at 9 P.M., Miss S. was taken sick with a chill, and Miss B. about 2 A.M., some five hours later, the period of incubation being less than seven days in both cases. No other person handled the fatal envelope or in any way came in contact with it, and there is, after the most careful inquiry, no suspicion of any other source of infection in these two cases. Miss S. died November 14th; Miss B. on November 16th.

This tragic event, that actually occurred in the very place which has been the starting point of our present troubles, may appear somewhat dramatic, but it is vouched for in every detail by Dr. Shannon, and Dr. Bemiss firmly believed in it.

The Essential Cause of Yellow Fever.—The profound impression produced by the epidemic of 1878 naturally led to many discussions as to the origin and cause of yellow fever, and the theories which were then entertained by many, even by some of the most competent in the profession, would now appear to us as being idle and absurd.

The "telluric" or "miasmatic," the "ship origin," the "fecal" and the "glandular" theories of yellow fever which are more or less dependent upon the supposition that the cause of the disease could originate spontaneously or *de novo* in certain places and in the human organism were still currently believed in, though never to the preponderating extent shown in the previous great epidemic of 1867.

That our sanitary authorities were most thoroughly convinced as early as 1878 of the microbic origin of yellow fever is most eloquently attested by the desperate but ineffectual efforts made by the President of the Board of Health, Dr. S. Choppin, to stamp out this disease by the profuse irrigation of the streets of this city with carbolic acid. The dominant theory was, therefore, the germ theory of the disease. All that was lacking was a tangible demonstration of the existence of the germ itself. It was not long before many anxious explorers began to see the coveted prize.

The first announcement of the discovery of a yellow-fever germ was made in 1878 by Dr. Joseph Richardson of Philadelphia. His alleged discovery was based upon the absolutely insufficient basis furnished by the *post-mortem* examination of a few specimens, and upon this slender foundation he labeled the new microbe the *bacillus sanguinis febris flavæ*.

Inspired by the disastrous experience of 1878 and

realizing the necessity of a systematic and careful study of yellow fever in its most prolific nursery—Havana—the United States National Board of Health determined to send a commission of experts to Cuba during the summer of 1879, and to this end selected Dr. Stanford E. Chaillé, chairman; Dr. Geo. M. Sternberg (bacteriologist), Dr. John Guiteras (pathologist and histologist), and the late Colonel Hardee of Louisiana, as sanitary engineer. It was my good fortune also to be selected while still an undergraduate and an interne of the Charity Hospital, to accompany the commission as its clerk and interpreter. I shall always remember the three months spent in Cuba in the company of these distinguished gentlemen and indefatigable workers as one of the most important events in my life, as experience and knowledge gathered in the hospitals of Havana, which were crowded with yellow-fever patients, and in the laboratory of the commission, were of immeasurable benefit to me in my subsequent experiences with this disease. It would be impossible and out of place on this occasion to give an account of the results obtained by the labors of the commission. Suffice it to say, that while the researches into the essential cause of the disease were only negative, owing in a great measure to the then rudimentary condition of bacteriologic methods, only the liquid-culture fluids being known and none of the various staining processes for studying bacteria in the tissues having been discovered, still, the indefatigable industry of Dr. Sternberg cleared many points in the histology of the blood which have been of the greatest value in his own subsequent work, as well as in that of other investigators. As to the study of the collateral questions, and especially the sanitary condition of Cuba, which determined the endemicity of the disease in that island, nothing more satisfactory, thorough, or complete has ever been given to the world than the data collated by the chairman, the distinguished dean of our medical department, Dr. Chaillé. I should mention incidentally that among one of the most notable results of this investigation was the fact, brought to light for the first time by Dr. Chaillé, that the immunity enjoyed by native Cubans, and in fact by all natives of endemic *foci* of yellow fever, was not due to the influence of climate, but solely the protection given by a previous attack experienced in early childhood. This explanation of native immunity, which was at first hotly contested in Cuba and elsewhere, is now definitely admitted everywhere, in consequence of the convincing evidence first furnished by Dr. Chaillé, and since by Dr. Guiteras while studying the same question in Key West and Matanzas.

Continuing with the record of the claims of discovery of the yellow-fever germ, we find that after

the negative researches of Woodward, Sternberg, and Schmidt, during 1879 and 1880, no discovery was definitely announced until 1881, when Charrin and Capitan believed that they had found a specific micrococcus in specimens of blood brought to Paris by Morand, from Senegal. During 1883, Dr. Lacerda of Rio de Janeiro, having discovered what he believed to be the specific micro-organisms in the liver and kidneys of yellow-fever patients, sent some material to Paris to Dr. Babes. For a time Babes believed that they were the veritable germs of yellow fever, but he subsequently renounced this claim. During 1884–85 Dr. Carmona y Valle of Mexico, in his memoir "*Leçons sur l'étiologie et la prophylaxie de la fièvre jaune*," described his *peronospora lutea*, a species of mucor, as the specific cause. During 1885, Domingos Freire of Rio de Janeiro, published his principal work, *La Doctrine Microbienne de la Fièvre Jaune*, in which he maintained the specificity of his *cryptococcus xanthogenicus*, and described his prophylactic inoculations and their results. This widely advertised announcement created considerable stir in the professional world, and prompted this government to detail Dr. Sternberg on a special mission of investigation.

The results of this notable inquiry are all embodied in the comprehensive and admirable report on the etiology and prevention of yellow fever published by the United States Marine Hospital Service during 1890, in which Dr. Sternberg completely refutes all the claims maintained by Freire and permanently disposes of the prophylactic value of his alleged vaccine.

The same fate awaited the claims in favor of the *micrococcus tetragenus febris flavæ* or *versatilis* (Sternberg) described by Carlos Finlay and Delgado of Havana, 1887–88, and in a similar manner, the bacillus which Dr. Paul Gibier found in the intestinal canal during 1887 while studying the disease in Havana. In the meantime Dr. Sternberg had been tireless in his investigations; he availed himself of every opportunity to fathom the cause of the disease. Starting with his first experience in Havana during 1879, he visited Rio and Vera Cruz in 1887, where he promptly eliminated the claims of Freire and Carmona; during 1888 he studied the disease again at Decatur, Ala., where the disease was epidemic; finally, during 1888–89 he again visited Havana and applied all the resources of the improved bacteriologic technic which he, above all others, could command. At the conclusion of his labors, which are all summarized in the complete report issued by the United States Marine Hospital Service in 1890, Dr. Sternberg was forced to the conclusion that the specific agent in yellow fever had not been demonstrated. Nevertheless, he emphasized the point that "among the facultative

anaerobics is one—my bacillus α —which has been isolated by the culture method in a considerable number of cases, and may have been present in all. This bacillus has not been encountered in the comparative experiments made. It is very pathogenic for rabbits when injected into the cavity of the abdomen. It is possible that this bacillus is concerned in the etiology of yellow fever, etc.” Here Dr. Sternberg rested. His laborious work had only succeeded in conclusively demonstrating that all the alleged discoveries previously made were fictitious, and the riddle of yellow fever remained as practically unsolved as ever. In this critical work, which swept away so many accumulations of bacteriologic rubbish, Sternberg’s conclusions were most ably confirmed and supported by the conscientious researches of Heineman of Vera Cruz, who, in a valuable paper contributed to *Virchow’s Archives*, 1888, also effectually disposed of the claims of Freire, Carmona, Gibier, and their followers.

It thus became evident that the germ of yellow fever was no common organism. If not imaginary, it certainly was endowed with the most elusive properties. It could surely be said of this microbe that the frequency with which it was seen was inversely proportionate to the skill and experience of the observer. There was reason for discouragement, but, nevertheless, it was evident in Sternberg’s interesting study of his bacillus that there was yet hope that with more time, opportunity, and improved methods the cunning culprit would at last be tracked and captured.

Such was the state of the professional mind when suddenly, after a silence of seven years, the bacteriologic horizon was illuminated by the almost simultaneous announcement of the discovery of the long-sought germ by Professor Guiseppe Sanarelli, the director of the Institute of Hygiene of Montevideo, Uruguay, and by Dr. W. Havelberg, a bacteriologist of Rio de Janeiro.

These announcements are regarded as of great importance, far in both instances they were made by men of acknowledged reputation and ability in the latest methods of bacteriologic research. According to the Roman correspondent of the *British Medical Journal* (February 23, 1897) Sanarelli is regarded as one of the most accomplished bacteriologists of the profession. “He is thirty-five years of age. His opportunities have been exceptionally fine. A graduate of Sienna, he continued his studies in experimental hygiene under Celli at Rome, Roux in Paris, and Behring in Berlin. In 1893 he received the appointment as Director of the Institute of Hygiene of Montevideo. During the summer of 1896 he went to the Island of Flores, where yellow fever was se-

verely prevalent. There he performed a number of necropsies, and was himself smitten with the disease. As soon as he recovered he resumed his investigations at Rio de Janeiro, where the disease was raging. Here at the end of two months of assiduous labor, his efforts were rewarded. For some time he was loath to give publicity to the fact that the specific microbe had been discovered. But at length he became so well convinced that he had in hand the yellow-fever microbe that he commenced in August the preparation of his serum-cultures. He encountered many obstacles, but these were finally overcome and he was able to state that “the microbe of yellow fever now splendidly presents itself, and is the strangest of all the microbes that are known.”

On the other hand, the fact that Dr. Havelberg’s report was first published in the *Annales de l’Institut Pasteur*, and that some of his work was done at the suggestion of M. Roux, would seem to indicate that he also has strong backing, and that we are likely to have a lively scientific tilt over the affair.

The most regrettable feature of the situation is that the respective microbes discovered by these men possess few, if any, traits in common, and are found in a different manner and in different parts of the body, so that there is in consequence decided antagonism between the respective claims.

According to Sanarelli the isolation of the specific microbe of yellow fever is only possible in fifty-eight per cent. of the cases, and in some rare cases may be effected during life. The reasons why in every case of yellow fever one cannot isolate the specific agent are easy to understand. In the first place, at the beginning of the disease the bacillus icteroides multiplies very little in the human organism, a small quantity of the toxin, as we shall see later, being quite sufficient to develop in man the very grave picture of the complete disease. In the second place, the toxin, either by itself or indirectly by means of the profound lesions which it determines, above all in the digestive mucosa and in the liver, facilitates in an exceptional way secondary infections of every kind. Such special infections may sometimes assume the type of true and special septicemias, with colon bacilli, streptococci, staphylococci, etc., capable of killing the patient by themselves alone. At other times they occur mixed, so that in the last stages of life they may transform the individual into a true culture of almost all the intestinal microbic species.

The bacillus at first sight presents nothing morphologically characteristic. It is a little bacillus with rounded extremities, for the most part united in pairs, in cultures, and in small groups in the tissues, from two- to four-thousandths of a millimeter in

length, and, as a rule, two or three times longer than broad. It is very polymorphous. A search for it in the tissues does not give good results, excepting in the cases in which the death of a patient occurs without secondary septicemia. Even in the cases which on bacteriologic examination give the purest results, it is not easy to see it in the section of the tissues, owing to the number being sometimes extremely small. Yet by employing suitable methods one can find it in the organs, usually united in little groups, *always situated in the small capillaries* of the liver, kidneys, stomach, etc. The best method for demonstrating not only its presence, but also the special tendency it has to be localized in small groups in the blood-capillaries, is to place a small fragment of liver, obtained from the body while fresh, in the incubator at 37° C. during twelve hours; this favors the multiplication of the specific microbes. Sanarelli's germ is stained readily by basic anilin dyes, but is decolorized by Gram's method. When stained by suitable media it is found to possess four to eight lateral cilia. It grows readily in all ordinary media above 20° C., the maximum temperature being 37° C. It does not liquefy gelatin, neither does it cause precipitation in meat broth, nor does it curdle milk. The most important diagnostic feature, however, is supplied by the colonies on the surface of agar when incubated for twelve hours at 37° C., and then allowed to develop further at room temperatures. The colonies, when incubated, appear merely as semitransparent round disks, but during subsequent growth at the room temperature a thick, opaque, white border forms around each colony, giving a very characteristic appearance, resembling a drop of sealing-wax. As their character fortunately may be determined within twenty-four hours, it serves to establish in the most rapid and certain manner the bacteriologic diagnosis of the fever. This statement is alone, if confirmed, of the greatest importance from a sanitary point of view. Taken with the possibility of obtaining a pathognomonic serum-reaction with typical cultures, just as is now done with Widal's test in typhoid fever, we at once grasp its full and enormous significance in dealing with the early and doubtful stages of yellow-fever epidemics. Should this test be available, we would not be compelled to wait for *post-mortems* to clear up a diagnosis, and the long hesitation and unseemly discussions which characterize medical consultations among official experts in non-typical cases would be promptly disposed of; neither would there be any likelihood of an entire country being infected while waiting for the percentage of mortality to decide as to whether the disease is yellow fever, dengue, or something else.

Causes of Death in Yellow Fever.—The patient suffering from yellow fever is in fact contemporaneously threatened by three imminent dangers, and the bacteriologic examination of the cadaver may approximately place the following in evidence as the principal causes of death:

1. It may be due to the specific infection, principally, when the bacillus *icteroides* is found in the cadaver in a certain quantity and in a relative state of purity. This happens only in the cases which run their special disease cycle to the end.
2. It may be due to septicemiæ successively established during the course of the disease, when the cadaver presents almost a pure culture of other microbes.
3. It may also be due in great part to renal insufficiency, when the cadaver is found almost sterile; the percentage of urea in the blood is very high, and death takes place before the malady has reached the end of the evolutionary cycle.

It is difficult to pronounce during the life of the patient on the prevalence or not of uremic symptoms over the specific, because the most salient symptoms of the yellow-fever intoxication are easily confounded with those of renal insufficiency.

The so-called "black vomit" is due to the action of the gastric acidity on the blood which is extravasated into the stomach in consequence of the grave toxic lesions of its mucosa. The act of vomiting is directly provoked by the specific emetic action which the toxic products of the bacillus circulating in the blood possess.

The hemorrhagic symptoms are due above all to the hemorrhage-producing (hemolytic) property possessed by the bacillus *icteroides* in common with other microbes, and, in the second place, to the profound and rapid fatty degeneration produced in the vessel walls.

The Specific Toxin.—The small numbers in which the bacillus *icteroides* are usually found in the human organism, and the violence of the symptoms which are immediately produced in dogs by injections of small cultures into the veins indicate the existence of a very active specific poison. This poison or toxin is obtained, like that of diphtheria, by simply filtering through porcelain the broth-cultures of the bacillus about twenty-four days old. The toxin bears heating to 70° C. (158° F.) almost with impunity, but boiling notably attenuates it. If cultures sterilized with ether are employed, the toxic power is much more active.

All the sympathetic phenomena, all the functional alterations, all the anatomic lesions which individualize and give the yellow-fever picture its wonderfully striking outlines are only the consequence of

an eminently steatogenic (or fat transforming), emetic, pyrogenic, hemolytic, and extraordinarily active toxin, elaborated by a germ which, for convenience, is called by its discoverer the *bacillus icteroides*. It is no doubt in consequence of these effects that yellow fever has been aptly compared to poisoning by the venom of certain serpents. Surely no one will deny, no matter what doubts he may entertain of the identity of Sanarelli's germ with the cause, if he has had any practical acquaintance with yellow fever, that no explanation has ever been offered more satisfactory to our pathologic and clinical sense, and that will better account for the train of symptoms which identify this disease—fever, vomiting, hemorrhages, albuminuria, anuria, fatty degenerations of liver, kidneys, and heart—than the effects of the toxin so clearly and impressively described by Sanarelli.

Now as to the mechanism of infection. By what avenue does this terrible germ enter into the organism, and where, or in what special tissues, does it establish its toxin factory? The first of these is a question of the greatest practical importance. We see that it produces its effects most rapidly when injected into the blood by intravenous or subcutaneous injection. But the normal or common way by which it gains entrance in epidemic conditions is not so clearly understood. It is evident that the *atrium* or gateway of infection must be by either of two ways—the respiratory or the alimentary passages. Sanarelli believes that it may be by both routes, but in accordance with clinical experiment and common observation, he lays stress upon the former route as by far the most frequent of the two.

The remarkable resistance to drying which Sanarelli has demonstrated in the *bacillus icteroides* warrants the assumption that this germ may be conveyed in the air as well as in water. Further, "contagion by the respiratory passages has been demonstrated to be possible by experiments on animals." As to the mechanism of contagion by water, milk, or other ingesta, it is difficult to understand it in healthy subjects, as it is now placed beyond a doubt that the epithelium of the digestive passages, when it is intact, does not, as a rule, permit the passage of any pathogenic germs. But in tropical countries the liver, especially of foreigners, is usually overtaxed, and it is possible to conceive that, owing to the weakness of this most important barrier against intestinal infection, the germ may gain an entrance into the circulation.

At any rate, the morbid process is clearly understood once the germ is admitted into the organism. Whether introduced by the nasal chambers, the fauces, tonsils, or lungs, or by the alimentary

tract, it is carried by the circulation to the capillary system of the liver, spleen, gastro-intestinal canal or kidneys, which are its preferred habitats. Here the germ develops slowly, for, like most potent microbes, its reproductive capacity is limited; in fact, five to eight days will be needed to form colonies which are so small that it will require the most skillful detective work with the microscope to discover them. While reproducing itself, however, it begins to manufacture its terrible toxin. This toxico-genetic function probably begins from the moment that the germ becomes fixed as a capillary embolus and when colonization begins. Its colonies are fully matured in the laboratory—outside of the tissues—in twelve to twenty-four hours. The dose and toxicity of the poison will no doubt depend upon the size and activity of the colonies. And here the vigor or weakness of the individual defenses of the host—phagocytic and humoral, will largely determine the future progress of the parasitic colony. The questions of the relative predisposition and immunity must largely decide whether the attack will be severe or mild. Certainly the effect of the first discharge of the poison into the blood stream is pyrogenic, then follows the emetic action probably on the nerve centers, then simultaneously begins the attack on the great bulwarks of defense—the liver, capillaries of the alimentary tract, the kidneys, and, lastly, the heart-muscle and the blood itself. Then the real danger begins—when these viscera and especially when the liver and kidneys are undergoing fatty change—then a gateway is at once opened for the admission of all the intestinal germs and their toxins into the blood, and by the destruction of the renal epithelium the great outlets by which they are to be carried out are plugged and auto-intoxication is inevitable. In the carnival of destruction which follows, the original parasitic host may itself be destroyed by the swarm of greedy guests that it has blindly admitted to its own banquet.

This account of the pathology of yellow fever may appear somewhat figurative and metaphoric, but it is, nevertheless, that which most clearly explains the phenomena of this remarkable disease.

We will now close by asking ourselves what is the practical outcome of all these researches—what bearing has Sanarelli's discovery to the prophylaxis, diagnosis, and treatment of yellow fever, if verified?

1. *Prophylaxis*.—It is legitimate to expect that in dealing with so specific and potent a micro-organism as the *bacillus icteroides*, it is possible, by attenuated culture or by an antitoxic serum, such as is now obtained from immunized horses after subjecting them to experimental diphtheria or tetanus, that

a reliable preventive and curative agent will be obtained.

2. *Diagnosis*.—That if the cultures obtained from the bacillus icteroides are specifically characteristic, as claimed by Sanarelli, a pathognomonic culture may be obtained in twenty-four hours from suspected cases. Again, if this should be impracticable during life, owing to the paucity of germs in the blood, it is possible that a specific serum reaction, similar to Widal's agglutination test, may be obtained, which will permit of an immediate and infallible diagnosis in the early stages of the disease. The enormous value of such a test to the sanitarian need only be mentioned to be appreciated.

3. *Treatment*.—Of course, the greatest value of Sanarelli's researches lies in the prospect of obtaining a specific antitoxin which alone can cope with the specific cause in the blood and the tissues. Apart from this, these researches would suggest some important conclusions which affect our present mode of treatment.

(a) That no hope of aborting or arresting the disease can be entertained by resorting to germicidal medication with the view of destroying the specific micro-organisms in the gastro-intestinal tract. When the symptoms of yellow fever present themselves, the specific germ and its toxins are already in the blood and tissues, and no amount of purgation or gastro-intestinal antiseptics could possibly affect its future course or development. This explains why all the emeto-cathartic remedies and antiseptic treatments have totally failed, either in the past or present, to control or abort the course of the disease.

(b) On the other hand, in view of the secondary infections, which so frequently complicate this disease by the invasion of the colon bacillus, staphylococci, streptococci, and other bacteria of the gastro-intestinal tract in the graver types of this infection, it is perfectly logical and proper to resort to laxatives and intestinal antiseptics and a total abstinence from all foods, with the view of diminishing these secondary intoxications to the minimum. In this way proper treatment may modify the course of the disease by diminishing the perils of its latest stages.

(c) At all times it should be borne in mind that, while attempting to secure the most complete asepsis of the gastro-intestinal tract, no violent drastics or germicidal agents should be resorted to, as the lesions of the mucosa produced by such agents would favor the very conditions which they are intended to prevent. For these reasons a mild triturate tablet of calomel and soda (aa gr. 1), followed by a saline draught, any of the purgative mineral waters, etc., given at the outset, will suffice. Then the most important means of maintaining gastro-intestinal asepsis

will be total fasting or abstinence from food until the latter stages, when fruit juices, hot or iced tea, champagne, and, lastly, peptonized milk, if the patient is convalescent, may be given with discretion.

One of the fundamental and pernicious errors in this disease is the belief that food is necessary in its treatment, because it is a prostrating disease. This is not a wasting disease, and when it is *typical* it is self-limited and of comparatively short duration. In this way it differs radically from typhoid. The cry of the organism is not for food, which will only help to clog up all the machinery of elimination, but for water, *water* which is needed from the very beginning, to dilute the toxins in the blood, to maintain the secretions of the poisoned organs, the skin, and, above all, to flush out the kidneys, which are blocked up so early in the struggle. Later on, when adynamic symptoms present themselves, stimulants may be given in moderation, and food of the most assimilable sort, and this only when convalescence has begun or secondary septicemias of long duration have set in. These are the cardinal principles which would guide my treatment in the present, and are essentially those that I have followed in the past. In no condition have I taken to heart more seriously the motto "*Primum non nocere*," and if my inexperienced junior friends will only remember this caution, even to the exclusion of all else I have said, I will feel that I have accomplished some good to-night.

THE TREATMENT OF YELLOW FEVER.¹

By T. S. DABNEY, M.D.,
OF NEW ORLEANS, LA.

THE treatment of yellow fever may be divided into (a) the hygienic, (b) the dietetic, (c) the therapeutic, and (d) the surgical. Pending the investigations being made by bacteriologists all over the world into the claims of the latest aspirant, Sanarelli, to the honor of having discovered the *vera causa* of yellow fever, the bacillus which has for ten years eluded Sternberg, which has successively baffled the brilliant Gibier, Carmona y Valle, Freire, and Finlay, and which he has named bacillus icteroides, we must fall back upon that line of treatment which, though possibly based upon false etiologic grounds, yet yields the best results, and, at all events, one which seems to meet plain and specific indications. Perhaps it would not be out of place to review briefly the line of treatment pursued here in the past. A brisk purgative; hot mustard foot-bath; patient covered with one or more blankets to promote profuse diaphoresis; hot orange-leaf tea *ad libitum*, and,

¹ Abstract of a paper read before the Orleans Parish Medical Society and published in *New Orleans Med and Surg. Jour.*, October, 1897.

at times, in the beginning an emetic; absolute interdiction of cold drinks, though cracked ice was allowed in small quantities for nausea. Spirits of nitre, or watermelon-seed tea, and some such diaphoretic as spirits of Mindererus, coupled with a four-days' fast, about completed the treatment up to the defervescence of the fever. Dry and wet cups and leeches were often used—the main reliance, however, was in sweating and starving the fever out. The results obtained by this method in simple and uncomplicated cases were most excellent, and were often better than those in which a more vigorous treatment was pursued.

The reasons for this success are not hard to find: (1) most patients with uncomplicated yellow fever tend to recover; (2) it usually did no harm, and (3) the great faith of the Creole nurses in its efficacy, by a species of hypnosis, gave much encouragement to the patient, thereby greatly facilitating his recovery. This treatment practically is the same as that pursued to-day by the Cuban peons, many of whom boldly assert that only those Cubans die who are treated by doctors. Thus it will be seen that this disease, if not over-treated, tends to recovery. The main indications being *Rest* in the horizontal position, a spare diet, perfect quiet, plenty of fresh air, gentle stimulation of all the emunctories, an abundance of cold water to quench the thirst, as well as to flush the kidneys, and the judicious administration of stimulants and easily digested liquid foods when the vital powers begin to fail. This will do in simple cases; but the difficulty lies in separating the complicated from the uncomplicated ones, as this disease, above all others, is very deceptive. Many cases which give every indication in the beginning of a happy termination end abruptly in death, and the converse; hence, we must resort to a method based upon more rational grounds if we would make any advance in the treatment of this affection, which seems to disorganize the blood *ab initio*. For a number of years it has been claimed by Sternberg, Joseph Jones, Bellver Mateo, Pedro Peñuelas, Alfredo García y García, and many other well-known students of this disease that it is a gastro-intestinal affection of microbic origin. Whether the bacillus or its toxins give rise to all the train of symptoms or not matters little, as the treatment, based upon this theory, must be one looking to ridding the intestinal tract of all offending substances, and of rendering it, by the use of antiseptics, unfit for the habitation of the bacillus. Acting upon this theory, Sternberg introduced to the profession his well-known bichlorid treatment; the Spanish surgeons stationed in Cuba—Mateo, Peñuelas and others—their naphtha and benzoate of soda treatment.

Dr. Alfredo Garcia of Santiago de Cuba, reasoning from the well-known fact that yellow fever does not occur in cold climates and that, when it does occur in the temperate zone, it tends to decrease with the fall of the temperature; yet, recognizing that its micro-organism can withstand 110° (centigrade) below zero, he conceived the brilliant idea of producing artificially in the tropics, by means of Cámara Polar, the frigid zone. This Cámara Polar is an ingeniously constructed building, somewhat on the order of our refrigerating storerooms, where the temperature can be rapidly cooled at will. Being a firm believer in the germ theory of the disease and of its well-known infectiousness, and having observed that its virulence was in proportion to the amount of infection present, and believing that each patient was subject to successive infections, during the five or six days of his illness, from the atmosphere around him, laden with the deadly germs contained in the gases thrown off by the skin, lungs, dejecta, and vomit in an atmosphere at a temperature suitable for their growth, he determined that as he could not transport his patients to a climate free from such surroundings, conditions, and temperature, he could at least transport the climate to his patients. He also claimed that the importance of these new infections has been demonstrated by the experiments of inoculation of Cheveaux Walson, Cheryne, and Bouchard, which go to prove that the number of microbes introduced into the organism influences the gravity and intensity of the disease. Garcia does not claim that the Cámara Polar exercises any specific action upon the microbe of yellow fever, but that the cold air of his chamber renders the micro-organisms and their products inert, as biology teaches that the microbe, like the cell, requires a suitable medium in which to live and fulfil its functions. By order of the Captain-General of Cuba a commission of learned medical men met in the military hospital of Havana on August 19, 1892, to discuss this new method. Dr. Garcia presented a list of 68 patients with yellow fever (after subtracting nine who suffered from intercurrent yellow fever) treated during September, 1890, at Santiago de Cuba, with a mortality of four, less than six per cent. Nine cases, all soldiers, were treated then, under the supervision of the commission in the military hospital in Havana, and two deaths occurred. The necropsies showed that one patient had ulceration of the pericardium, while the other suffered from mitral insufficiency together with adhesions of both pleuræ and congestion of the lungs which antedated the yellow fever and for which both soldiers had entered the hospital. The finding of the the commission was that neither of these fatalities was in any way due to the yellow fever or its treatment.

by the Cámara Polar. Now it is well known that the Spanish soldier is, at best, but a poor subject for yellow fever.

Pardon me for taking up so much of your time in describing this treatment, but I did not think any article on the treatment of this dreaded visitor from the Indies, now knocking at our doors, would be complete without mentioning a method yielding such results. For as private practitioners the plan is *not feasible*, yet, if upon further investigation it proves valuable, there is no reason why a hospital, devoted to the treatment of the fever by this method, should not be erected. For the present, we will have to content ourselves with a plan of treatment suitable to private practice.

Hygiene.—The hygienic treatment consists in having the surroundings scrupulously clean; vaults, kitchen-drains, and gutters should be rendered as aseptic as possible by using solutions of sulphate of iron and bichlorid of mercury. Remove unnecessary draperies from the patient's bedroom and let the ventilation be free. Sunlight, that great foe to dampness, molds, and various bacteriologic forms of life, is to be insisted upon when practicable. The microbe of yellow fever, like the thief in the night, seems to delight in stalking in dank, dark places. We know that the bacillus of many diseases seems to owe to molds its power of proliferation, if not life itself. Patients treated in tents prove the benefit of ventilation, sunlight, and freedom from mold. All alvine dejecta, vomited matters, and urine must be promptly removed, and some deodorizing disinfectant used. All forms of excitement, such as much talking, reading aloud, and *whispering* ought to be interdicted in the sick chamber. The attendants must answer questions only, and not lead in conversation. Visitors must be rigorously excluded, and even nervous members of the family when their presence excites the patient. Nothing but cheerful facts should be imparted. The prevalence of the disease, business matters, the death of friends and loved ones should not be discussed. Should it become necessary to call in a consultant the patient's suspicions must not be aroused as to the gravity of his illness.

Dietetics.—There exists a wide diversion of opinion on this subject for the first four or five days. Most of the older and many of the modern practitioners recommend an absolute fast of four days at the least. No less an authority than Dr. Segundo Bellver Mateo, Surgeon-Major in the Spanish army and chief of the body of the military sanitation of Cuba, states in his "Tratamiento Médico del Vómito Negro," published in *Transactions of Pan-American Medical Congress*, 1893, that an absolute fast of at

least five days must be insisted upon, asserting that the American cholera (typhus icteroides), like its Asiatic congener, must be destroyed by hunger and drowned in water (matalos de hambre y en agua a porgarlos). We cannot treat lightly the opinion of one whose table of mortality shows such brilliant results. He claims a death-rate of 1.5 per cent. in cases wherein treatment is commenced within twelve hours of the invasion of the attack; 3 per cent. in those of the second twelve hours of the first day; 13 per cent. in those of the second day; 30 per cent. in those of the third day, and 70 per cent. in those of the fourth and fifth day. Figures, if true, needing no comment, figures which show that the fate of the patient is dangerously compromised by delay—each twelve hours augmenting the danger. This point is further emphasized by the statistics of the Military Hospital of Havana, where the same relative results are obtained under a different plan of treatment. It will be seen from this the imperative necessity of promptness in beginning treatment, a necessity so great that to neglect it were criminal. Dr. H. D. Geddings, Past Assistant-Surgeon, United States Marine Hospital Service, advises milk and lime-water for the first few days, then light broth, with fat removed, and as the fever defervesces, soft-boiled eggs, milk-toast, bits of the white meat of chicken, and small portions of very tender broiled steak; the variety and the quantity of food to be cautiously increased for ten days at least before the patient's customary diet is allowed. Dr. C. Faget (*vide* Annual Report of U. S. M. H. S., 1894) recommends, from the beginning, milk in abundance, broth two or three times daily, and from two to six soft-boiled eggs a day. Dr. Alfredo Garcia does not advise any food before the third or fourth day, unless Jaccoud's tonic; brandy and gin can be classed in that category. These he administered sparingly during the first few days, as stimulants, not food. Dr. Viegas, a highly educated physician (four-years' study in the French capital), and a practitioner in Cuba for years and now a temporary resident of this city, assures me that he, together with many, if not all "practical" physicians in Cuba, prohibit all food the first few days, and after defervescence takes place its administration is cautiously begun and carefully limited as to quantity and digestibility. Our own distinguished colleague, Dr. Matas, pursues a similar plan.

I will not tire you by citing other authorities for this preliminary fast, varying from three to five days, *pro re nata*. In this connection we can all appreciate the aphorism of the great Sydenham, that "one-fourth of what we eat keeps us and we keep three-fourths at the peril of our lives." Let us look into

the *rationale* of this fast. First, yellow fever is *not* a wasting disease, hence needs no preparative treatment; second, the short duration of the fever precludes the necessity for sustenance; third, the action of the liver, kidneys, stomach, and intestines, together with their digestive apparatus, are so badly handicapped by the deadly micro-organism of this disease, or its toxalbumins, as to render the absorption of any food improbable, if not impossible; fourth, as the liver, by reason of its degeneration, is no longer able to filter the bile from the blood, and the kidneys, for the same reason, the urea—it holds good, founded on practical experience, that to add further material in the shape of food to the already surcharged blood-current were to add fuel to the flame.

When the patient's condition warrants it the physician, at his discretion, may select from the following diet-list: Sweet milk, buttermilk, Horlick's malted milk, whey, white of a raw egg in half-glass of ice water, soft-boiled and shirred eggs, Valentine's beef juice, broths, well skimmed and strained, of chicken, beef, or mutton; oyster stew (not the oysters), corn-meal gruel, and oaten porridge. That preparation so much in vogue during 1878, miscalled beef-tea, cannot be too severely condemned, as it is neither beef nor tea. Most of the beef extracts in the market are valueless and should never be ordered. The best extract of beef, by all odds, can readily be made by expressing the juice from a rare round steak, free from fat, by means of a cheap meat extractor obtainable at any hardware store. The juice thus obtained, rich in albuminoids and organic salts, after being properly seasoned, is readily digested and extremely palatable. It should be taken as soon as made—hot. Should stimulation be required, champagne (dry preferred), brandy, rum, gin, Ducro's Elixir, Panopepton, elixir coca erythroxyton, hypodermics of strychnin and trinitrin will be found of great value.

Neither fruits nor vegetables should be allowed until convalescence is well assured.

Therapeutics.—Granting that Sanarelli is correct in believing the germ of this fever to have its habitat in the blood itself, and not in the gastro-intestinal tract, the fact still remains that yellow fever must be classed and treated as a septic disease, and the intestines, reeking with fetid and at times putrid contents, as evidenced by the odor of the dejecta, must be swept out promptly, and kept swept out, to prevent auto-intoxication. Granting Sanarelli's claim true, and let its logical sequence—serum therapy—follow, we would still have to remove the results of these germs, just as we open an hepatic abscess to remove the pus caused by a streptococcus or a

staphylococcus, or the bacillus coli communis. All of our energies are bent on curing this septic fever by removing—not the *fons et origo*, the coccus—but the detritus, the pus, that slowly but surely is sapping the patient's vitality.

Intestinal antiseptics has been practically abandoned by even its most ardent admirers, for the average micrococcus seems better able to withstand germicides than his host. What an array of these germ-destroyers have been flaunted before the profession during the past ten years! and what claims have been made for them by our manufacturing pharmacists! Although we now recognize our utter inability to asepticize the intestinal tract, we can remove therefrom, by means of enemata, medicated or not, and purgation systematically employed, the great mass of septic matter.

Furthermore, we have reasons for believing that we may render the remaining contents of the intestines less actively poisonous by the use of such remedies as naphthols α and β , salol, benzoate of soda, bichlorid of mercury, peroxid of hydrogen, and so on to the end of the list. I have purposely left out the latest aspirant to public favor—formaldehyde—though its claims seem based upon good grounds. Believing this, the first indication in this disease would, logically, be the administration of a prompt and efficient purge, to be repeated if necessary; for, bear in mind that constipation, in this disease, is the rule. I deem it very important to state that I consider salines preferable to all others; and, furthermore, I place sulphate of soda at the head of the list, and this in doses of from 1 to 2 ounces in 6 ounces of water, *pro re nata*, to be repeated if vomited, for the following reasons: on account of its well-known action upon the liver; then it is the most active of the series, and last, though not least, it has stood the test of that hot-bed of yellow fever, Cuba, and is habitually employed by many of the eminent practitioners of that unhappy island.

Within two hours after the administration of the saline, I would put the patient, by preference, upon Sternberg's modified bichlorid treatment, which is:

℞	Natrii bicarbonatis		3 iv
	Hydrarg. bichlorid		gr. ss
	Aquæ dest.		O. ij.

M. Sig. One and a half ounces, every hour, ice cold.
—THE MEDICAL NEWS, vol. liv, June 15, 1889.

This treatment was used very successfully at Jacksonville, in the Garcini Hospital, Havana, and at Rio de Janeiro. In the first-named place, a mortality of 4.7 per cent. in 106 cases was obtained. The twelve patients so treated at Havana all recovered. Of the four in Rio one died.

Or I would order Beta Naphthol in $7\frac{1}{2}$ grain

doses every hour or two, according to the indications, to be supplemented by a drink to be taken *ad libitum*, composed as follows:

R	Natrii benzoate	3 ijss-ij
	Sacchari albi	3 ij-3 iv
	Aquæ dest. . . .	O. ij.

M. Sig. To be drunk freely, mixed with an equal quantity of seltzer water, ice cold.

This is practically Mateo's formula. Copious enemata of from one to three quarts of cold water, containing 2 ounces of sulphate of soda, should be administered each day, and high rectal irrigation by means of the tube is especially commended. The effect on the well-being of the patient and the temperature is often most marked. In spite of the well-known inhibitory effect of the anilin derivatives over the oxygen-carrying power of the blood and its ozonizing function, as well as their cardiac depressant effect, I would *yet* recommend, as do Drs. Geddings, C. Faget, and many others, their moderate use, the *first twelve* hours and no longer, under *any consideration*. Usually, one dose of acetanalid grains 5, or phenacetin grains 7 or 8, suffices to calm the excited patient and relieve his intense cephalalgia. The well-known analgesic properties of these drugs commend them. Never should more than three doses be administered to any patient. It is customary with some timorous practitioners to combine the citrate of caffein with these remedies to counteract their depressant action. This I believe to be based more upon theory than practice.

Of course, the use of pleasant effervescent purgatives, such as the solution of the citrate of magnesia, is not condemned, but, on the contrary, endorsed where the state of the stomach demands it. Castor oil, like hot drinks, is only mentioned to be condemned. With the olive-oil and lime-juice treatment I have no experience, but I would state that the Cubans esteem it very highly. Should nausea prove obstinate, all medication *per oram* and drinks should be discontinued, and a hypodermic of $\frac{1}{4}$ -grain of cocain hydrochlorate be given, or else $\frac{1}{6}$ -grain of morphia combined with atropia gr. $\frac{1}{10}$. Cracked ice is often an efficient remedy. Creosote, also, is of great repute here. Sinapisms and dry-cups to the epigastrium are also valuable, as I can personally attest.

It has seemed to me that a mixture composed of Liquor ammoniæ acetatis and acetic ether, in sweetened water, has had a most happy effect in many cases treated by me; but I fully realize that such treatment is purely symptomatic. Salicylate of soda is inferior to the benzoate in several particulars and superior to it in none, hence it cannot be recommended. For the reduction of hyperpyrexia I re-

gard nothing so good as cold water—baths, spongings, and enteroclysis. Patients should also be encouraged to drink cold water freely.

Dr. A. P. Merrill used, in 1820, during the epidemic at Bay St. Louis, nothing but cold shower-baths for reducing hyperpyrexia, the patient being well rubbed and covered up afterward. His treatment was calomel gr. xx, or oil, bleeding to faintness, and shower baths. Diet: Corn-meal gruel. Merrill claims to have treated 700 of Zachary Taylor's soldiers, with a mortality of seven. He claims equally favorable results elsewhere. Could it be possible that the results were due to his treatment or in spite of it? Personally, I believe judicious blood-letting in selected cases to be very valuable. I can never forget an accidental bleeding I gave a young girl, suffering from intense cerebral congestion and profoundly unconscious, the dreaded black vomit, harbinger of death, being hourly expected. I applied at midnight six large leeches, three on each side of the neck, swollen with its turgid vessels, directed the nurse to remove them when they had gorged themselves; went to bed and was aroused at 4 A.M. with the cheerful news that the girl was bleeding to death. The blood had saturated the mattress and run in a little stream on the floor to the fireplace, half-way across the room. I found my patient well-nigh exsanguinated, her face blanched, but her intellect clear, and she was practically convalescent. She made a good but slow recovery. Viewed from Sanarelli's standpoint, the loss of that amount of blood meant also the getting rid of just so many bacilli, and was scientifically, what it proved to be practically, good treatment. This subject will be briefly alluded to under the surgical caption.

The exhibition of the cinchona salts in yellow fever is believed to be productive of no good results, but of several untoward ones—notably, that of predisposing to hemorrhage, and of intensifying the nervousness. Unless malarial complications are *well* defined, these salts should never be given. I see no reason for Blair's celebrated initial treatment.

R	Calomel	gr. xx
	Quinin	gr. xxiv.
	At one dose.	

Very many remedies have been suggested for checking black vomit, which, being but the result of the hyperemic condition of the stomach, should not be treated as a cause, but as an effect. Dr. Faget places great reliance upon the tincture of the chlorid of iron; Dr. Llenas of Santo Domingo, upon the perchlorid; others upon ergot. These and all other remedies are but broken reeds to lean upon at this crisis of the disease.

Quite a number of patients recover after this symp-

tom develops under any or no treatment, but not on account of it. The most fatal of all symptoms, anuria, taxes the physician sorely, and many are the expedients resorted to for stimulating renal secretion, but, in the vast majority of cases, all prove useless in the hour of need. Gone is my faith in nitre, watermelon-seed tea, local applications of squills and digitalis in equal parts (quijano), and the much-vaunted pilocarpin—that remedy which was supposed to make the skin take on the vicarious action of the kidney. That pilocarpin sometimes does good, and oftentimes harm, I do not deny. Wet cups have seemed to be beneficial at times; but in this connection it may not be amiss to state that *cured* cases of anuria often turn out to be cases of retention. Patients do recover after the occurrence of this grave symptom—but not many. That most violent and painful of all counter-irritants, the moxa, holds out some faint hope in this direction. Turpentine in dram doses, now readily administered in Planten's hard or soft capsules, is often given in this country; whereas gin, practically possessing the same therapeutic effect upon the kidneys, is given the preference in Cuba. This remedy is worthy of trial.

Surgical Treatment.—Intravenous injections of normal saline solution; toxidiffusion; blood-letting; hypodermoclysis; cupping. Great results are obtained from the use of the first of these procedures. Dr. Mateo considers that he has wrested from the very jaws of death a number of patients suffering from anuria by this means. There is no question about the very great value of this saline solution injected into the veins, in just the very conditions so often found in yellow fever—septicemia, uremia, and lack of arterial tension. This solution should be sterilized and perfect asepsis enjoined in its use. When the vital powers are flagging great good may be expected from it. Two or three pints of sterilized normal saline solution thrown into the circulation often acts magically. Toxidiffusion is strictly in line with modern thought, as, by its use, a portion of blood charged with septic matter and laden with microbes is removed from the patient, and an aseptic, life-giving fluid substituted. This added fluid serves to attenuate the remaining blood and renders it less septic. Blood-letting is only useful at the commencement of the disease. It is then often very valuable. Dr. J. P. Davidson thought it of unquestioned value. Leeches are embraced under this head.

Hypodermoclysis is but another form of “drowning” the patient—that is to say, of introducing water into the system. It is reported as especially efficacious in oliguria and anuria.

Cupping, once so much in vogue, has, to use Mr. Cleveland's hackneyed expression, sunk into “innocuous desuetude,” a very undeserved fate, as both wet and dry cups are important adjuncts to our armamentarium.

THE SANITARY DISPOSITION OF GARBAGE.

By FRANK DONALDSON, M.D.,

OF NEW YORK;

MEMBER OF COMMISSIONER WARING'S SPECIAL STAFF.

No measure in the sanitation of a city is more fruitful of beneficial results than that embodied in the proper care of the streets and in the sanitary disposition of garbage. In a great city the removal of ashes, paper, and similar waste products is a comparatively simple matter, but the final disposition of garbage is not the least important and troublesome task of the Department of Street-Cleaning. In seaport towns it is customary to tow the mixed wastes to sea and dump them far from shore. This was the method employed in New York until about one year ago, and theoretically, with the strong tides which prevail in the vicinity of the entrance to the harbor, it should have been entirely satisfactory. Such, however, was not the case, the shores of Long Island being continually strewn with a mass of putrifying rubbish, a constant menace to public health. While this practice proved efficient as far as the city itself was concerned, it rendered seashore resorts comparatively uninhabitable during the summer months. Moreover, the absolute loss of whatever valuable products the garbage was capable of producing, when subjected to proper treatment, violated all laws of economy. These considerations led to the establishment of crematories or reduction-plants, not only for New York but for other cities, notably Philadelphia. Early attempts to get rid of garbage and at the same time to derive benefit from its destruction were defective, but the evolution of the process and final triumph was worked out by the authorities of New York City, and it furnishes an interesting and instructive lesson.

The first efforts in this direction resulted in the building of an ordinary furnace, a long brick affair with provision at the top for dumping in whole cartloads of rubbish, and an arrangement for maintaining a fire. Many noxious fumes were driven off by this process, and a second fire was maintained near the entrance to the chimney or smokestack, through which all the fumes passed and were largely decomposed and destroyed. Such furnaces simply destroyed the waste, and to that extent were satisfactory; but in order to extract products of commercial value from the garbage elaborate modifications were necessary. The process, as now conducted at Barren Island, will perhaps be best understood by

following the garbage in the various processes to which it is submitted. The garbage, separated from ashes, paper, tin-cans, and such waste material, is collected daily from each house in the city. The garbage-carts make their rounds on schedule time, and each householder sets out the garbage-can on the sidewalk, as nearly as possible, at the time the cart is expected. The scows promptly receive the contents of the carts at the dumping-stations. Thus, the average exposure of the garbage is eighteen to twenty-four hours, this time being necessary for loading a scow. Six hours are required to unload a scow, after which it is cleaned and disinfected before returning for another load. The average daily amount of garbage reduced during September was nearly six hundred tons, which is considerably less than the daily capacity of the reduction-plant. The receptacles are kept as clean as possible, their contents are dumped into carts and conveyed to scows moored at convenient dumping-places along the water-front, and these are towed by steam-tugs a distance of ten miles to the reduction-plant at Barren Island, on the southern shore of Long Island. Here the contents of the garbage-boats are carried by machinery up an inclined plane to the top of one of the buildings and dropped through chutes directly into perpendicular cooking-tanks, or digestors, about fifteen feet long and five feet in diameter. These number forty-eight, and are steam tight. The garbage is cooked by steam, which is forced through pipes opening into the bottom of the digestors. This process is continued five hours, at a temperature of about 300° F. This not only disintegrates, but completely sterilizes the contents of the tanks.

The cooking being completed, the mash is emptied into sheet-iron receiving-tanks, from which it is received into bags about thirty inches square. The filled bags then are placed in presses. The presses are sufficiently large to receive nine of these bags, one above the other, with appropriate slats between. Gradual pressure is applied, and the liquid as it is forced out runs into a tank, and the grease contained therein, as it rises to the top, is removed and placed in barrels for transportation. This grease is used largely for wheel lubrication, but some of it is refined and finds its way into other channels. The dark liquid remaining was formerly allowed to escape into the ocean, but it is now passed through a series of condensers, the final product being a substance rich in ammonia and phosphates. There remains a chemically pure and odorless water which is discharged into the bay. The solid material is then conveyed to the drying-house and placed in a masticating-machine, after which it is taken to the dryers, which are horizontal, steam-jacketed cylinders sixteen feet long, containing

revolving shafts with arms. This drying operation continues from three to five hours, and when the mass, which is called tankage, has been sufficiently reduced, it is conveyed to the storage-floor, where it is put into bags for use as fertilizers. This fertilizer-filler formerly came from the dryers as very fine powder, and had a distinct odor; but recent improvements have been made, and the filler now comes out in the form of coarse grains. In this the odor is less, and there is no possibility of its being carried by the wind.

The relation of such a factory to the health of the community in which it is located is naturally determined by the cleanliness of the building and machinery, the condition of the garbage-water, and the manner in which it is disposed of, and the character and amount of odor which escapes. The sanitary condition of the building and machinery is such that little more odor is noticeable than that naturally arising from a large kitchen. This is accomplished by preventing the escape of the unpleasant gases which result from the cooking process. These gases are drawn through condensers, and after being chemically washed, are discharged into the bay diluted with from 50 to 100 times their volume of salt water. The grease is conveyed through closed pipes and promptly barreled, and the dark foul-smelling liquid from which it is drawn off is in its turn condensed, and finally escapes as a chemically pure, limpid water. Moreover, it has been demonstrated by this plant that as a mercantile enterprise the results are most satisfactory.

In making these assertions regarding the absence of objections to the presence in a neighborhood of a reduction-plant, like the one described, the writer is cognizant of the fact that many complaints have been made about the odors which at times annoy the inhabitants of the shores of Long Island, and which have been, and still are, attributed to the reduction-plant. Undoubtedly, as the plant was originally set, much of the odor complained of came from the cooking garbage, but the method as conducted to-day is practically free from these charges. When we consider what a menace to public health putrifying garbage in the streets and alleyways of a large city and along the neighboring shores is, the great importance of its prompt collection and sanitary disposition can hardly be exaggerated. At the present time, the question of garbage disposition seems to be satisfactorily answered by the success of the Barren-Island plant.

It is a significant fact that during the past summer the death-rate in the city of New York has been less than at any time in its history. No one would affirm that the clean streets and prompt disposition of the

garbage has been the only factor in producing this result, but undoubtedly it claims its fair share of credit. The Commissioner of Street Cleaning, in a recent article, declares that the improved methods of disposing of garbage has contributed largely to the reduced death-rate. The average death-rate from 1882 to 1894 was 26.78 per thousand; during 1895, 23.10; during 1896, 21.52; and during the first half of the year 1897, 19.63. He further calls attention to the important fact that if the latter figure is maintained throughout the year, there will have been 15,000 fewer deaths than there would have been had the average death-rate of the thirteen previous years been maintained.

THE NEW YORK QUARANTINE STATION AND ITS WORK.

By A. H. DOTY, M.D.,
OF NEW YORK;
HEALTH-OFFICER OF THE PORT OF NEW YORK.

THE New York Quarantine Station is well equipped for the protection of this port against the entrance of infectious diseases. During the past two years active experimental work has been in progress at the laboratory connected with this department. The pathogenic organisms, the bacilli of the plague, cholera, anthrax, and diphtheria have been cultivated and studied. In conjunction with this the germicidal power of different disinfectants, particularly steam and formaldehyde, has been carefully investigated. The results obtained, which were very satisfactory, have already been published in the *American Journal of the Medical Sciences*, August, 1897, and the *New York Medical Journal*, October, 1897.

We are now dealing with facts, not with theories, and are able to perform disinfection in a prompt and scientific manner, with a certainty as to the result. Thorough disinfection is one of the great safeguards in preventing the extension of infectious diseases. Without it we are practically unable to deal with such an emergency. The failure to appreciate the importance of this has frequently been followed by disastrous consequences; therefore, every effort has been made at the New York Quarantine Station to prepare for the disinfection of vessels of all kinds. With the improvements which have been made during the past two years, including the construction of a disinfecting-steamer and laboratory, and the radical changes which have been made in the disinfecting outfit at Hoffman Island, I feel justified in saying that this station is the best equipped of all in the world. The means for disinfection consist of the steamer "James W. Wadsworth," which is about 115 feet in length and is fitted with a steam-chamber of the most improved and modern pattern, placed in the

stern of the vessel for disinfection with steam. A steel tank or chamber, having a space of 115 cubic feet and constructed for disinfection with formaldehyde gas, has been placed in the forward cabin. In addition, there is a furnace for the generation of sulphur dioxide, tanks for disinfecting solutions, etc. Bath and dressing-rooms are placed on each side of the boat, the ceilings, walls, and floors of which are supplied with enameled metal covering, in order that they may be properly cleaned and disinfected.

On the arrival of a vessel requiring disinfection, the "Wadsworth" steams alongside, and all persons, clothing, bedding, etc., which are to be disinfected are transferred to it. While this is in progress the ship, or that portion of it, presumably infected, is also submitted to a thorough disinfection. In this manner the work is promptly and thoroughly done, and commerce is interfered with as little as possible. This steamer can reach a vessel at any part of the bay or adjacent waters. The vessels usually disinfected by the "Wadsworth" are comparatively small, carry but few passengers, and come from Southern ports, in some of which infectious diseases usually exist. Occasionally, it is necessary to disinfect a steamer carrying a large number of steerage passengers. In such an instance, persons held for observation, with their baggage, and also the bedding belonging to the ship, are removed to Hoffman Island for treatment. The "Wadsworth" acts as a transport, and, after having removed the people to the island, returns to disinfect the ship.

About 2000 persons can be cared for on Hoffman Island. Bath-houses have been constructed which can accommodate one hundred bathers at one time. The large disinfecting-apartment on the island contains three double-jacketed rectangular steam-chambers, constructed of steel, each twenty feet long and about four by five feet in diameter. On the arrival of the persons above referred to, they are conducted to the bath-houses, where their clothing is removed, tied in bundles, tagged, and sent to the disinfecting-chamber. After the bath, woolen gowns are supplied. These are worn until the clothing is returned. These persons are detained until the expiration of the period of incubation.

The hospitals on Swinburne Island will accommodate about 200 patients, and although the buildings are old and not of modern construction, they are well supplied with beds, bedding, and apparatus for heating and lighting, and will answer the purpose until new pavilions are substituted. The State legislature has already appropriated money for the drawing of plans for the erection of new buildings both at Swinburne and Hoffman Island, and as these have been made and submitted to a committee it is ex-

pected that the necessary money for the buildings will be appropriated during the coming winter. Each of the islands is in charge of a superintendent, with a sufficient corps to keep the buildings and property in order and ready for immediate use. This duty is faithfully performed.

During 1896, 252,350 steerage passengers were examined at this station, and out of 12,127 vessels which arrived at the principal ports of the United States during the same year (1896), 6241, or more than one-half of the entire number, were inspected at the New York Quarantine Station. The work of 1897 will show about the same result. During this period, the plague, cholera, smallpox, yellow fever, and typhus have existed in numerous ports throughout the world, which have been in constant communication with New York, and although numerous cases of smallpox and yellow fever have reached this harbor no infection has passed the station. This fact will be appreciated when it is remembered that during certain portions of last year, also of this, from 200 to 300 cases of yellow fever, and an equal number of cases of smallpox, daily existed in the city of Havana. As this place is about three-and-one-half days' journey by water from New York, it is within the period of incubation of both diseases. In order that passengers arriving from Havana and other ports on the north side of Cuba, shall not be a menace to the health of this country, and at the same time that commerce should not be unnecessarily interfered with, it is required that all persons coming from Havana shall be supplied with a certificate to the effect that they have had yellow fever, or are natives of Cuba. In either case these persons are rarely subject to this disease and can be safely allowed to pass quarantine. Persons who do not present these certificates on their arrival are removed to Hoffman Island, there to remain until the difference in time between the period occupied by the passage and five days (the period of incubation of yellow fever) has elapsed. A number of persons thus held have developed yellow fever and have been transferred to the hospital at Swinburne Island. All vessels arriving from Cuban ports are subjected to disinfection. Their crews are not held for observation, as these persons are not allowed to leave the vessels, which are not docked but remain in the stream, where they are loaded and unloaded.

During the past summer yellow fever appeared at Panama and during a short period was quite active. A number of persons who reached Panama in transit to Colon, to embark on the Panama steamer bound for New York, became infected and the disease developed during the voyage; some died and were buried at sea and others were removed at this port.

This condition required careful inspection of all persons on board, the removal of some for observation, and thorough disinfection of the ship. As some types of malarial fever are very similar to yellow fever and are frequently found among the passengers and crew of these vessels, it will be appreciated that a differential diagnosis is not easily made; consequently it is the rule to remove suspicious cases until the diagnosis has been fully decided. I am glad to say that in no instance has a case of this disease reached New York. These results have been secured only after the greatest care and watchfulness on the part of the officers of this department and the carrying out of most thorough disinfection.

In order that authentic information may be procured from ports which are frequently infected, and with which New York is in more or less constant communication, representatives or correspondents have been appointed at some of the Mediterranean ports, Egypt, and South America. For a comparatively small sum these correspondents, who, as a rule, are physicians, keep this department supplied with a knowledge of the sanitary condition of these places. This is usually done by letter, although in some instances the cable is brought into use. Such information is usually more valuable than that which is obtained by the ordinary bill of health issued by a consul or consular agent.

With the arrangements above described I feel confident that the Health-officer's Department of the State of New York is prepared for any emergency which may occur at quarantine.

WATER PURIFICATION HYGIENICALLY CONSIDERED.

BY C. G. CURRIER, M.D.,
OF NEW YORK;

ASSOCIATE OF THE AMERICAN SOCIETY OF CIVIL ENGINEERS, ETC.

(Continued from page 589.)

SKILFULLY constructed sand-beds, usually an acre more or less in area, are capable of purifying river and other surface waters very acceptably, provided there has been formed upon the surface of the fine, top sand layer a delicate and continuous film of confervoid vegetation, silt, and other fine particles which occur in such natural waters as require filtration. Since the first half of this century practical English working has demonstrated this very completely. This principle was introduced into Germany during 1856, but the true merit of the process and the essentials upon which its great hygienic value depends were not fully appreciated till more than a quarter of a century later. It was carried out in a very successful form at the Tegel river-lake supply of the Berlin water-works in November, 1883, to remove the trouble-

some, pipe-obstructing growths of *crenothrix* which resulted from the admission of deep well-waters. There the process has been studied most carefully since that time, and the thorough chemic and biologic results, noted by Proskauer and others, have furnished an invaluable guide to the understanding of the conditions which underlie success with such filters. So, too, have the corresponding investigations by the English Local Government Board and by the Massachusetts Board of Health, whose results are given in detail in their reports published during the last seven years.

It is found that, unlike sewage filters, the sand-beds employed to purify water for public supply do their important work chiefly by virtue of the upper layer of fine sand, and particularly by reason of the presence of an unbroken, fine film allowed to settle upon the surface of the sand before the filtering begins. In proportion to the perfect quality of this very fine straining medium is the efficiency of the filter as regards the separating of all (or practically all) bacteria from the water that passes slowly through the filter-bed. This removal of bacteria is the criterion of hygienic merit. As the flow through is at the slow rate of not much more than four inches an hour, considerable chemic purification of the water takes place during its downward passage through the masses of sand and gravel. On the immense area of sand and gravel surfaces bacterial slime (zoöglea), containing great multitudes of nitrifying bacteria, is attached. As the water, containing one per cent. of oxygen or more (if quite cold), flows slowly over these, the putrescible organic matters present are, to a varying extent, still further converted into inorganic compounds. This chemic change is due to the vital activity of the permanently adherent nitrifying bacteria whose presence, especially at the top, makes an old filter more efficient in this respect than a new one; yet, as Gill and Piefke first showed, simple washing does not cause sand to lose this zoöglea slime. Before the paramount importance of the separation of bacteria was recognized, greater stress than now was laid upon determining the degree of this chemic action. At the most, the chemic improvement is, as Frankland expresses it, "slight," and is not of much hygienic importance as compared with the bacterial efficiency of the film on the surface.

Suppose, then, a plant carefully constructed. It has a settling-basin large enough to hold several days' supply of crude water. Each filtering-basin is an acre or more in area; the firm walls and especially the bottom are water-tight by means of several inches of good concrete. There should be no ventilating pipes rising through the bed, and no projec-

tion or irregularity on the walls to restrict the facility of maintaining a continuous, smooth surface of sand. That of the upper portion of the bed is very fine, although it is not found best to have the grains less than one-fourth millimeter ($\frac{1}{16}$ of an inch) in diameter. Two feet or much more of fine, washed sand (although some have even less than a foot and yet work very satisfactorily, as at Alexandria, Egypt¹), are supported by coarse sand, and this by gravel and broken stone. This makes the filter about six feet deep. In some the sand rests on two courses of porous brick, and is reported to work well. The writer has not tested such thin filters. After filtering for from one to eight weeks, according to the condition of the crude water supplied, the sand surface will have collected so much slime and dirt that it is clogged, and water passes through only very slowly under any safe pressure. Then the inflow is stopped and water is drawn off through the outflow sufficiently to render the sand firm. Practised employees, having broad boards attached to the soles of their boots, go over the surface systematically, shoveling off the upper half inch or more of the fine soiled surface-sand together with the accumulated sediment above it. This is then removed to a neighboring washing arrangement. If this scraping has caused any disturbance of the even surface of the sand, this must be completely rectified, then all made smooth and perfectly level. At times more sand has to be added very carefully to replace that taken away by repeated scrapings. It is largely to obviate this that the sand-layer is made several feet thick at first, for the bacteria-separating efficiency may be equally good or nearly so if even less than a foot of fine sand be present, yet the brief increase in the number of bacteria, with the effluent which comes just after cleansing of the surface, is greater in shallow than in deep filters, probably because of mechanical disturbance of the bed in its deeper parts. The majority of experts think five-foot layers of sand yield better results than very thin beds.

After being cleaned and leveled, the filter-beds should have some of the purified water returned through the outflow pipe until the surface of the sand is just covered. Then crude water is gently introduced, through the regular supply-pipe, until the ordinary working height of three or four feet is reached. Care taken to accomplish this refilling without any disturbance of the sand surface is repaid by superior efficiency of the filter from the commencement of working, and by these means little or none of the first effluent may have to be wasted on account of containing too many bacteria. Before any water flows through, that carefully introduced should be al-

¹ *Ann. d. Hyg. Publ.*, 1895, p. 487

lowed to stand for twenty-four hours. At the end of that time the all-important film will usually have formed upon the sand surface. If the sediment be insufficient, some coagulant, such as alum or iron salts, may be added to produce this; yet the natural film, especially if of minute earthy particles, works best. When once the film is sufficient to separate bacteria properly, as determined by the usual gelatin-culture test of samples allowed to flow through, but not yet turned into the hydrant supply, the filter may begin to work. The impure water above the filter-bed is constantly maintained at the same level, not exceeding fifty inches, and the outflow is automatically regulated so that not much more than four inches flow through the sand each hour. That gives a yield of not more than from two to three million gallons per acre in twenty-four hours. This is the highest safe yield generally considered practicable. Yet in the Twenty-seventh Report of the Massachusetts State Board of Health (1895), pages 517 and 518, it is stated that upon experimental filters of very small size ($\frac{1}{20000}$ of an acre) filtration at the rate of from five to nine million gallons daily has been shown capable of removing more than ninety-nine per cent. of all bacteria! The unfiltered water contained several thousand bacteria, being from the Merrimac River, which at Lawrence contained considerably less than 30,000 bacteria per cubic centimeter, the average being over 16,000. The sand was five feet deep and 0.38 millimeter ($\frac{1}{1000}$ of an inch) was its "effective size," this term indicating the "maximum diameter in millimeters of the finer ten per cent. of the sand grains." (See Twenty-fourth and Twenty-sixth Reports, pp. 541 and 703, respectively.)

Intermittency in operation, while necessary, for sewage filtration, is both practically and theoretically less satisfactory than constant operation without cessation from one cleaning-time to another. This is especially so during winter. These filter-beds work continuously, then, when once the water is started running through them. The clearer the crude water, the longer the interval between cleanings. It is an advantage to employ settling-basins as large as practicable as a preliminary to the filtering process. They are indispensable when the supply is very turbid, such as are, notably, the waters of the Ohio and Missouri rivers. Gravity sand filter-beds, properly conducted and carefully managed, afford, on the whole, the most reliable artificial means of rendering an impure water fit for both domestic and general consumption. At their best they not only clarify the water, but also reduce the average number of bacteria to considerably less than one per cent. of the amount in the original crude water. At the same time, practically all disease bacteria are re-

moved, yet some filters yield very poor results, whether because of incompetent management or through inherent defects in the construction, or by forcing a sand-bed to produce beyond its capacity. When the surface is frozen the results are more apt to be defective.

(To be continued.)

MEDICAL PROGRESS.

The Direction in Which Cancer of the Breast Spreads.—

GEROTA (*Centralbl. f. Chir.*, Sept. 4, 1897) has made investigations to determine the course of secondary infection from cancer of the breast. He finds that the lymph-vessels are intimately associated with the branches of the internal mammary artery. This explains the occurrence of the infection of the retrosternal glands and the early adhesion of the pectoral muscles; and further, the occurrence of secondary nodules in these muscles. He also found that the glands of the thorax do not have independent sets of lymph-vessels but that these are in intimate relation with one another, which explains the spread of cancer from the right side to the left side, or the reverse.

Forty-six Cases of Placenta Previa.—PLATZER (*Centralbl. für Gynäkol.*, Aug. 14, 1897) presents a clinical report of forty-six cases of placenta previa. The results were as follows:

1. After expectant treatment, that is to say, by tampons or artificial rupture of the membranes (23 cases), the mortality of the mother was 0, that of the child, 39 per cent.; really, however, only 18 per cent., as two of the births were premature and in four cases the child was already mascerated.

2. After podalic version and spontaneous expulsion (8 cases) the mortality of the mother was 0, that of the child, excluding two mascerated fetuses, 83 per cent.

3. After version and immediate extraction (13 cases) the mortality of the mother was 23 per cent., that of the child 46 per cent.

From these statistics it appears that extraction is unfavorable for the mother and ought, therefore, to be rejected, even though it is somewhat more favorable for the child.

Paralysis of the Intestines after Abdominal Operations.—

ENGSTROM (*Centralbl. für Gynäkol.*, Sep. 11, 1897) says that paralysis of the intestines which follows laparotomy, sometimes producing death, does not always result from sepsis. He cites four cases in which death followed operation after fifty-seven hours, seven, eight, and ten days respectively. In these four cases there was not the least trace of peritonitis, which there would certainly have been if death had been due to sepsis after such an interval of time. Moreover, in one case the contents of the abdominal cavity were examined bacteriologically one hour after death and were found to be absolutely sterile. According to the author, a careful stimulation and nutrition of the patient, if necessary, per rectum, is a most important factor in preserving life.

The Advantages of Castration in the Defective.—FLOOD (*Jour. of the Amer. Med. Assoc.*, Oct. 23, 1897) presents conclusions upon the above subject drawn from observation of twenty-six cases. The boys were nearly all between seven and fifteen years of age. The first castrations were performed with the idea of preventing masturbation in certain cases in which the habit was most constant and the boy had no sense of shame, in addition to being a confirmed epileptic, and, of course, somewhat feeble-minded. The written consent of the parents or guardian was obtained. In every case masturbation ceased and the boy became fairer in complexion. A few also gained flesh. They became more manageable and more capable of reasoning and less inclined to quarrel. They ceased to give expression to lascivious thoughts and no longer enticed other boys to masturbate in their company. No melancholia has so far followed the operation. The mental effect was always good and in every instance the epileptic spasms became less frequent, though this improvement did not manifest itself until one or two years had elapsed. The effect upon girls was noted in only two cases, in both of which castration was performed before the patients were admitted to the institution. The results were favorable.

Influence of Castration upon the Mucous Membrane of the Uterus.—COHAN (*Centralbl. für Gynäkol.*, Aug. 14, 1897), by experiments upon rabbits, concludes that the immediate result of removal of both ovaries is atrophy of the uterus. The mucous membrane also decays, the changes being similar to those which occur at the climacteric though not identical with them. The causes of the changes in the genital organs which follow castration are unknown. The ligation of the tubes or of the spermatic arteries is of secondary importance in this connection.

The Constitutional Factor in the Causation of Hay Fever.—GRAYSON (*Ther. Gazette*, Oct. 15, 1897) mentions three factors which make up the etiologic combination of hay fever, *viz.*: an external irritant, some intranasal abnormality, and a constitutional element—"defective nutrition." The physician unaided cannot restore the nose to a state of health. In order to overcome the self-indulgence of the patient, regularity is recommended in eating, work, and play, while indiscretions of diet, lack of exercise, objectionable fancies in matters of clothing and bathing, and, finally, vicious excesses, alcoholic, narcotic, or sexual, will require the constant and most determined effort of the patient himself. The whole environment of the patient must be separately studied and provided for in the dietary scheme.

While it is true that if a man takes care of his muscles his nerves will take care of themselves, there is no closing of the eyes to the fact that to the average man exercise is distasteful; therefore, it is the more necessary to be explicit in instructions concerning it. Though there is nothing brilliant about this method of removing the constitutional factor of the disease, what it lacks in brilliancy is more than made up in certainty, and if the patient is possessed of grit and determination it brings a sure reward. It penetrates to and combats the very beginnings of the

pathogenesis, and with this fact in mind, we can scarcely be over-confident in anticipating and prognosticating success.

THERAPEUTIC NOTES.

Pulque, in the Treatment of Scurvy.—IDE (*Phila. Poly-clinic*, July 31, 1897) advocates the use of pulque, a Mexican drink, made from the juice of the *Agave Americana* (century-plant) in the treatment of scurvy and the scorbutic state. Pulque is an acid, unrectified wine, produced by fermentation, and contains in abundance the salts the lack of which is supposed to be the cause of scurvy. In an epidemic occurring in Puebla, Mexico, during 1892-3, 325 Mexican Indians were attacked, and were treated with large doses of pulque. The epidemic was quickly quelled, no new cases arising after the end of a week from the time the remedy was first administered to all the inhabitants.

Lactophenin in the Treatment of Typhoid.—F. GORDON MORRILL (*Archives of Pediatrics*, March, 1897) reports that lactophenin is used in the treatment of typhoid fever at the Boston Children's Hospital, and that 3- to 8-grain doses are very effective, and do no harm, producing a drop of 3.5° F. in the temperature within four hours, and inducing restful sleep.

The Ichthyol Group and Dermatitis.—KLOTZ (*Jour. of Cut. and Genito-Ur. Dis.*, October, 1897) writes of his experience during the last four years with strong solutions of ichthyol, thiol, and tumenol. Thiol has the same therapeutic advantages as ichthyol and costs about the same, but it lacks the well-known and rather disagreeable odor of the latter. One advantage which both possess that has not been mentioned by Unna, to whom their popular use is largely due, is the formation of a film upon the skin, if it is painted with the pure drugs, or a strong solution of the same, say fifty per cent. This film almost immediately forms, is not sticky, and affords an elastic covering which does not shrink, and is readily removed by water. Tumenol is not affected by water, and hence is of service in the neighborhood of the glans penis, etc. Over such a film an indifferent powder, such as the stearate of zinc, should be dusted. These preparations will rapidly relieve pain, burning, and itching in the various forms of dermatitis, including erysipelas, herpes zoster, acute eczema, and acute exacerbations of chronic eczema. Even on moist surfaces no pain worth mentioning follows their application. Unna reported a case of lichen urticarius, in which he painted the entire body of a six-year-old child with a fifty-per-cent. watery solution of ichthyol morning and evening. No doubt its use would be equally gratifying in variola, measles, and scarlatina. In chronic inflammatory conditions of the skin Klotz cauterizes the affected parts with liquor potassii diluted to suit the case. A swab of absorbent cotton soaked in this solution is thoroughly rubbed over the diseased area, which is then washed with water, and dried, and finally painted with ichthyol.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

THE YELLOW-FEVER EPIDEMIC.

AFTER an immunity from yellow fever extending over a period of ten years, the Gulf States have had a rude awakening from their fancied security by another invasion of the dread disease. Compared with previous epidemics the present one has not assumed alarmingly fatal characteristics, nor, thanks to the vigorous enforcement of sanitary and quarantine measures, has it included a very wide territory in its ravages. Still, the number of cases has not been inconsiderable (about 1800 to date) and the deaths have been sufficiently numerous (about 300) to sadden the entire community in which the epidemic prevails. Moreover, alarm among the people has been widespread, regular lines of traffic have been interrupted, and the suspension of business has caused a loss of millions of dollars.

The latest reports from the infected districts indicate fewer cases and more recoveries. Fortunately that natural sanitary agent, Jack Frost, has appeared upon the scene, the quarantine at various points is being raised, and the country is rejoicing in the conviction that the epidemic nears its end.

This incursion of yellow fever has awakened re-

newed interest on the part of bacteriologists, therapeutists, quarantine officials, and sanitarians throughout the country, not only in the etiology and treatment of this disease, but also in more efficacious quarantine measures. This issue of THE MEDICAL NEWS is largely devoted to these subjects, and cannot fail to be of unusual interest and profit at this time.

THE MARINE HOSPITAL SERVICE AS A NATIONAL GUARDIAN OF PUBLIC HEALTH.

THE time, perhaps, has not yet arrived for the management of endemic disease by other than local authority. In dealing with contagious and infectious diseases brought from other countries a national jurisdiction is imperative. Quarantine regulations affect foreign commerce; the detention, inspection, and disinfection of vessels and the management of crews, passengers, and merchandise concern the people and commercial interests of the whole country, and should be uniform and consequently national. For all practical purposes, therefore, the most important function of a guardian of public health is to administer a strict and impartial quarantine against alien diseases, such as plague, cholera, and yellow fever.

The recent terrorizing invasion of our country by the last-named exotic has aroused the people to the point of demanding more efficient protection from foreign and preventable disease. That a guardian of public health is needed no one will deny, but it is needed *at once*, and it must be capable and potent. The speedy creation and organization of a Department of Public Health fulfilling such conditions is impossible. Any effort in that direction would be an experiment, the ultimate results of which could be determined only after years of trial. Such experiments are uncertain except in the single item of expense. It is the duty, therefore, of every thinking, patriotic citizen to urge his Representative at Washington to hasten by legal enactment the endowment of the Marine Hospital Service with full Public-Health duties and powers.

Some captious critics have inveighed against the youth and inexperience of Marine Hospital surgeons. Let such know that the average age of the 16 surgeons is fifty years, of the 26 passed assistant surgeons, thirty-five years, and of the 19 assistant surgeons, twenty-nine years, and let them also remem-

ber that "a prudent youth is superior to a stupid old man."

Marine Hospital surgeons are well educated. Many of them have held and some still hold professorships in medical colleges, in spite of the fact that they are subject to change of station every four years or oftener. For admission to the grade of assistant surgeon they pass an examination, and must have an average of eighty per cent. in all branches. Successful candidates are relatively few. Of the 61 medical officers of the corps, 53 have had a previous hospital experience, 7 have been in private practice, and only 2 have had neither private practice nor hospital service.

There are no men more experienced in the theoretic and practical workings of quarantine than the members of the medical corps of the Marine Hospital Service. They make investigations into the cause, nature, life history, and prevention of epidemic diseases, and work in a laboratory fully equipped with the best modern appliances.

The discipline of the force is excellent. The surgeons assume posts of danger with alacrity, submit to great personal privation and exposure, and unflinchingly face a death which has come to several of their number in preventing and combating epidemic disease. Direct testimony as to the efficiency and capability of the Service has been demonstrated in the present epidemic of yellow fever. In many localities the authorities have asked to have a Marine Hospital surgeon detailed to their district to verify or disprove diagnoses, to direct quarantine matters, to organize detention-camps, and to render other assistance for which their experience and training especially fit them.

The Marine Hospital Service at present is supported by the authority of the Treasury Department and is advised by the Department of Justice. Belonging as it does to the Treasury Department, the Marine Hospital Service can decide and enforce any quarantine regulation properly and promptly.

With judicious additions to its ranks, with added authority and duties, and complete control of coast, border, and interstate quarantine, the Marine Hospital Service would give us what we have never had, a practical, scientific, and effectual quarantine, free from vexations, fees, devoid of unequal, oppressive exactions, and administered with military precision.

In the Marine Hospital Service, therefore, we have an organization ready for *immediate, capable, and potent* administration not only of quarantine affairs, but also of *all matters of Public Health*.

REDUCTION OF GARBAGE: ITS SANITARY IMPORT.

For a period of one week during the past summer the average death-rate per thousand in New York City was less than in any one week since the establishment of the Bureau of Vital Statistics. The weather from early spring until late in the autumn was characterized by sudden exacerbations of extreme temperatures, the thermometer registering over 90° F. several days in succession, to be followed by a period of equal duration in which the humidity was extreme; this in turn succeeded by a period of low temperature. The unusual death-rate, therefore, cannot be justly attributed to the salubrity of the climate; on the contrary, the weather was such as to favor prompt decomposition of animal and vegetable matter and the development of malignant germs. No little credit for the steady improvement in the health of the city must be attributed to the thorough work of the summer corps of inspectors which has been organized by the Board of Health. By means of the information furnished through this source, many cases of simple disease secured prompt medical attendance and all contagious and infectious diseases were immediately suppressed in consequence of the timely action of the health authorities. The marked improvement in the health of the people during the past summer points to some other active agent as the prominent factor in producing these salutary results. It is accepted by all authorities that this agent is none other than the clean streets and efficient method of disposing of the city's garbage and household waste which was inaugurated three years ago, and brought to its present high state of perfection during the recent summer months.

The prominent features of this system are: (1) careful separation of the garbage from ashes and other waste; (2) its prompt collection and transportation to the city's reduction-plant, a distance of about twenty miles, where it is submitted to a process which is fully described in this issue of THE MEDICAL NEWS.

The facility and care with which the streets have been cleaned and the waste collected and disposed of are facts to be noted. The efficient manner in which this is done has contributed largely to the sanitary condition of the city—the heedless methods which formerly characterized the disposition of garbage, the uncertain hour of its collection, the careless handling by which much of it became scattered about the streets, have been effectually corrected. The revolting appearance and noisome odors due to the endless rows of garbage-barrels, which in past years characterized the streets of New York, have disappeared, it is to be hoped, forever.

Not the least important feature of the present system is the economic element which enters into it. By carefully separating such articles as have a commercial value, such as rags, paper, bones, tin-cans, etc., and by extracting marketable products from the garbage at the reduction-plant, it is estimated that even in the city of New York where municipal business is credited with being conducted in the most extravagant manner, one-half of the expense of disposing of the waste products of the city is saved.

The enormous cost of keeping cities of even moderate size in a sanitary condition prevents the adoption of methods to that end; but if it can be satisfactorily demonstrated that fully one-half, and probably in smaller communities a still larger proportion, of the expenses can be extracted from the waste products, thorough methods of sanitation can be brought within the reach of every well-conducted municipality. The experience of New York should prove a most instructive object-lesson to the intelligent communities of this country, situated in more southerly latitudes where infectious and contagious diseases are more rife.

New York maintains a low mortality because its inhabitants are protected in two ways, *i.e.*, by careful and stringent quarantine, and by such sanitary measures as have been detailed. Mark Twain in a recent article describes Mauritius as “an island which depends for its health upon quarantine and not upon sanitation.” The decimating epidemics which periodically sweep over the island render it a by-word and a reproach; but where efficient quarantine and wise sanitation are combined, an intelligent community may laugh disease to scorn in any land and under any sky.

ECHOES AND NEWS.

Medical Students in Germany.—The various German universities enrolled 8232 medical students during the first six months of 1897.

New York Foundling Hospital.—Dr. Henry C. Coe has been appointed Consulting Gynecologist to the Hospital to succeed the late Dr. Lusk.

Bequests to Chicago Charities.—By the will of the late George M. Pullman, \$130,000 will be divided among thirteen charitable institutions of Chicago.

Tubercle Bacilli in a Cigar.—Dr. J. C. Spencer, bacteriologist of the Board of Health of San Francisco, Cal., reports that he discovered tubercle bacilli in a cigar made in China.

Intravenous Injections of Sea Water.—M. Quinton recently advocated, at a meeting of the Paris Biological Society, the use of sea-water instead of artificial serum for intravenous injections.

Dr. Joseph Collins Elected to Professorship.—Dr. Joseph Collins has been elected to the Professorship of Nervous Diseases in the New York Post-Graduate Medical School made vacant by the resignation of Dr. Charles L. Dana.

Abuse of Hospital Charity.—In a recent issue, *The Lancet* comments upon the fact that a pugilist who had defeated his antagonist and won a purse of \$3000 went to a charitable institution to be treated for a broken arm received in the fight.

Death of a Centenarian Doctor.—The death is announced of Dr. William B. Sprague at Cold Water, Michigan. He was born more than a hundred years ago at Malta, Saratoga County, N. Y., and practised medicine until he was ninety years old.

King of Sweden's Donation to Tuberculosis Sanatoria.—On the twenty-fifth anniversary of his accession to the throne, the King of Sweden donated a sum of 2,200,000 kroners to be applied toward limiting tuberculosis by the erection of sanatoria and other means.

Smallpox at Montreal.—Smallpox has again appeared at Montreal, in the person of a young girl who had been attending a school kept by the nuns of the Congregation of St. Catherine, and which has about 500 resident pupils. As a result the school has been quarantined.

Delegate to International Congress of Hygiene.—Major Alfred C. Girard, surgeon, U. S. A., is detailed as a delegate to represent the Government of the United States at the Ninth International Congress of Hygiene and Demography, to be held at Madrid, Spain, April 10 to 17, 1898.

Another Typhoid Epidemic in an English Town.—Typhoid is prevalent at King's Lynn, England, more than two hundred cases having been reported. The cause of the outbreak is attributed by the sanitary authorities to pollu-

tion of the water-supply by surface water after a thunder-storm.

Consolidation Officially Postponed.—The Regents of the University of the State of New York, in accordance with the request of Bellevue Hospital Medical College and the New York University, have reconsidered the ordinance of April 8th providing for the consolidation of the two medical colleges; the matter of the proposed consolidation was laid on the table.

Mismanagement of Sanitary Service in the French Army.—Typhoid fever has recently appeared in many of the garrison towns in France, and its origin has been traced to a faulty water-supply. This has led to complaints of mismanagement of the sanitary department of the army. It is also said that the Commissariat Department has permitted the purchase of meat unfit for food.

Michel Angelo's Collection of Prescriptions.—There has been found in the Vatican Library a collection of prescriptions and directions for treating various eye diseases in the handwriting of Michel Angelo. These were probably obtained from medical friends for his own use, for the great sculptor suffered from an eye trouble which nearly made him blind before he died.

No Football in Georgia.—On account of the fatal injuries received during a game by a member of the University of Georgia football team, a bill was recently passed in the House of Representatives prohibiting football in all universities and other institutions in Georgia which receive aid from the State. A similar bill was also introduced in the Senate.

Notification Fees.—In Huddersfield, Eng., the notification of cases of infectious disease is enforced under a law which provides that a medical practitioner shall be paid the fee of 1 shilling for each certificate. He need not notify, however, and will not be paid any fee in regard to other cases of the same disease occurring in the same house during the thirty days following the date of the first certificate.

Typhoid Fever and Certain Games.—An English practitioner, in writing to *The Lancet*, refers to the fact that many cases of typhoid fever occur in the autumn, and attributes the cause of the disease to games, such as marbles and peg-top, which are played in the street during this time of the year after the cricket season is over. In playing marbles a boy frequently licks his fingers to prevent the marble slipping, and the whip-cord of a top is wet in the mouth for the same reason. In this way germs are conveyed into the alimentary tract. The writer's theory is borne out by the fact that the disease almost exclusively affects boys.

Obituary.—The death from pneumonia of Dr. Joseph E. Culver, of Jersey City, N. J., is announced. He was born in Groton, Conn., in 1823. He studied medicine at Pittsfield, Mass., and also at the College of Physicians and Surgeons, New York, where he graduated in 1849. He was a charter member of the New Jersey Medical

Academy, a member of the New York Pathological and Neurological Societies, and one of the staff of St. Francis' Hospital, Jersey City.—Dr. Charles H. Avery, Secretary of the New York County Medical Society, died of diabetes on the 2d inst., at his home in New York City, in the sixty-third year of his age. He was born in Perryville, Madison County, N. Y. He was a graduate of the Long Island College Hospital, and for more than thirty years practised medicine in New York.

Health Reports.—The following statistics, concerning smallpox, yellow fever, cholera, and plague, have been received in the office of the Supervising Surgeon-General of the United States Marine Hospital Service, during the week ended November 6, 1897:

YELLOW FEVER—UNITED STATES.

		Cases.	Deaths.
Mobile, Ala.	October 30–November 5	74	5
Montgomery, "	October 30–November 3	25	3

Yellow-Fever Notes.—On the night of November 2d there was a slight frost at New Orleans and throughout the State of Louisiana. On the 4th inst. the Board of Health of Louisiana issued an order raising quarantine against all points. Passengers from Montgomery, Mobile, and coast points, coming to New Orleans are obliged to have certificates from health-officers to the effect that for ten days previous to their departure there had been no yellow fever in the houses in which they were residing. All baggage and household effects from the points mentioned will be disinfected at the Rigolets Station under the supervision of the quarantine officers.

No new cases were reported in Montgomery, and quarantine against all points has been raised and travel and trade are no longer restricted.

On the 5th inst. twenty-five new cases and ten deaths were reported in New Orleans. No new cases occurred at Montgomery, Ala., and none at Selma, Ala.; one new case and one death were reported in Highland Park, Ala. Eleven new cases and two deaths occurred at Mobile, Ala. Two new cases were reported at Cayuga, Miss.

On the 6th inst. the record in New Orleans was twenty-one new cases and five deaths; many recoveries were reported. Five new cases and one death were reported in Mobile, Ala., and quarantine has been raised at that place. One new case occurred at Memphis, Tenn., and three new cases at Montgomery, Ala.

Twelve new cases and eight deaths were reported in New Orleans on 7th inst. The general feeling is that the epidemic is practically over. Up to date the cases are as follows: Total number, 1743; deaths, 236; recovered, 940; still under treatment, 566. One death occurred at Montgomery, but no new cases. Four new cases were reported at Mobile, Ala., and one death at Memphis, Tenn. The opinion is expressed by health-officers that the open-air development of the disease is at an end and that it will soon die out.

CORRESPONDENCE.

THE FOURTH DIVISION EXPLAINS.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: The Fourth Division of Bellevue Hospital declines to enter upon a personal controversy as to its action in making such nominations as it has deemed most conducive to the interests of the institution. In the exercise of its properly delegated authority and in its discretion, it recently nominated to the Commissioners of Charities a gentleman to fill an existing vacancy upon the division. This nomination was rejected, and the nominating privilege abrogated in order that a purely political appointment might be made. The division had been unpledged to any candidate, either as a unit or by the action of its individual members. The names of three candidates were presented for its consideration; two were those of gentlemen exceptionally well qualified in every way and representative members of the medical profession, and it was no disparagement to either that only one could be chosen. The third name was that of a very persistent

gentleman, then holding a subordinate position, whose appointment, it was thought, would be in every way less to the interests of the hospital. The correctness of that opinion may be estimated from the nature of the public communication which we are compelled to notice.

As this response to an editorial suggestion will end, so far as we are concerned, the discussion of an unpleasant matter, and lest silence should be construed as a recognition of the truth of various gross misstatements, it may be said briefly: (1) That the former assistant physician who makes complaint was appointed in 1896 at the request of a political friend, and was reappointed in 1897 at his own urgent solicitation. (2) That no member of the division has ever stated that the name of any applicant for appointment would be refused consideration. (3) That the Commissioners of Charities in returning the nomination did not assign the reasons for rejection and did not ask that additional names should be submitted.

(It may be added that the complainant himself was insistent that more than one nomination should be made, and his own name included, as he at the same time declared that in such case he would be appointed whoever else might be nominated. To have acceded to his demand would have been tantamount to the withdrawal of the nomination already made. His reiterated assertion that he would be appointed whether nominated or not, proved to be true.)

(4) That the Fourth Division submitted no plan for the reorganization of the hospital.

(5) That the intimation that the Fourth Division has refused consideration to any applicant for appointment on the ground of his financial disability, lack of social position, or the fact that his practice was among the poor, is utterly unfounded and unwarranted.

Finally, we are unable to perceive that the appointment of the gentleman nominated would have been in any way an affront to the general profession which we represent in the service of Bellevue Hospital, or to believe that it would have been less acceptable than the one which has been made without our approval.

Adopted at a special meeting of the Division.

W. F. FLUHRER, M.D.,
Secretary.

NEW YORK, November 10, 1897.

TRANSACTIONS OF FOREIGN SOCIETIES.

Paris.

ORIGIN OF HEPATIC CIRRHOSIS—DANGERS OF OPERATIONS UPON THE THYROID IN EXOPHTHALMIC GOITER—IMMEDIATE LAPAROTOMY IN GUNSHOT WOUND OF THE ABDOMEN—INTESTINAL PARASITES AMONG CHINESE AND EUROPEANS IN PEKIN.

AT the session of the Academy of Medicine, held September 7th, LANCEREAUX spoke of *hepatic cirrhosis in alcoholic subjects*. An experience of many years has convinced him that cirrhosis is caused by wine drinking rather than the drinking of strong liquors. Granting the truth of this statement it is necessary to seek for some substance other than alcohol as a cause of the cirrhosis. Lanceriaux believes that he has found such a

substance in the bisulphate of potassium, which exists in considerable quantities in some wines. Guinea-pigs, rabbits, and dogs, which receive daily from 2 to 7 grams (30 to 100 grains) of bisulphate of potassium die in from six to eighteen months with all the symptoms of hepatic cirrhosis. When one considers the exact location of alcoholic cirrhosis it is seen to be situated chiefly in the perilobular branches of the portal veins; and it is rational to believe that the potassium salts introduced into the blood exercise a direct action upon these vessels and the adjacent connective tissue. The sale of wines containing large quantities of bisulphate of potassium (4 to 6 grams per liter in some instances) ought to be prohibited by law.

At the session of September 14th, PONCET spoke of the *dangers of thyroidectomy in exophthalmic goiter*. It is not so much the operation that is dangerous as is the removal of the thyroid gland. Those surgeons who have operated extensively have had cause to regret a number of deaths probably produced by one of two causes: (1) An acute intoxication by the products of an altered gland suddenly discharged in large quantities into the circulation; or (2) grave disturbances in the cardiac and arterial mechanism due to irritation of the sympathetic nervous system. At any rate thyroidectomy in this variety of goiter has an immediate mortality of from fifteen to thirty per cent. The patients die after well-marked symptoms, consisting of a sharp rise of temperature, a pulse of from 180 to 200 per minute, agitation, anxiety, profuse sweating, and finally collapse in from one to three days subsequent to the operation. Because of its dangers the operative treatment of exophthalmic goiter ought to be abandoned, or be confined to resection of the sympathetic in cases in which the tumor is not very large. If it is so large as to threaten suffocation an attempt may be made to relieve the pressure upon the trachea by long incisions over the hypertrophied thyroid gland.

At the session of September 21st, CHAUVEL mentioned an instance in which *immediate laparotomy was performed for gunshot wound of the abdomen*. He advocated in all cases of abdominal wound, whether made with ball or blank cartridges, an immediate laparotomy, and search for, and repair if possible, of injuries of the intestines without waiting for the development of symptoms (a practice which has been followed in America for a good many years).

The *value of a pure water-supply* is clearly shown by a report made by MATIGNON on the relative frequency of intestinal parasites among the Chinese and Europeans in Peking. Among Europeans who, as a rule, use boiled water, ascariides occur in only about one-fourth of the population, a percentage which is far below the occurrence of the same parasite among the Chinese who use water of a poor quality. On the contrary tenia is more common among the Europeans than among the Chinese, due apparently to the fact that the former eat much more beef than the latter.

MOTY read a paper in which he attempted to prove that most *accidents connected with wisdom teeth* are due to the proliferation and inflammation of the epithelial

processes included between the roots of these teeth. The pus of the abscesses thus caused is originally aseptic, but the difficulty it has in reaching the surface causes the inflammation to spread into the dental canals and into the neighboring bony tissue. To this extension is due the gravity of the affection.

Moscow.

At the Twelfth International Congress recently held at Moscow, CZERNY read a paper upon *Therapy of Carcinomatous Stricture of the Esophagus, Pylorus, and Rectum*. In the first of these three situations, one has little to hope from a radical operation. The cancer is only exceptionally situated so high up that an esophagotomy is possible below it. Dilatation by means of esophageal bougies is only allowable in dense growths, as it has a tendency to hasten the destructive processes in soft or ulcerating cancers. The operation to be considered is, therefore, a gastrostomy. Of those methods which have been advocated, one of the latest by Marwedel, is the most satisfactory. Its essential principle is to open the stomach wall as well as the abdominal wall by means of an oblique incision. Using a catgut suture the stomach is fastened to the abdominal parietes, and then opened, and a tube obliquely stitched into its wall. These sutures loosen in five to eight days sufficiently to permit removal of the tube, and feeding is then continued by means of a catheter, while the fistula is readily kept closed between meals by the use of a gauze pad. If the canal shows any tendency to contract it may be dilated with tubes, gradually increasing in size, until the required dilatation is affected. Czerny has performed the operation fourteen times, losing only three patients, one from inanition within the first day, one from pneumonia within five days, and one from ulceration of the carcinoma into the trachea, eighteen days after operation. All the others rapidly gained in weight.

With the development of gastro-enterostomy, resection of the pylorus for cancer has become more infrequent. From 1881 to 1893 Czerny performed the former 20 times and the latter 18 times; since 1893 he has resected the pylorus 10 times, and performed 70 gastro-enterostomies. As the results after the simpler operation are so good, as far as improvement in general condition is concerned, it is unwarrantable to subject the patient to the greater risk of removal of the pylorus unless, as is too rarely the case, it is freely movable. If a radical operation is still a possibility, it of course makes a more favorable prognosis possible; but if the surgeon waits to have the diagnosis established by a well-marked tumor, cachexia, absence of hydrochloric acid, or metastasis, then it is almost surely too late. The best operation is that of V. Hacker, the anastomosis being made between the posterior wall of the stomach and the jejunum. With the aid of Murphy's button and good assistants, this operation may be performed in uncomplicated cases within fifteen minutes. If the stomach is so infiltrated that the posterior wall is inaccessible, the anastomosis may be made with the anterior wall (Wölfler's method). Naturally these are the worst cases, and it is not surprising to find that the mortality from this method

is forty-six per cent., as against a mortality of seventeen per cent. from the method of V. Hacker. In three cases the clinical diagnosis of carcinoma was apparently complete. Nevertheless, they all gained rapidly after the gastro-enterostomy, and ultimately recovered. Czerny is, therefore, in doubt whether the diagnosis was faulty, or whether these were instances of spontaneous disappearance of a malignant growth. Unfortunately no section for microscopic examination was made in any one of these cases. Resection of the pylorus was performed 22 times for cancer, 9 of these patients dying within the first month, 2 of them are still living after thirty-seven and seventy-eight months respectively, with no sign of recurrence.

The permanent results in cancer of the rectum are far more satisfactory than those obtained in cancer of the upper portions of the alimentary canal. Thus, of 109 radical operations, 10 died from the operation; 12 lived or are living less than two years without recurrence; 21, over two years; 15, over three years; 13, over four years; and 8, over five years. When such results as these are possible after a radical operation, palliative measures are not to be considered in suitable cases. It is the duty of surgeons to so improve the technic of the operation as to still further reduce the mortality and the probability of recurrence after operation; and it is the duty of physicians by careful local examination to establish an early diagnosis, and to persuade the patients to submit to early and radical treatment.

In 21 instances the rectum was curetted. As this procedure was twice the cause of perforative peritonitis, and at best had only a temporary good effect, Czerny has abandoned it for colostomy, which he has performed 45 times, with a mortality of seven per cent. Linear rectotomy, which is fitted only for scirrhus cases, and like curetting gives relief merely for a few weeks, has also been abandoned for colostomy. The mortality of the resections of the rectum by the sacral (Kraske) method is 13.64 per cent.; while that of the perineal method is only 3.6 per cent. But this is again an unfair comparison, as the simpler cases alone were attacked by the perineal route. Enough time has not yet elapsed to say which method gives the best ultimate results, though it seems probable that the sacral operation, by affording a clearer field, enables the operator to more surely remove all affected tissue.

The retention of feces after operation depends upon the seat of the new growth. It is a safe rule to cut through healthy tissue at least one inch from the tumor. If this is done, and the whole or part of the sphincter remains incontinence is usually avoided. Even if the sphincter is wholly removed, the use of a rectal irrigation once or twice daily, will in many cases prevent incontinence. Gersuny's plan of twisting the bowel to prevent incontinence has not been found practical.

Czerny said he prefers the parasacral incision. He divides the sacrum below the third foramen, as paralysis is likely to follow a higher section, reflects the bone flap, separates the bowel, ligates and divides it above and below the neoplasm, removes the tumor, secures all bleeding points, and sutures the cut ends of the bowel at least

partially before the elastic ligature is removed from the upper end. The pararectal wound is washed out with a 1-3000 bichlorid solution, and then with salt solution. A large rubber tube covered with iodoform gauze is introduced into the bowel to provide for the escape of feces. Czerny prefers the osteoplastic method as giving a support to the bowel. He sutures the wound very lightly or leaves it open altogether.

Of the palliative operations, only colotomy was spoken of. The relief which follows in cases in which the bowels are evacuated with difficulty inclines one much to this operation in hopeless cases, even though it gives but temporary amelioration of the symptoms. If the carcinoma causes diarrhea and pain the relief after colostomy is less striking, although authors have mentioned instances in which the withdrawal of the irritation of the feces has so benefited the disease, as to render it amenable to operation when before it was not so considered. Nevertheless, the feelings of the patients after a colostomy are by no means universally good; a prolapse of the bowel, or the frequent appearance of fecal masses, are very unpleasant sequels. At its best the operation of colostomy is not a perfect one.

When there is time for this procedure it is best to fix the sigmoid in the abdominal wall, and to open it with a thermocautery from two to six days later.

SOCIETY PROCEEDINGS.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Twenty-fifth Annual Meeting, Held at Philadelphia, October 26, 27, 28, and 29, 1897.

(Continued.)

THIRD DAY—OCTOBER 28TH.

MORNING SESSION.

DR. E. A. DE SCHWEINITZ of Philadelphia was appointed a delegate to represent the Association at the Congress for the Study of Tuberculosis which meets at Paris during 1899.

DR. HOWARD S. ANDERS introduced a series of resolutions in which certain churches were commended for having adopted the use of individual communion cups to prevent the spread of disease, and "recommending to the public the general use of individual cups, particularly in schools, on railway trains, in stations, at public fountains, and the like, as contributory to the better preservation of the public health and the prevention of communicable disease." The matter was referred to a committee.

The Committee on Health Legislation presented a report containing a draft of a bill, very broad in its scope, to create a Department of Public Health at Washington.

RECENT RESEARCHES RELATING TO THE ETIOLOGY AND SPECIFIC TREATMENT OF YELLOW FEVER was the title of a paper read by SURGEON-GENERAL GEORGE M. STERNBERG, U. S. A. (See page 613.)

DR. M. P. RAVENEL of Philadelphia then read a paper, entitled

TUBERCULOSIS AND MILK-SUPPLY,

in which reference was made to the fact that about one-seventh of all deaths are caused by tuberculosis, and the statement was made that in the vast majority of cases man contracts the disease through his food, particularly though milk which contains tuberculous matter. As a remedy, the author advocated the careful inspection of milch cows and the condemnation of all diseased animals, such inspection being made at frequent intervals in order that the presence of the disease may be discovered before it has made much progress. He also advised the sterilization by boiling of milk from suspected cows, and said that under no circumstances should it be given to invalids or children.

THE SANITATION OF CARS.

A paper on this subject by DR. GRANVILLE P. CONN, President of the State Board of Health of New Hampshire, was read by DR. SCHWARTZ. It contained portions of a report of a commissioner on the subject of car-sanitation, which seemed to show that not much is to be complained of on this score. It was said that the present means of ventilating railway carriages and keeping them in a sanitary condition would be better adapted to the necessities of the case, if employees were compelled to carry out the rules and regulations adopted by the railroad companies.

DR. JOHN N. HURTY, Secretary of the State Board of Health of Indiana, said that credit for the adoption of the rules and regulations referred to is due the "Big Four" Railroad Company, which was the first to take action in the matter. On this road the cars are cleaned and ventilated at the end of each hundred-mile trip, the cushions and draperies being taken out, aired and dusted, and the woodwork washed; moreover, every car is fumigated once a month. The speaker said that other Western roads talk of adopting similar regulations, and that the subject was recently discussed at a meeting of division superintendents of the Pennsylvania Railroad.

DR. JAMES of Baltimore remarked that some form of automatic ventilation should be provided in cars, and that the windows should not be used for this purpose, as passengers themselves often make proper ventilation impossible by closing windows which ought to be kept open.

AFTERNOON SESSION.

URGENT NEED OF SANATORIA FOR THE CONSUMPTIVE POOR OF LARGE CITIES

was the title of a paper read by DR. S. A. KNOPF of New York.

The author dwelt upon the importance of the establishment of sanatoria for the reception of the thousands of tuberculous patients of the tenement-house districts of large cities, who unconsciously disseminate the germs of the disease among their relatives, friends, and neighbors, or who fill the wards of the general hospitals to the detriment and danger of the other patients. He stated that a consumptive expectorates during twenty-four hours as many as seven billions of bacilli, which, if not properly disposed of, contaminate others. The sputum containing the bacilli becomes dry and pulverized, and is inhaled in the form of dust. The vigorous and healthy are not so

apt to become infected as are the weak and ill-nourished and the very young.

Reference was made to the Adirondack Cottage Sanitarium in New York State and the Chestnut Hill Hospital for the Consumptive Poor near Philadelphia, where excellent results have been obtained in spite of the fact that at the latter institution very advanced cases are received. The author called attention to the fact that in the villages of Goerbersdorf and Falkenstein, where two of the largest German sanatoria are situated, the mortality from tuberculosis has actually decreased among the inhabitants, being now one-third less than it was before the establishment of the institutions. This can be considered as proof positive that a well-conducted sanatorium for consumptives is not a center of infection. He also expressed his belief that these institutions serve as hygienic educators of the people, in that the inmates set a good example as to the proper mode of life for consumptives to lead.

DR. L. F. FLICK of Philadelphia strongly urged the establishment of hospitals for consumptives, in order that the latter might be removed from the home circle. He said that during the last ten years efforts have been made to educate the people of Philadelphia in regard to tuberculosis by the distribution of literature, and that during this period the mortality of this disease has decreased twenty-five per cent., and he expressed the opinion that if this education can be further extended, the disease will be practically stamped out within twenty-five years.

DR. LYDIA RABINOWITCH of Philadelphia then read a paper on

MICROBES IN BUTTER AND MILK,

in which she gave the results of bacteriologic examinations of various samples of butter and milk. In none of her experiments was the tubercle bacillus discovered.

DR. E. T. STEWART of East Orange, N. J., read a paper, entitled

THE PURIFICATION OF WATER AND DISPOSAL OF SEWAGE,

in which he described in detail the working of several of the large sewage-disposal plants of European cities.

INVESTIGATIONS OF WATER-SUPPLY BY THE UNITED STATES GEOLOGICAL SURVEY.

This report was read by MR. F. H. NEWELL, hydrographer of the United States Geological Survey. It discussed from a geologic or engineering point of view the question of municipal water-supply and stream-pollution, and described the work accomplished by the Division of Hydrography in bringing together facts concerning the daily flow of typical streams in various parts of the United States, showing how the quantity varies from day to day, the results and duration of floods and of low water, and other details connected with the behavior of streams.

FROM SEWAGE TO DRINKING-WATER; A STUDY OF THE NATURAL PROCESSES OF SEWAGE-PURIFICATION AND THE MEANS WHEREBY THEIR EFFICIENCY MAY BE INCREASED

was the title of a paper read by COLONEL GEORGE E. WARING, Commissioner of the Department of Street

THE OPERATIVE TREATMENT OF LUMBAR (POTT'S) ABSCESS.¹

By JAMES K. YOUNG, M.D.,

OF PHILADELPHIA;

PROFESSOR OF ORTHOPEDIC SURGERY IN THE PHILADELPHIA

POLYCLINIC; CLINICAL PROFESSOR OF ORTHOPEDIC SURGERY

IN THE WOMAN'S MEDICAL COLLEGE; INSTRUCTOR IN

ORTHOPEDIC SURGERY IN THE UNIVERSITY OF

PENNSYLVANIA; SURGEON TO THE HOS-

PITAL FOR CRIPPLED CHILDREN.

In the *Transactions of the American Orthopedic Association* for 1891, I reported a case of external lumbar abscess, and suggested a division of lumbar abscesses into external and internal, according to their

FIG. 1.

Internal lumbar abscess, showing primary and counter incisions.

location, relative to the lumbar fascia. During the past fourteen years, a large number of these cases have come under my observation; a few of the abscesses, of small size, have been absorbed under con-

servative treatment, but a majority have required operative interference of some kind.

When the abscess is small and the contents not very thick, aspiration, with or without the use of antiseptic injections, is often followed by the disappearance of the lesion. This is particularly true of external lumbar abscess. When the contents are thick, or consist of caseating material, incision and

free drainage under aseptic precautions is the only plan of treatment likely to be followed by success. The incision must be made at the most favorable point for drainage, and, when possible, through-and-through drainage by means of a rubber drainage-tube or iodoform gauze, will be followed by the best results. When repeated aspirations fail, or when, for other surgical reasons, they do not appear to be indicated, incision and drainage will be necessary. Aspiration has seemed to me to be unsatisfactory and tentative on account of non-withdrawal of caseous clots, except in the cases above indicated. I have not em-

¹ Read by title at the Eleventh Annual Meeting of the American Orthopedic Association, held at Washington, D. C., May 4, 5, and 6, 1897.

ployed injections of carbolic-acid solution because of the reported fatal results, nor early radical operations, especially erosion of the vertebra, for the same reason. Dr. Rupprecht of Dresden informed me nine years ago that after a fair trial he had abandoned the radical operation, because fifty per cent. of the patients subjected to it had died.

FIG. 3.

A case of bilateral lumbar abscess, showing posterior deformity and lateral sinuses.

The different forms of lumbar abscesses are shown in the accompanying table :

Course.	Exit.
<i>a. External Lumbar Abscesses.</i>	
Burrow between the fasciæ of the quadratus lumborum and abdominal muscles, through the internal oblique.	Posteriorly beneath the external oblique and latissimus dorsi at the outer border of the erector spinæ muscle.
<i>b. Internal Lumbar Abscesses.</i>	
1. Enter psoas sheath.	As psoas abscess.
2. Gravitate beneath the internal iliac muscles over the posterior brim of the pelvis, perforating the great sacrosciatic foramen.	As gluteal abscess, or as iliac abscess.
3. May be directed to the iliac region along the aorta and external iliac arteries.	As gluteal abscess.

During 1894, I showed two cases of iliolumbar abscess, and referred to a third, before the Philadelphia County Medical Society, all the patients having recovered after through-and-through drainage. The operation advocated in these cases is performed under strict aseptic precautions. The abscess is opened

by careful dissection, the incision being made in the direction of Poupart's ligament, half an inch to the inner side of the anterior superior spinous process. The external oblique muscle is divided in the direc-

FIG. 4.

tion of its fibers, and the internal oblique at right angles, or the fibers are separated. The contents of the sac are evacuated, and a long, heavy grooved director or eye probe is carefully passed up to a point above the sacro-iliac junction, and a straight longitudinal incision made upon it. The counter incision

FIG. 5.

Diagram illustrating position of the counter incision in a case of lumbar abscess.

in two of the cases reported was half an inch to the outer side above the posterior superior spinous process of the ilium. In one case, in which I was associated with Drs. Willard and Ashhurst, it was con-

sidered advisable to remove a portion of the crest of the ilium with a rongeur forceps, so as to permit the drainage-tube to lie flat in the iliac fossa. This appeared to facilitate the drainage and healing of the abscesses rather than to retard them.

The abscess cavity is thoroughly irrigated with boiled water and boric-acid solution. A rubber drainage-tube is passed through it and secured by safety-pins. This is allowed to remain in place for two or three days, after which it is gradually shortened. Half an ounce of a 10-per-cent. emulsion of iodoform is introduced into the cavity, iodoform gauze packed about the wound, and a bichlorid dressing applied.

The indications for this operation are: (1) When the abscess is large and makes pressure upon important organs. (2) When the abscess is increasing rapidly in size. (3) When there is danger of rupture of the abscess into the peritoneal cavity. In the case of a psoas or gluteal abscess it is rarely possible to make a counter opening, and to accomplish through-and-through drainage, a rubber drainage-tube should be inserted into the cavity as far as possible, and the cavity irrigated daily or every other day with boiled water and boric-acid solution, followed by the use of the iodoform emulsion.

In all cases requiring operation it is absolutely necessary to fix the spine as thoroughly as possible by apparatus of some kind. In one of these cases of ilio-lumbar abscess in an adult female, who was under the care of another surgeon, the abscess sinus would not close until the spine was thus secured.

SYPHILIS OF THE NOSE, THROAT, AND LARYNX.

By PAUL TURNER VAUGHAN, M.D.,
OF HOT SPRINGS, ARK.

PRIMARY syphilis of the nose and nasopharynx is of extremely rare occurrence, but several cases have been reported in which the infection was supposed to be due to contact with improperly disinfected Eustachian catheters. Erythema, mucous patches, ulcerations, and gummata may at various times be found in the nose of a syphilitic patient. Usually the secondary manifestations are so slight that they are overlooked, although they often assume a severe form in infants. A nasal catarrh in a child, when very obstinate in responding to treatment, is very suggestive of syphilitic origin. When attended by copious secretions with resulting formation of crusts in the nose, thus occluding the nasal air-passages, a very aggravating and troublesome complication is presented. Not infrequently tertiary manifestations occur early in the course of the disease, and occasion extensive necrosis, both of the cartilaginous

and bony septum and the turbinated bodies. The necrotic process is invariably attended by a most offensive odor, which must not be confounded with that present in atrophic rhinitis. There is a decided difference in the odor caused by the two affections, which is immediately noticed by the expert. Fortunately for the patient, when necrosis begins there is a decided impairment of the sense of smell, or in some instances this sense is entirely lost. It must be remembered that in individuals who are deficiently nourished, syphilitic ulceration and necrosis progress much more rapidly than in well-nourished subjects, and the chances of recovery without serious deformity are much less.

While working in the clinic of Professor Störk in Vienna, and that of Professor Seifert in Würzburg, many opportunities were daily afforded me to study the effects, both recent and remote, of the various syphilitic affections of the nose, throat, and larynx. Primary sores of the pharynx, while moderately common in some parts of Europe, are of comparatively rare occurrence in America; but should a patient present himself with a suspicious-looking sore in the mouth, with enlarged submaxillary glands, and if these symptoms are followed by the appearance of a skin eruption, there can hardly be a doubt that the condition is one of primary syphilis of the pharynx. The initial sore, when found in the throat, usually lasts from four to six weeks, and does not differ materially from the primary syphilitic sore occurring in any other part of the body. The throat manifestations of syphilis during its secondary stage occur either as mucous patches or as erythema of the fauces. The latter condition is considered by the best authorities to be merely a passive hyperemia of the faucial mucous membrane, which, owing to the very vascular condition of the tissue involved, causes a dark, purplish-red discoloration of the throat, particularly marked in the region of the faucial pillars and of the soft palate. There are no markedly uncomfortable symptoms produced by the erythema. It makes its appearance in from six weeks to four or five months after infection. Some authorities consider the erythema of the fauces, and the cutaneous eruption occurring in the secondary stage analogous, and it has frequently been observed that upon the disappearance of the cutaneous eruption the faucial mucous membrane undergoes desquamation.

Mucous patches are considered a rather characteristic symptom of syphilis, and when present in the pharynx they appear by preference to locate about the base of the tongue, on the tonsils, and on the soft palate. They usually occur as bluish-white elevations, and may make their appearance at any time after the initial lesion—even a number of years after

—but are generally observed as a secondary manifestation. In the tertiary state, gummata usually appear, and at first are situated just beneath the mucous membrane. During their early stages they are very small, and often pass unnoticed for a long time, but they gradually enlarge, soften, break down, and finally a yellow, ulcerating surface is presented. These ulcerations are of two kinds, superficial and perforating, and are generally located upon the soft palate, or the tonsils. Their edges are rather irregular, but sharply defined, and they are covered with a dirty, purulent secretion. Granulations are frequently found under this secretion. The ulcers usually extend rapidly, and destroy a great deal of tissue. Neither cartilage nor bone appears to offer much resistance to their extension, and consequently it is imperatively necessary to stop their progress by suitable medication as early as possible in order to avoid disastrous consequences, particularly from cicatrization after the healing process begins to take place.

The diagnosis of a syphilitic ulcer in the pharynx is sometimes very difficult to make, but one cannot be far wrong in suspecting as syphilitic any ulcer occurring in the throat which has a floor covered by a dirty purulent slough, and which is surrounded by angry-looking, very much inflamed mucous membrane. It has been my good fortune to observe several cases of tuberculous ulceration of the pharynx, and of malignant disease of the tonsils, which simulated very closely ulcers of syphilitic origin, and in which the diagnosis was determined with great difficulty. If ulceration has already commenced in malignant disease of the tonsil before a patient presents himself for examination, the differential diagnosis will be difficult, but when one bears in mind the history of the case, the fact that tuberculosis and malignant disease of the pharynx are rather rare conditions, that tertiary syphilis in this locality is commonly observed, that the syphilitic condition responds readily to treatment, while malignant tonsillar disease is not materially benefited, and that tuberculous disease of the pharynx is positively made worse, and all the symptoms of tuberculosis increased by antisyphilitic treatment, the diagnosis is somewhat simplified. A very safe rule, and one recommended highly by Lennox Browne, is to put the patient upon treatment for syphilis, and have him weighed daily; if he gains in weight steadily for several weeks the trouble usually is of specific origin; if he gains in weight for several days, and then begins to lose, the affection probably is malignant, while if all the symptoms are intensified, the probability is that the disease is of a tuberculous nature.

I have never seen a primary sore situated in the

larynx, but the erythema, mucous patch, ulcerative process, and gummata, followed later by breaking down of the gummy tumor and subsequent formation of cicatricial tissue and occurrence of stenosis of the larynx in various degrees, are, with the possible exception of the mucous patch, common pictures to the laryngologist.

A quite marked symptom in a great many cases of syphilis in its early stage is the appearance of laryngeal catarrh, and only in one particular does this differ from an ordinary catarrh, the last-named variety being usually relieved by topical applications, while they are only of limited value in the specific type, one being compelled to resort to antisyphilitic treatment in order to relieve the condition. The erythema is not so marked and is not so characteristic as when present in the pharynx, but it is sufficiently noticeable, particularly when associated with alternating patches of red and white situated on the vocal cords, to lead one to suspect its specific origin. Pain is generally absent. The condition may last a long time if untreated, but shows no tendency to pass into one of the graver manifestations of syphilis. If the vocal cords are involved there may be much impairment of the voice; in fact sometimes the voice is completely lost. Mucous patches are of exceedingly rare occurrence in the larynx, but when present are generally situated upon the upper surface and free margin of the epiglottis, on the arytenoids, or on the false vocal cords, sometimes being found on the interarytenoid commissure. The mucous patch in this position, as elsewhere in the body, is resistant to treatment and is very likely to recur.

Probably the most common manifestation of the disease in its tertiary form in the larynx is ulceration. This is preceded by an infiltration of the mucous membrane with inflammatory products, and is usually diffuse in character. Gummata are commonly situated near the posterior commissure, upon the arytenoid cartilages and epiglottis. At first they are small and of the same color as the contiguous mucous membrane, but gradually they enlarge, soften, a small yellow spot appears in the center of each gumma, and finally a destructive ulcerative process begins. This is usually rapid, and frequently large areas are completely destroyed. When it occurs on the epiglottis entire destruction of the valve may occur before the patient can be brought under the influence of medicine. When much tissue has been destroyed, there will of course, after healing begins, be a formation of cicatrices, with resulting stenosis, and sometimes distortion of the larynx. When this occurs, the voice is permanently much altered in character.

In regard to the treatment of syphilis, when

occurring in the nose, throat, and larynx, I know it is generally considered that to await the development of secondary symptoms and then begin constitutional treatment, is the better course to pursue; but it appears to me that more favorable results are obtained when the patient is put upon some one of the mercurial salts as soon as the diagnosis of syphilitic infection is absolutely decided upon. Local cleansing of the primary sore with some mild antiseptic, as boracic-acid solution, and dusting it with iodoform, eucalypti, calomel, or better still, with iodoform (a most efficient but disagreeable remedy on account of its penetrating odor) is all that will be necessary during the first stage. Caustics locally applied during this stage undoubtedly do harm. Upon the appearance of secondary symptoms, either inunctions with mercurial ointment, or the internal administration of some salt of mercury, will cause subsidence of the symptoms. When a mucous patch occurs it should be touched repeatedly with tincture of iodine, or solid nitrate of silver. Catarrh of syphilitic origin requires the administration of ferruginous preparations, and the spraying of the nasopharynx with mild antiseptic and alkaline solutions. In the coryza occurring in infants, the nose should be sprayed *cautiously* with a weak solution ($2\frac{1}{2}$ grains to the ounce) of cocaine, or, better still, should be cleansed, particularly when the crusts are very adherent, with a ten-per-cent. solution of menthol in olive oil. Menthol is somewhat similar in its action to cocaine; its anesthetic action is very much less, but it is particularly efficient in that it relieves the congestion of the turbinate bodies and allows respiration to take place through the nasal passages. Upon the appearance of tertiary manifestations the administration of iodide of potassium or sodium is indicated, beginning with doses of from five to ten grains, depending upon the tolerance of the patient, three times a day, and increasing it several grains daily until the progress of the disease is checked. In some cases it is best to combine the iodide with mercurial inunctions. It must also be kept constantly in mind that the alimentary canal, the excretory apparatus, and the skin must receive particular attention. Wholesome, nutritious food is absolutely essential to a sound condition of the alimentary tract. Mild salines and laxatives are occasionally required to stimulate excretion, and nothing is of more benefit in keeping the skin in a healthy condition than warm or hot bathing, which should be regulated by the attending physician. Smoking, and the drinking of alcoholic beverages should be prohibited.

A Surgeon Nominated for Mayor.—The English surgeon, Mr. Thomas Webb Fowler, has been nominated for the mayoralty of Coventry.

**THE PRESENT MORTALITY OF DIPHTHERIA;
UPON WHAT ITS FURTHER REDUCTION
BY THE ANTITOXIC SERUM
DEPENDS.***

BY I. NEWTON SNIVELY, M.D.,
OF PHILADELPHIA;

INSTRUCTOR IN PHYSIOLOGY AND LECTURER ON PHYSICAL DIAGNOSIS IN THE MEDICO-CHIRURGICAL COLLEGE.

THE American Pediatric Society is authority for the significant statement that the results of the serum treatment of diphtheria will gradually and still further improve.¹ The reasons given for this opinion are: that (1) antitoxin is still used at too late a stage of the disease, either on account of procrastination on the part of the physician, or objections on the part of relatives; (2) it is often administered in a half-hearted way, and in doses one-tenth to one-fourth as large as they should be. It has frequently been observed that the percentage of recoveries under this treatment has steadily increased from the beginning. The present mortality from diphtheria—the lowest ever recorded—is pronounced by most observers of large experience with the remedy, especially in private practice, as being too high to represent its powers. "From the most trustworthy statistics which are now available, it appears that the actual mortality from diphtheria (including membranous croup) has been reduced at least one-half by the general adoption of the serum treatment; and that in cases injected during the first two days, the mortality is less than five per cent."²

The mortality from diphtheria under the antitoxin treatment (all brands of the remedy as found in the market being used, and all cases being included irrespective of the time when the treatment was inaugurated) may be stated as follows:³ diphtheria in general, eight to ten per cent.; laryngeal, twenty-one per cent.; operative-laryngeal, twenty-seven per cent.; non-operative-laryngeal, seventeen per cent.; general mortality when antitoxin is used reasonably early, five to seven per cent.; number of cases requiring operative interference, seventeen per cent.

A study of the great volume of literature on the subject shows a pronounced gradual improvement in potency of the serum and the method of its employment. A third element of progress is more than merely implied, *viz.*, a growing appreciation of its efficiency and harmlessness, and a consequent readiness on the part of the physician to employ it. The progress heretofore made in gradually reducing the death-rate of diphtheria⁴ and robbing this disease of its long-sustained high mortality has been made along the line of these three correlated elements of progress.

*Read at the Twenty-fifth Annual Meeting of the American Public Health Association, Held at Philadelphia, October 26, 27, 28, and 29, 1897.

The writer's experience, dating back to the first case treated with antitoxin in Philadelphia (Sept. 22, 1894), corresponds with that of many others, and must become the general experience of the profession in order that the full powers of the remedy may be appreciated. Whereas, in his first cases doses ranging from 400 to 800 units were timidly administered late in the course of the disease (when the condition had become hopeless and other recognized remedial agents had been employed without avail), now, curative doses ranging from 1000 to 4000 units, according to the severity of the disease, are early and boldly given. From three to ten times as many antitoxic units are administered with increasing confidence in from one-third to one-tenth the amount of serum at first required. All these factors have worked together to render the results of the employment of antitoxic serum more favorable.

The further reduction of mortality by the serum-treatment will depend (1) upon still greater improvement in the production and selection of the remedy; (2) upon the general and hearty acceptance of the established principles underlying serotherapy, and (3) upon the employment of the remedy upon a purely rational, rather than upon an empiric basis.

1. The greatest improvement yet made in antitoxin lies in the strength or concentration of the serum.⁵ The most concentrated product now supplied to the profession contains 500 antitoxic units to each cubic centimeter of serum. The serums now available vary in strength from 50 to 500 units per c.cm.; the major portion containing from 100 to 200 units per c.cm., and are not standardized, *i.e.*, a specified number of units is contained in a variable quantity of serum. The great advantage of concentrated serums has been recognized from the first, and only such products are recommended by the American Pediatric Society.³ The smaller quantity of serum required to secure a full curative dose permits of the use of a much smaller syringe and insures quicker absorption. An antitoxin of 400 to 500 units to each cubic centimeter may be administered in full curative doses by means of an ordinary hypodermic syringe. When a small quantity of serum and a small instrument are used, a little patient is not so easily frightened at a time when it is important to avoid every semblance of excitement. For the same reason it is advantageous to administer the serum between the scapulæ where it is not possible for the patient to witness the procedure.

The advantages of smaller dosage and earlier absorption are, however, always secondary to the gain in time required to secure the full therapeutic effects of a given dose. This gain, by the employment of the strongest serums, amounts to several

hours, and is the means of saving many otherwise hopeless cases. This result is due to the smaller quantity to be absorbed and the greater rapidity of absorption. Experience has taught that the more concentrated the serum the more pronounced and immediate are the therapeutic effects. The superiority of tinctures and fluid extracts has led to the almost complete disuse of infusions. Such will also be the case with the weak antitoxic serums when the superior value of the concentrated product becomes generally known. Since the function of antitoxin is to neutralize toxins it may be conjectured that a maximum limit of advantageous concentration probably exists. However, this limit has not yet been reached, and since highly concentrated serums are very difficult to obtain, such a limit is probably not practicable.

In the early days of the antitoxin treatment it was proper to speak of obtaining effects within twenty-four to forty-eight hours. During this time many severe cases necessarily terminated fatally, especially since repetition of the dose was delayed till this period had fully elapsed. At present effects are expected within twelve to eighteen hours, and are early secured in proportion to the degree of concentration of the serum. The general use of concentrated antitoxins of uniform quality will insure increasing success in the treatment of diphtheria.⁶ The importance of great care in selecting an antitoxin cannot be overestimated, as some of the serums upon the market have been proved to contain but one-third to one-half the potency stated on the label.^{7 8 9 10}

2. No therapeutic principles are more firmly established than those upon which the serum-treatment of diphtheria is based. An adequate appreciation of these principles as well as of the indications for the administration of the remedy will produce better and better results. "If an animal has been artificially protected against a particular infection (*e.g.*, diphtheria), its blood or serum acquires the power, when injected in sufficient quantity into another animal, of directly transmitting immunity to the latter."¹⁰ This is a law so firmly established, experimentally and clinically, that it is appropriately called one of the "articles of faith of the bacteriologist." There is no reason why the profession should not accept it. Such acceptance will prove very salutary to the further reduction of the mortality-rate of diphtheria.¹¹

As the remedy is antidotal and the lesion of diphtheria toxic, it follows that in no other disease is an intelligent appreciation of the immutable relation existing between remedy and disease so potent a factor in obtaining the highest possible results from treatment. Similarly, the appreciation of the importance of the early administration of antitoxin is es-

sential to the highest success. The lesion of diphtheria being toxic, and death, if not caused by obstruction to respiration, being due to poisoning, it follows that the longer the tissues are exposed to the action of the toxin, and the more virulent the poison is, the more surely fatal will be the result. To appreciate this is to understand the necessity for the administration of maximum doses in malignant cases and in all cases seen late in the course of the disease, and also to know the importance of supplementary, general, sustaining, and tonic treatment. Jacobi¹² has well said that "many cases might be saved by the timely use of a few grains of digitalis, camphor, musk, or other cardiac tonics." It is expected that a physician will know beforehand whether or not, in a given case, the heart will be likely to carry its owner through an inflammatory or infective process in the absence of sustaining treatment. Incidentally, it may be remarked that when the laity, instructed by the profession, understand the importance of reporting all cases of throat disease early, a further reduction of mortality will easily become possible. The tentative treatment of diphtheria is sufficiently condemned by centuries of high mortality under its general employment.¹³ Harsh mechanical interference merits the same fate.

3. Antitoxin must be employed in the same manner as any other antidote in order to obtain the best possible results. No rule can be formulated for dosage, except that it should always be strictly graded to the severity of the case. A dose containing less than 1000 units should not be regarded as curative, and the general acceptance of this truth will be powerfully efficacious in reducing the present mortality. Curative doses of 500 units, experience has proved, are not to be relied upon. Treated very early, it has happened that several successive cases responded almost miraculously to such doses, while, on the other hand, several others, following these in succession, speedily proved fatal. The severity of the infection is not easily recognized early in the course of the disease. Clinically, it is probably impossible to determine which cases will require the antidotal effect of but 500 units.

The importance of the initial dose, as compared with any other that may be subsequently required, cannot be too strongly emphasized in this connection.¹⁴ No maximum dosage has as yet been determined, and probably never will be. Reports from many large users of diphtheria antitoxin show that at present curative doses ranging from 1000 to 6000 units are employed, and, when graded to the severity of the case are yielding the best results. The necessity of a second dose is evidence that the first did not contain enough antitoxic units. During the in-

terval the tissues are still exposed to the unneutralized toxins, and, meanwhile, the necessity for the remedy is increasing and the resistance of the patient is decreasing. When repetition of the antitoxin is necessary, the interval between doses should be short—when concentrated antitoxin is employed, never less than twelve hours. With this end in view, in the malignant form of the disease from 2000 to 4000 units should be injected as early as possible. One dose of 2000 units, experience has explicitly proved, will result in a larger proportion of cures in this form of diphtheria than will three or four doses of 1000 units each, given at intervals of from twelve to thirty-six hours. The writer's first antitoxin case terminated fatally for want of a sufficiently large initial dose. By aggressive treatment truly moribund cases are saved, as testified by many observers.

The double function of the diphtheria antitoxin is to neutralize toxins and arrest the disease. In pharyngeal types the danger is in early toxemia; in laryngeal types, from suffocation. In the former abundant vascularity and glandular structures favor rapid absorption, and in treatment facilitate the arresting of the disease. In the latter the dense basement membrane underlying the local lesion retards absorption, and in treatment resists the antitoxin. For these reasons, in severe cases of the former, especially when nasal, and in all cases of the latter, the initial dose should never be less than 2000 units.

It should be remembered that it is possible to neutralize the absorbed toxins so slowly or so late that death results from the damage sustained before the remedy was given. Likewise, in laryngeal cases, care must be exercised lest suffocation result from the copious expectoration which follows the full effects of the remedy.¹⁵

While the serum treatment has greatly simplified the management of diphtheria, reduced the personal risk to the physician, and already at least doubled the number of cures formerly obtained, each case continues to be a subject for special study, especially, in regard to the individual adaptation of doses and other measures of treatment.

WATER PURIFICATION HYGIENICALLY CONSIDERED.

By C. G. CURRIER, M.D.,
OF NEW YORK;

ASSOCIATE OF THE AMERICAN SOCIETY OF CIVIL ENGINEERS, ETC.

(Continued from page 635.)

THE cost of constructing a complete filter-bed an acre in size varies from \$20,000 to \$100,000, according to the topography, the availability of suitable sand and other material, the cost of labor, and other elements. An open filter-bed, having tight concrete bottom and sides, with proper regulators and piping, not including settling or receiving basins, may roughly be said to cost at least \$1 for every square foot of filtering surface. Half as much again must be added for a suitable covering to prevent the growth of algæ and keep the water of more even temperature. In northern localities some covering is desirable because of the considerable impairment in efficiency caused by ice during winter. At Hamburg, open filters are employed and successful cleaning of an ice-covered filter is accomplished, without the usual removal of the water, by using a sort of trawl scraper suspended at the right level by floats and moved across the sand-bed. This is explained and very well illustrated in the *Journal für Gasbeleuchtung und Wasserversorgung*, 1897, page 4, a portion of the illustrations and summary of which appeared in the *Engineering Record* for May 1, 1897.

When suitable fine sand is not procurable in the neighborhood, the expense of procuring it may be too great to warrant its use. Crushed quartz, especially adapted for sand-filters, costs at the rate of more than 60 cents per cubic foot, weighing about ninety pounds. When the cost of the sand is thus prohibitive, and when ground enough properly located is not to be obtained at a reasonable price, recourse may be had to mechanical filters, which occupy much less space and require much less sand, since water flows through them fifty or more times as rapidly as through the same area of gravity sand-

bed. While these are more expensive to construct, the operating expense is much less than that of mechanical filters, being mainly that of cleaning and restoring the surface. It may be roughly estimated at nearly \$10 per million gallons of filtered water. It is claimed that a few plants require much less than half this outlay, while others cost half as much again. At Lawrence, Mass., the cost was less than \$7 per million gallons during 1895. Nearly forty per cent. of the expense was for removing ice, while less than half was for scraping and replacing sand. Nearly fourteen per cent. of the charge was for washing the removed sand.

Filter-galleries, situated in the low banks of rivers, are fed rather by ground waters from the upland side than by filtration of river water, which does not filter with practicable speed through the very resistant mud and silt. When the river rises and its water flows into the galleries through coarse sand and gravel, it is likely to render the supply less wholesome by reason of the ease with which bacteria can pass through. Thus, at Dresden, where a ground water-supply of this sort is used for a demand a third larger than originally planned for, it is found that when the Elbe rises more than a meter above its normal level, the bacteria of the water (usually twenty to forty per cubic centimeter) increase to several thousand. With this increase a greater number of gastro-intestinal disorders than usual occur, especially among infants, and their mortality is increased (Meinert). For such filter-galleries it is essential to have water-tight barriers constructed to keep out any inundation or any inflow of water through ground that is not of a perfectly filtering character.

While figures may prove very misleading when not carefully interpreted in the light of the exact conditions obtaining, it is not un instructive to give a few statistics to illustrate the hygienic value of good filtration. The great cholera mortality (8200) at Hamburg during 1892, while the similarly situated neighboring city, Altona, using worse water from the same much-polluted river was comparatively free, was because the latter had good filtration, while at Hamburg the old filters were defective and the new ones not quite finished. The typhoid mortality there is only 58 deaths per 1,000,000, while at Altona it is 41, and at Berlin, between 40 and 65. Amsterdam, filtering water from sand lakes or canals, has but 28 deaths per 1,000,000. These figures compare favorably with those of cities supplied with first-class mountain water, Munich having 32, Vienna 40, and Nuremberg 42 deaths from typhoid per 1,000,000. As against the results of these naturally or artificially pure waters, may be quoted Maline, supplied by

shallow surface wells, the mortality there being 993.¹ This, however, is exceeded by the Chicago typhoid death-rate for 1891, which Hill gives as 1600. He gives that of Pittsburg (for 1893) as 1110, St. Louis (1893) as 1030, and of Lawrence, Mass. (1892), 1020.

Artificial sand-plate filters (Fisher system) are said to be employed with great success at Worms, Westerhüsen (near Magdeburg), and at the Müggel-lake intake near Berlin. The writer has never tested these, but credible reports would make them seem about equal to good gravity filters as regards bacteria-removing efficiency, while the yield is proportionately much greater. If thorough tests, carried out impartially at the last-mentioned station, confirm the excellent results claimed elsewhere, it may well be believed that this method, which seems the revival of an older idea, is practicable on a large or small scale. The plates are easily and quickly cleaned and, like mechanical filters, have the advantage over gravity sand filter beds that they can be sterilized promptly and completely by steam in case of typhoid, cholera, or other infection having entered. They are very strong and have the especial merit of simplicity and freedom from increase of bacteria at the beginning of the flow just after cleansing, as also under a considerable increase of pressure. This would mean that attempts to overwork them, so common with mechanical sand-filters, would not produce such bacteriologically bad water as results from the latter under such circumstances. They are said to be composed of fine sand and finely ground soda-water-bottle glass mixed and heated to 1200° C. The slabs are nearly forty inches square and four inches thick. They are screwed together and the edges cemented. A number of them may be arranged in line to form a pipe into which water filters from without.

In some cases in which filtration is deemed necessary for a municipality, an industrial plant or even individual systems, the slow, gravity-sand-bed system above considered appears impracticable, or less desirable than mechanical filtration, even for a large supply. This may be due to remoteness from a supply of good sand, or the ground may be limited, or other economic reasons may obtain. Whatever make be selected, even including the invertible patterns as that of Kröhnke or of Carl Schultz, it will be quite similar to its numerous rivals. These mechanical filters operate by causing the crude water to flow rapidly, usually under hydrant pressure, through comparatively small masses of fine sand, coke-powder, or similar substance enclosed in cylinders of wood or iron. Mere sand (or coke, etc.) alone will

not be capable of holding back many bacteria, nor will it strain turbid water sufficiently clear, but the preliminary addition of one or two (or more) parts of a coagulant, such as an alum or iron salt, to one hundred thousand parts of water usually causes the formation of a gelatinous film which, settling within an hour upon the surface of the sand and also to a certain extent between the grains, when skilfully managed will cause such a filter to produce clear water which compares favorably with that from good gravity sand-filters. A permeable bottom supporting the sand allows water to flow downward into the outlet and also permits purified water to be driven backward for the (from one to five) daily washings. Upon this a layer of coarse sand or crushed quartz about a foot deep should be placed. This supports a two-foot layer of fine sea sand or crushed quartz (or coke, etc.) of an effective size of from .3 to .5 mm. (from $\frac{1}{80}$ to $\frac{1}{50}$ of an inch). Into the space above this, crude water for purification is introduced after alum has been added.

Both as an expert trying to aid in obtaining the best possible results, and also as an impartial scientific observer wishing to determine how widely such filters vary in efficiency, the writer has tested many of these. While his investigations have been less complete than those conducted at Providence, R. I., during 1893, and at Louisville, Ky., during 1896, as regards thorough and constant study with one kind of water, they yet serve to show the results accomplished by such filters under ordinary as well as expert management in actual every-day use under practical working conditions. Tested regularly and irregularly in this way, mechanical filters generally show less constant and perfect results than do gravity sand filter-beds, but this is more owing to lack of careful management and insight into the principles of operation than because of any inherent defect in the method. Almost all of the various makes will do excellent work, clearing muddy water and reducing the number of bacteria to less than one per cent. of the original amount; and yet some of the best makes, as typified by filters established in permanent operation, and referred to in the makers' circulars, have been found to produce an effluent having more than fifty per cent. of the bacteria (of all varieties) occurring in the crude water. On the other hand, some of them at times are found, without any unusual care, to produce water almost entirely free from bacteria, provided they are worked at much less than their full capacity. Others, when overworked, offer insufficient resistance to bacteria and turbidity. They are comparatively complex and usually dependent upon constant skilled supervision. Their all-important bacteria-separating film, unlike that of the surface of

¹ Smee, *Lancet*, March 13, 1897.

gravity sand-beds, not lasting for weeks perhaps when once established, but rather being destroyed by the necessary washing at least once daily, and perhaps five times, the operation cannot be so well controlled as that of the slow filters. With the latter, the yield may be stored in a separate basin until the usual gelatine test shows whether the film is separating bacteria properly. But with mechanical filters the essential filtering-film must have been removed, as also a number of subsequent ones, under conditions of economic working, long before a bacteriologic test can have been completed. This is a very important consideration especially at times of epidemic and actual infection of the water.

A point in favor of mechanical filters is that they can be completely disinfected by steam or boiling water, the most satisfactory of all means. Within these filters the sand does not remain in as permanently good working condition as in those parts of gravity sand-beds which lie beneath the surface. Accordingly, it needs to be steamed or else scoured with a four- or five-per-cent. solution of caustic soda, or both processes may be employed, at least twice yearly. Otherwise, bacteria, not removed by the daily washings, grow in time so numerous as to contaminate the effluent, and among these may be disease germs. If their presence be suspected, and certainly if demonstrated by culture-tests of the sand or water, sterilization of the filter is necessary. Mechanical filters involve considerably greater expense for operating than do gravity-beds. On the other hand, the plant costs less than the best water-tight slow sand-beds complete. Although alum costs less than two cents a pound, this proves a costly item when used for large quantities of water. When the filter is working well, the proportion of alum used may be only one part to a hundred thousand parts of water, or less than half a grain to the gallon. In practice, however, this proportion of the coagulant is often considerably exceeded, whether through carelessness or because of very muddy or peaty quality of the water, and this of course increases the expense. From such permissible small amounts of alum as remain unchanged in the purified water we cannot recognize any danger to health or detrimental influence upon boilers or industrial processes. This alum is almost entirely decomposed in making the desired film of flocculent alum hydrate and of a combination with organic matter present. The sulphuric acid set free combines with the earthy carbonates present and thus tends to become neutralized. At the beginning of filtration, after the film and dirt have been washed out, an excess over the usual minute amount of the coagulant is commonly added to hasten the formation of the necessary film. What-

ever of the salt remains uncombined is washed out with the first few minutes' flow of water. Since this water has very many bacteria present, it is purposely wasted from well-managed filters. This amount of water wasted varies from three to eight per cent.

While only vertical cylinders are spoken of above, it should be mentioned that horizontal cylinders are in some cases employed in large plants, yet both are the same in principle. Even an invertible one, such as that of Mr. Carl Schultz, or like those used for the Kröhnke deferrating process, work in practically the same way, the peculiar construction being only a modification designed to facilitate cleansing. Mechanical filters may be combined to any number to make "batteries" and thus millions of gallons be produced by one plant. Individual filters vary in size from one foot to ten feet in diameter. Since the water is meant to flow through nearly sixty times as rapidly as through a slow gravity filter-bed, a filter ten feet in diameter, and having an effective filtering surface of about seventy-eight square feet, would be expected to yield from 100 to 250 gallons per minute, but should not be allowed to exceed that amount. Filters one foot in diameter are capable of yielding 100 gallons per hour, and in complete working order cost not far from \$100. They are intended for private houses and serve the purpose of clearing all the water for the household under ordinary conditions, but they cannot respond to sudden demands for a large quantity of good filtered water as the combined draft for laundry, and other purpose, coming at the same moment would produce unsatisfactory water. Accordingly, storage-tanks are needed, and wood will usually be selected as the material. This, and also the filter, usually do not receive careful attention and the water is then too often likely to yield many bacteria when tested. Pure drinking-water would be better insured by a battery of Berkefeld filter-tubes kept in good order and sterile, which, even at present high prices, would prove less costly. A drawback to some of the best varieties of mechanical filters is threatened litigation if the coagulant be added just as the water enters the filter. The Hyatt patent, controlling this, expires within four years. The use of a preliminary settling-tank or basin is not thus restricted, but seems less satisfactory.

Sedimentation is of recognized value in reducing the number of bacteria as well as turbidity of a mass of water, which can remain at rest or nearly so as in storage-basins, and in lakes, or lake-like enlargements of rivers, when the current is very sluggish. Various bacteriologists have found this to be the case, and the writer's studies of lakes and reservoirs, especially when much silt was present, have tended to

confirm this view. The presence of settling-basins, with or without aerifying arrangements for the inflow, is of value as an auxiliary, but is not of enough absolute potency to warrant exclusive reliance upon such means. In most of our streams and bodies of water which receive bacterial contamination from sewage and other filth, sedimentation does not seem to accomplish much. It is, as already said, the element of great dilution which seems to be the chief factor in improvement of the water. Light (which favors the production of algæ) lessens bacteria, especially when the water is well aerified, according to most experiments conducted in that directions; and strife among bacteria is regarded as aiding the process. If a small volume of infectious washings from a privy-vault, manured field, or sewage outlet, mingle with abundant water of a large stream, the tendency to diffusion throughout the large volume of water causes a sample taken lower down stream to show many less bacteria, as well as greatly diminished chemic impurity, unless some intervening contamination complicates the conditions. In small streams, flowing through densely peopled industrial districts, this natural purification is so much less potent that English investigators have declared that a stream much polluted cannot again become pure. In our copious rivers, as also on the Continent of Europe, such an assertion is easily disproved, yet the experiences of some of our cities show that extreme vigilance must be exercised if the water-supply comes from a contaminated river. An arbitrary statement that fifteen or even fifty miles of flow insures the destruction of all harmful contamination is not always substantiated by facts. In this connection, although the same principle has not been shown to be operative in our streams, it seems proper to mention Hankin's observations on the peculiar quality of the water of the great rivers of India¹, in which certain acid substances, volatile on heating, destroy all cholera bacilli that enter the streams, although these dangerous germs increase vigorously in well waters of those regions.

Observation shows that storage for months tends to lessen or remove color and odor from water; but when light is not excluded, algæ are likely to flourish, if nitrogenous elements in an assimilable form, and special mineral constituents, and other conditions, are present to favor their growth. Even when such storage is practicable, it is always preferable to have water in the beginning so pure that none of the causes of odors, such as infusoria, sponges, nostoc, etc., or any dead animal or vegetable matter, are likely to occur. Although such waters are not known to have directly caused disease, a fishy, or other re-

pellant odor or taste, can make a water so offensive that people will not drink it, and it will arouse more emphatic protest than even the known presence of disease-causing germs. If a reservoir be created by damming up and overflowing fertile slopes or meadows, the soil should be dug away so as to remove roots of grass and bushes, may be to a depth of more than two feet; otherwise, decomposing organic matter may cause bad odors to arise in water stored there.

Heat kills the germs of disease and all other living things. If water be boiled long enough, no bacteria or other organisms will remain alive in it. This, in its practical bearings, has long been recognized. The writer pursued a prolonged and careful series of experiments some years ago in this country (chiefly in the Carnegie Laboratory) and in Koch's laboratory in Berlin, employing various natural and artificially infected waters, and demonstrated that simply bringing water to nearly the boiling-point, and then allowing it cool gradually, sufficed to destroy the elements of infection. Thermophilic bacteria and some common kinds require very much longer heating for their annihilation, but practically a brief heating answers the hygienic purpose. This means can be employed almost anywhere and is to be recommended at least as a makeshift under urgent circumstances, as when the water-supply is bad or even suspicious and yet no adequate purification obtains. Since boiling drives off air and also carbonic-acid gas (causing the separation of lime and magnesia), the water in most cases is thereby made somewhat less palatable; although the taste of some malodorous and unpalatable waters is improved by heating. Subsequent aerification, as by use of a bellows or more elaborate appliance for exposing the water to as pure air as possible, effects an improvement. The addition of a small amount of tea improves the taste for some people.

Within the last ten years several economic contrivances for heating water to the boiling-point and cooling it to within a few degrees of its original temperature have been perfected by Yaryan, Siemens, Grove, Rouart, and others. The apparatus of the first-named inventor, as designed for the use of a large municipality, was carefully tested by the writer in Toledo and found capable of completely sterilizing the hydrant water of that city. The principle employed by all these independent inventors is a series of pipes so arranged that by connection the cold inflowing water cools the outflowing sterilized stream and is at the same time gradually heated before it arrives at the boiler. Thus a minimum expenditure of fuel is required. The accompanying illustration (Fig. 4), supplied through the courtesy of Rouart Frères of Paris, shows an apparatus which is claimed to have

¹*New York Med. Jour.*, April 10, 1897, p. 503.

achieved a practical success. The arrows indicate the course of the water from the inflow E. to the outflow F. The yield is of better quality than non-aerified, boiled water, since not much more than half of the oxygen is lost in a well-constructed apparatus. Lime and magnesia are considerably reduced, as also are the other mineral salts and the organic matter. Despite the theoretic merits of these economic sterilizers for water which is clear but infected, they have not found practical acceptance unless in a very limited way.

Distilled water is considered desirable for the most economic and satisfactory results in certain processes, as also for human consumption, when the natural supply is of poor quality, and especially when it is charged with poisonous or other mineral salts. To supply this need at a low cost, on a large scale, excellent stills exist. On shipboard, particularly when the vessel is on a prolonged voyage or cruise away from ports where good, fresh water can be obtained, distilled water, easily prepared and palatable, is not only very convenient as saving the space of storage-tanks (too often defective) and casks likely to become foul, but is also of considerable sanitary value. This is evidenced by statistics of the naval and marine service before and after the introduction of the regular use of the Baird, Niemeyer, and other excellent stills. All properly constructed ones yield water free from bacteria if due care be taken to have the condensing and outflow portion and any filter there sterilized by steam before using. Instructions should also be given to waste for ten or twenty minutes the first flow of water after long disuse of the apparatus. This is to avoid chemic impurities. Lead should never enter into any part of the construction of tanks or stills, for the danger of poisoning is considerable, even from solder. Tin shown by assay to be pure should be used for joints of tin plates and tubes, although

more difficult to work with than solder. Iron rusts, and is, therefore, inferior to well-tinned copper plates or drawn brass coils well tinned inside and outside. Abundant sea-water cools the steam coils by flowing in at the bottom and out at the top on one side of the tight casing inside of which are the smooth or corrugated coils of vertical pipes into which steam under low pressure enters at the top. At the lower end of the condenser the distilled water flows out or is drawn out by a pump where a filter (of asbestos or pure bone, charcoal, and sand) is present, for the purpose of relieving the water of the whitish flecks and oily taste which come from slight quantities of lubricating oil going over with the steam. When the steam pressure is high this oily taste is more likely to occur than when the pressure is quite low, as from an evaporator especially introduced for the sole purpose of vaporizing sea or other water in order that it may, on condensation, become distilled water. From a perfect still very pure distilled water can be produced, having none of the salt or other undesirable constituents of the original water. If petroleum lubricants are used, they tend to cause an increase of ammonia above the small amounts which can be detected in almost all distilled water. At the end of every voyage the filter attached to the condenser of a vessel's still should be cleansed and sterilized by steam sent through the still. The distillate should also be tested from time to time to detect any leakage of the cooling salt water into it. One need only add a drop or two of a solution of silver nitrate, slightly acidulated with nitric acid. If any salt has entered the distilled water, this reagent will produce a visible whitish cloud or precipitate when added to the water in a glass.

Aerification of distilled water should be so managed as to introduce no bacteria, and certainly no harmful ones. Previous filtering of the raw water and boiling long enough to insure the driving off of the more volatile organic matter previous to distillation is regarded by Mr. Hallock, the expert chemist of the Schultz establishment, as the best means of preventing the usual taste of ordinary distilled water, and more satisfactory than the preliminary addition of such an oxidizing agent as permanganate of potash. For the Witteman still the water is twice boiled and superheated before being vaporized. Thus, for artificial ice or artificial mineral waters the maker who is careful enough to use distilled water avoids the necessity of aerifying it, which process too commonly allows the introduction of bacteria of numerous kinds which may be in the air, and which, despite cotton and other filters of the air, are always found in waters of most establishments.

(To be continued.)

CLINICAL MEMORANDUM.

A CASE OF POISONING FROM EATING LOBSTER.¹

By CHARLES SCHRAM, M.D.,
OF NEW YORK.

THE case which is here presented is offered with some diffidence, as I am aware of the vulnerable points in the diagnosis. However, it is the one at which I arrived, and which has been strengthened by the peculiar complex of symptoms manifested during the progress of the illness.

The patient, a married woman, twenty-nine years of age, was born in Russia. I saw her for the first time on the afternoon of October 9th. Her health had always been good; digestion excellent; disposition calm and cheerful. She is the mother of two healthy children, the youngest being ten months old. Nine days previous to the time the illness began a death somewhat unexpectedly occurred in the family the shock of which caused mental depression and impairment of appetite. Four days before coming under my observation the patient partook of boiled lobster, of which other members of the family also ate. Three days later persistent and uncontrollable vomiting began, and the vomitus at first consisted of food taken that morning, then of bile, mucus, and finally everything swallowed was at once rejected. Concomitant symptoms were obstinate constipation, frontal headache, dizziness, excessive thirst, gastric and abdominal pain, severe pain in the limbs and in the small of the back, and ringing in the ears. These symptoms had continued up to the time of my first visit. The patient appeared to be a robust, well-nourished woman. She was anxious, irritable, and apprehensive as to recovery. Her face was pale; tongue thickly coated; breath fetid; skin hot and dry; pulse hard, 112-116 per minute. The lungs were normal; the heart-sounds sharp, but not indicative of disease; abdomen somewhat distended and tympanitic. The abdominal tenderness was general, though more acute over the epigastrium and course of the colon, particularly at the flexures of the latter; there was gurgling on pressure.

I prescribed 8 grains of calomel in divided doses, but through a misunderstanding the patient received eight, $\frac{1}{4}$ -grain tablets; she was given boiled water in abundance, and brandy in dram doses repeated every two hours, no food being allowed. In the evening the temperature rose to 102.5° F., and remained near this point until the crisis of the illness, which occurred three days later. The day following my first visit the vomiting ceased. As the bowels had not moved, she was given 8 grains of calomel in four equal doses, which caused two small liquid movements. There was no amelioration of the symptoms except the emesis. Meanwhile, the bacteriologist, to whom a specimen of the blood had been sent, reported that the Widal test gave a positive reaction; in fact, Dr. Park of the Health Department assured me that I undoubtedly had to deal with typhoid fever. On the strength of this re-

port I placed the patient upon a fluid diet, sponge-baths, and β naphthol-bismuth, beginning with 5 grains every three hours.

On the morning of October 12th the general condition seemed much improved, although the backache and tenderness over the epigastrium and descending colon still continued. The intestinal distention had nearly disappeared. The patient expressed a desire for solid food. As no evacuation of the bowels had occurred during the previous thirty-six hours, an enema of salt water was ordered. This resulted in a large semisolid movement, and was followed, within one-half hour by a severe chill, subsequent to which the patient collapsed and became pulseless. When I again reached the bedside, after an urgent call by telephone, the patient was bathed in a cold perspiration; pulse about 136, feeble, but regular. The mind was clear, though the patient was anxious and momentarily expected death. There was slight dyspnea; excessive thirst; abdominal distention diminished, and tenderness gone. No sharp abdominal pain preceded the chill. The morbid picture presented vividly reminded me of several experiences which I had while an interne in the Boston Lying-In Hospital, when I observed septic patients, after the uterus had been irrigated and curetted, who were seized with violent chills and subsequent collapse.

The stool, following the enema, had been carefully examined by the patient's husband, and in it a piece of lobster, apparently not much altered by its passage through the alimentary canal, was found. The portion of lobster must have remained in the canal just one week. The patient gradually rallied during the night, the pulse and temperature becoming normal. During the week following there was extreme prostration, and from four to six liquid stools daily, containing much mucus but no blood. The urine was turbid during the three or four days following the crisis, blood or albumin not being present. At the present time the patient is up and about.

In reaching a diagnosis three diseases were considered; *viz.*, appendicitis, subacute gastro-intestinal catarrh, and typhoid fever. The first, though strongly indicated by the emesis and rapid pulse, was considered improbable; for the local manifestations were slight as compared with the subjective symptoms. The patient being an adult, the symptoms seemed too grave to be attributed to a simple gastro-intestinal catarrh. The history was rather short for typhoid fever; yet it was most favored in making a diagnosis. The positive reaction to the Widal test seemed conclusive. The crisis, however, and the subsequent course of the illness necessitated a radical change in conclusions. At one time I was forced to consider the possibility of an intestinal perforation following an appendical inflammation. I was glad to conclude that such could not have been the case; as, following the collapse, the patient's condition gradually improved. It seemed to me, therefore, that the illness was due to the ingestion of lobster, the toxins of which had been absorbed, and that the violent crisis was the result either of poisoning by naphthol or of the absorption of a large quantity of

¹ Read at a Stated Meeting of the Harvard Medical Society of New York, held October 23, 1897.

ptomains at one time. The patient received in all thirty-five grains of naphthol, four doses of which had been taken the preceding day, and, if she had been particularly susceptible to the drug it seems as though the symptoms of poisoning would have been manifested at that time. Larger doses have been administered over much longer periods without ill effect. It is, therefore, safe to conclude that the amount of the drug received by the patient was not the cause of the symptoms. Further, the urine did not display evidences of naphthol poisoning. As a final resource ptomain poisoning remains. To this the patient, owing to the temporarily depressed condition of health, was peculiarly susceptible. Symptoms resembling those presented in this case have been observed in other instances subsequent to the ingestion of lobster. The severe chill and prostration were apparently due to the overwhelming discharge of poison into the system. The reaction to the Widal test lends, in my opinion, additional confirmation to this diagnosis; as Aresdarnoro, quoted by Vaughan and Novy, in eleven cases of salmon and sturgeon poisoning, detected in the livers, spleens, and kidneys of the fish, and also in the same organs of those who ate of them, bacilli resembling, but not identical with, typhoid bacilli. Did not such bacilli give the typhoid reaction with Widal's test, and produce the ptomains which, apparently, poisoned may patient?

AN ADDRESS.

INTERNAL MEDICINE AS A VOCATION.¹

By WILLIAM OSLER, M.D.,
OF BALTIMORE;

PROFESSOR OF MEDICINE IN JOHNS HOPKINS UNIVERSITY.

It was with the greatest pleasure that I accepted an invitation to say a few words before this section of the Academy on the importance of internal medicine as a vocation. I wish there were another term to designate the wide field of medical practice which remains after the separation of surgery, midwifery, and gynecology. In itself it is not a specialty, but embraces at least half a dozen, and so its cultivators cannot be called specialists, but bear without reproach the good old name physician, in contradistinction to general practitioners, surgeons, obstetricians, and gynecologists. I have heard the fear expressed that in this country the sphere of the physician proper is becoming more and more restricted, and perhaps this is true, but I maintain (and I hope to convince you) that the opportunities are still great, and that the harvest is truly plenteous, while the laborers, though not few, are scarcely sufficient to meet the demand.

At the outset I would like to emphasize the fact that the student of internal medicine cannot be a specialist. The manifestations of almost any one of the important diseases in the course of a few years will "box the compass" of the specialties. Typhoid fever, for example, will not only go the rounds of those embraced in medicine

proper, but will carry its student far afield in morbid psychology, and sometimes teach him, perhaps at the cost of the patient, a little surgery. So, too, with syphilis, which after the first few weeks I claim as a medical affection. I often tell my students that it is the only disease which they require to study thoroughly. Know syphilis in all its manifestations and relations, and what remains to be learned will not stretch the pia mater of a megaloccephalic senior student.

Each generation has to grow its own consultants. Hosack, Samuel Mitchell, Swett, Alonzo Clark, Austin Flint, Fordyce Barker, and Alfred Loomis served their day in this city, and then passed on into silence. Their works remain; but enough of a great physician's experience dies with him to justify the saying "there is no wisdom in the grave." The author of "Rab and His Friends" has a couple of paragraphs on this point which are worth quoting: "Much that made such a man what the community, to their highest profit, found him to be, dies with him. His inborn gifts, and much of what was most valuable in his experience, were necessarily incommunicable to others; this depending much on his forgetting the process by which, in particular cases, he made up his mind, and its minute successive steps . . ., but mainly, we believe, because no man can explain directly to another man *how* he does any one practical thing, the doing of which he himself has accomplished not at once or by imitation, or by teaching, but by repeated personal trials, by missing much before ultimately hitting."

Wherewithal shall a young man prepare himself, should the ambition arise in him to follow in the footsteps of such a teacher as, let us say, the late Austin Flint—the young man just starting, and who will from 1915 to 1940 stand in relation to the profession of this city and this country as did Dr. Flint between 1861 and the time of his death. We will assume that he starts with equivalent advantages, though this is taking a great deal for granted, since Austin Flint had a strong hereditary bias toward medicine, and early in life fell under the influence of remarkable men whose teachings molded his thought to the very end. We must not forget that Dr. Flint was a New Englander, and of the same type of mind as his great teachers—James Jackson and Jacob Bigelow.

Our future consultant has just left the hospital, where, for the first time, realizing the possibilities of his profession, he has had his ambition fired. Shall he go abroad? It is not necessary. The man whom we have chosen as his exemplar did not, but found his opportunities in country practice, and in Buffalo and Louisville, then frontier towns, and had a national reputation before he reached New York. But would it be useful to him? Undoubtedly. He will have a broader foundation on which to build, and a year or two in the laboratories and clinics of the great European cities will be most helpful. To walk the wards of Guy's or St. Bartholomew's, to see the work at the St. Louis and at the Salpêtrière, to have put in a few quiet months of study at one of the German university towns will store the young man's mind with priceless treasures. I assume that he has a mind. I am not heedless of the truth of Shakespeare's sharp taunt,

¹ Read before the Section on General Medicine of the New York Academy of Medicine, October 19, 1897.

How much the fool that hath been sent to Rome
Exceeds the fool that hath been kept at home.

At any rate, whether he goes abroad or not, let him early escape from the besetting sin of the young physician, *Chauvinism*, that intolerant attitude of mind which brooks no regard for anything outside his own circle and his own school. If he cannot go abroad let him spend part of his short vacations in seeing how it fares with the brethren in his own country. Even a New Yorker could learn something in the Massachusetts General and the Boston City Hospital. A trip to Philadelphia would be most helpful; there is much to stimulate the mind at the old Pennsylvania Hospital and at the University, and he would be none the worse for a few weeks spent still farther south on the banks of the Chesapeake. The all-important matter is to get breadth of view as early as possible and this is difficult without travel.

Poll the successful consulting physicians of this country to-day, and you will find they have been evolved either from general practice or from laboratory and clinical work; many of the most prominent having risen from the ranks of general practitioners. I once heard an eminent consultant rise in wrath because some one had made a remark reflecting upon this class. He declared that no single part of his professional experience had been of such value. But I wish to speak here of the training of men who start with the object of becoming pure physicians. From the vantage ground of more than forty years of hard work, Sir Andrew Clark told me that he had striven ten years for bread, ten years for bread and butter, and twenty years for cakes and ale; and this is really a very good partition of the life of the student of internal medicine, of some at least, since all do not reach the last stage.

It is high time we had our young Lydgate started.¹ If he has shown any signs of *nous* during his student and hospital days a dispensary assistantship should be available; anything should be acceptable which brings him into contact with patients. By all means, if possible, let him be a pluralist, and—as he values his future life—let him not get early entangled in the meshes of specialism. Once established as a clinical assistant he can begin his education, and nowadays this is a very complicated matter. There are three lines of work which he may follow, all of the most intense interest, all of the greatest value to him—chemistry, physiology, and morbid anatomy. Professional chemists look askance at physiological chemistry, and physiological chemists criticize pretty sharply the work of some clinical chemists, but there can be no doubt of the value to the physician of a very thorough training in methods and ways of organic chemistry. We sorely want, in this country, men of this line of training, and the outlook for them has never before been so bright. If at the start he has not had a good chemical training, the other lines should be more closely followed.

Physiology, which for him will mean very largely experimental therapeutics and experimental pathology, will open a wider view and render possible a deeper grasp of

the problems of disease. To Traube and men of his stamp, the physiological clinicians, this generation owes much more than to the chemical or *post-mortem*-room group. The training is more difficult to get, and nowadays when physiology is cultivated as a specialty few physicians will graduate into clinical medicine directly from the laboratory. On the other hand, the opportunities for work are now more numerous, and the training which a young fellow gets in a laboratory controlled by a pure physiologist will help to give that scientific impress, which is only enduring when early received. A thorough chemical training and a complete equipment in methods of experimental research are less often met with in the clinical physician than a good practical knowledge of morbid anatomy, and, if our prospective consultant has to limit his work, chemistry and physiology should yield to the claims of the dead-house. In this dry-bread period he should see autopsies daily, if possible. Successful knowledge of the infinite variations of disease can only be obtained by a prolonged study of morbid anatomy. Of special value in training the physician in diagnosis, it also enables him to correct his mistakes, and, if he reads its lessons aright, it may serve to keep him humble.

This is, of course, a very full program, but in ten years a bright man with what Sydenham calls "the ancient and serious diligence of Hippocrates" will pick up a very fair education, and will be fit to pass from the dispensary to the wards. If he cannot go abroad after his hospital term, let it be an incentive to save money, and with the first \$600 let him take a summer semester in Germany, working quietly at one of the smaller places. Another year spend three months or longer in Paris. Lay schemes in advance, and it is surprising how often the circumstances fit in with them. How shall he live meanwhile? On crumbs—on pickings obtained from men in the cakes-and-ale stage (who always can put paying work into the hands of young men), and on fees from classes, journal work, private instruction, and from work in the schools. Any sort of medical practice should be taken, but with caution—too much of it early may prove a good man's ruin. He cannot expect to do more than just eke out a living. He must put his emotions on ice; there must be no "Amaryllis in the shade," and he must beware the tangles of "Neæra's hair." Success during the first ten years means endurance and perseverance; all things come to him who has learned to labor and wait, who bides his time "ohne hast, aber ohne rast," whose talent develops "in der Stille," in the quiet fruitful years of unselfish devoted work. A few words in addition about this dry-bread decade. He should stick closely to the dispensaries. A first-class reputation may be built up in them. Bryon Bramwell's "Atlas of Medicine" largely represents his work while an assistant physician to the Royal Infirmary, Edinburgh. Many of the best-known men in London serve ten, fifteen, or even twenty years in the out-patient departments before getting wards. Lauder Brunton has only recently obtained his full physicianship at St. Bartholomew's after a service of more than twenty years in the out-patient department. During this period let him not lose the substance of ultimate success in grasping at

¹ This well-drawn character in George Eliot's "Middlemarch" may be studied with advantage by the physician; one of the most important lessons to be gathered from it is—marry the right woman!

the shadow of present opportunity. Time is now his money, and he must not barter away too much of it in profitless work—profitless so far as his education is concerned, though it may mean ready cash. Too many quiz classes or too much journal work has ruined many a promising clinical physician. While the Pythagorean silence of nearly seven years, which the great Louis followed (and broke to burst into a full-blown reputation) cannot be enjoined, the young physician should be careful what and how he writes. Let him take heed to his education, and his reputation will take care of itself, and in a development under the guidance of seniors he will find plenty of material for papers before medical societies and for publication in scientific journals.

I would like to add here a few words on the question of clinical instruction, as with the great prospective increase of it in our schools there will be many chances of employment for young physicians who wish to follow medicine proper as a vocation. To-day this serious problem confronts the professors in many of our schools—how to teach practical medicine to the large classes; how to give them protracted and systematic ward instruction? I know of no teacher in the country who controls enough clinical material for the instruction of classes of say 200 men during the third and fourth years. It seems to me there are two plans open to the schools: The first is to utilize dispensaries for clinical instruction much more than at present is the rule. For this purpose a teaching-room for a class of twenty-five or thirty students immediately adjoining the dispensary is essential. For instruction in physical diagnosis, for the objective teaching of disease, and for the instruction of students in the use of their senses, such an arrangement is invaluable; and there are hundreds of dispensaries in which this plan is feasible, and in which the material now is not properly worked up because of the lack of this very stimulus. In the second place I feel sure, that ultimately, we shall develop a system of extramural teaching similar to that which has been so successful in Edinburgh; and this will give employment to a large number of the younger men. At any large university school of medicine there might be four or five extramural teachers of medicine, selected from men who could prove that they were fully qualified to teach and that they had a sufficient number of beds at their command, with proper equipment for clinical work. At Edinburgh there are eight extramural teachers of medicine whose courses qualify the student to present himself for examination either before the Royal Colleges or the University. If we ever are to give our third and fourth year students protracted and complete courses in physical diagnosis and clinical medicine, extending throughout the session, and not in classes of a brief period of six-week's duration, I am confident that the number of men engaged in teaching must be greatly increased.

Ten-years' hard work tells with colleagues and friends in the profession, and with enlarged clinical facilities the physician enters upon the second, or bread-and-butter period. This, to most men, is the great trial, since the risks are greater, and many now drop out of the race,

wearied at the length of the way and drift into specialism or general practice. The physician develops more slowly than the surgeon, and success comes later. There are surgeons at forty years in full practice and at the very top of the wave, a time at which the physician is only preparing to reap the harvest of years of patient toil. The surgeon must have hands, and better, young hands. He should have a head, too, but this does not seem so essential to success, and he cannot have an old head with young hands. At the end of twenty years, when about forty-five, our Lydgate should have a first-class reputation in the profession, and a large circle of friends and students. He will probably have precious little capital in the bank, but a very large accumulation of interest-bearing funds in his brain-pan. He has gathered a stock of special knowledge which his friends in the profession appreciate, and they begin to seek his counsel in doubtful cases, and gradually learn to lean upon him in times of trial. He may awake some day, perhaps, quite suddenly, to find that twenty years of quiet work, done for the love of it, has a very solid value.

The environment of a large city is not necessary to the growth of a good clinical physician. Even in small towns a man can, if he has it in him, become well versed in methods of work, and with the assistance of an occasional visit to some medical center he can become an expert diagnostician and reach a position of dignity and worth in the community in which he lives. I wish to plead particularly for the wasted opportunities in the smaller hospitals of our large cities, and in those of more moderate size. There are in this State a score or more of hospitals with from thirty to fifty medical beds, offering splendid material for good men on which to build reputations. Take for example, the town of Thelma, which I know well, to which young Rondibilis, a recent resident at the Hôtel Dieu, has just gone. He wrote asking me for a letter of advice, from which I take the liberty of extracting one or two paragraphs:

"Your training warrants a high aim. Say to those who ask, that you intend to practice medicine only, and will not take surgical or midwifery cases. X. has promised that you may help in the dispensary, and as you can count blood and percuss a chest you will be useful to him in the wards, which, by the way, he now rarely visits. Be careful with the house physicians, and if you teach them anything do it gently, and never crow when you are right. The crow of the young rooster before his spurs are on always jars and antagonizes. Get your own little clinical laboratory in order. Old Dr. Rolando will be sure to visit you, and bear with him as he tells you how he can tell casts from the ascending limb of the loop of Henle. He was once as you are now, a modern, but he crawled up the bank twenty years ago; the stream has left him there, but he does not know it. He means to impress you; be civil and show him the new Nissle-stain preparations, and you will have him as a warm friend. His good heart has kept him with a large general practice, and he can throw *post-mortems* in your way, and may send for you to sit up with his rich patients. If Y. asks you to help in the teaching, jump at the chance.

The school is not what you might wish, but the men are in earnest, and a clinical microscopy-class or a voluntary ward-class, with Y's. cases, will put you on the first rung of the ladder. Yes, join both the city and the county society, and never miss a meeting. Keep your mouth shut too, for a few years, particularly in discussions.

"Foote's (Philadelphia) is the catalogue to which I referred. Let the old men read new books; you read the journals and the old books. Study Lænnec this winter; Forbes' 'Translation' can be cheaply obtained, but it will help to keep up your French to read it in the original. The old Sydenham Society editions of the Greek writers and of Sydenham are easily got and are really very helpful. As a teacher you can never get *orientiert* without a knowledge of the Fathers, ancient and modern. And do not forget, above all things, the famous advice to Backmore, to whom, when he first began the study of physic, and asked what books he should read, Sydenham replied, 'Don Quixote,' meaning thereby, as I take it, that the only book of physic suitable for permanent reading is the book of Nature."

A young fellow with staying powers who avoids entanglements, may look forward in twenty years to a good consultation practice in any town of 40,000 to 50,000 inhabitants. Some such man, perhaps, in a town far distant, taking care of his education, and not of his audience, may be the Austin Flint of New York in 1930.

"Many are called, but few are chosen," and of the many who start out with high aims, few see the goal. Even when reached the final period of "cakes and ale" has serious drawbacks. There are two groups of consultants, the intra- and the extraprofessional; the one gets work through his colleagues, the other, having outgrown the narrow limits of professional reputation, is at the mercy of the *profanum vulgus*. Then for him "farewell the tranquil mind, farewell content." His life becomes an incessant struggle, and between the attempt to carry on an exhausting and irksome practice, and to keep abreast with young fellows still in the bread-and-butter stage, the consultant at this period is worthy of our sincerest sympathy.

One thing may save him. It was the wish of Walter Savage Landor always to walk with Epicurus on the right hand and Epictetus on the left, and I would urge the clinical physician, as he travels farther from the East, to look well to his companions—to see that they are not of his own age and generation. He must walk with the "boys," else he is lost, irrevocably lost; not all at once, but by easy grades, and every one perceives his ruin before he, "good, easy man," is aware of it. I would not have him a basil plant, to feed on the brains of the bright young fellows who follow the great wheel uphill, but to keep his mind receptive, plastic, and impressionable he must travel with the men who are doing the work of the world, the men between the ages of twenty-five and forty.

In the life of every successful physician there comes the temptation to toy with the Delilah of the press—daily and otherwise. There are times when she may be courted with satisfaction, but beware! sooner or later she

is sure to play the harlot, and has left many a man shorn of his strength, *viz.*, the confidence of his professional brethren. Not altogether with justice have some notable members labored under the accusation of pandering too much to the public. When a man reaches the climacteric, and has long passed beyond the professional stage of his reputation, we who are still "in the ring" must exercise a good deal of charity, and discount largely the *on dits* which indiscreet friends circulate. It cannot be denied that in dealings with the public just a little touch of humbug is immensely effective, but it is not necessary. In a large city there were three eminent consultants of world-wide reputation; one was said to be a good physician but no humbug, the second was no physician but a great humbug, the third was a great physician and a great humbug. The first achieved the greatest success, professional and social, possibly not financial.

While living laborious days, happy in his work, happy in the growing recognition which he is receiving from his colleagues, no shadow of doubt haunts the mind of the young physician, other than the fear of failure; but I warn him to cherish the days of his freedom, the days when he can follow his bent, untrammelled, undisturbed, and not as yet in the coils of the octopus. In a play of Oscar Wilde's one of the characters remarks, "there are only two great tragedies in life, not getting what you want—and getting it;" and I have known consultants whose treadmill life illustrated the bitterness of this *mot*, and whose great success at sixty did not bring the comfort they had anticipated at forty. The mournful echo of the words of the preacher rings in their ears, words which I not long ago heard quoted with deep feeling by a distinguished physician, "Better is a handful with quietness than both hands full with travail and vexation of spirit."

THERAPEUTIC NOTES.

Treatment of Large Effusions into the Knee-Joint.—DÜMS (Centralbl. für Chir., September 18, 1897) recommends an active therapy for tense effusions into the knee-joint, either by puncture or incision. Although massage, compression, etc., will in time cause the disappearance of the fluid, yet in the meantime the joint-capsule has been so long stretched that a return of the affection is probable? Even when the fluid is promptly removed from the joint there is still danger of a recurrence, and the limb should be protected from strain for some time by being very gradually brought again into service. Dums' plan of treatment is as follows: As soon as the fluid is removed, a firm bandage is applied, and the limb fixed in an immovable apparatus in an extended position. At the end of a week the bandage is removed, a few passive motions made, and a starch bandage applied. One week later the patient may go about on crutches. From this time on a gradually increasing amount of passive and active motion is allowed, and at the end of six or eight weeks a complete cure may be expected. This treatment appears tedious, but the relapses are fewer than those which follow the ordinary methods.

Atony of the Rectum.—ACHESON (*Quart. Jour. of Rect. and Gastro-int. Dis.*, October, 1897) says that atony of the rectum is a result of constipation, a sedentary life, disregard of Nature's calls, or the continued use and abuse of large enemata of cold, or, still worse, warm or hot water. The subjective symptoms of fulness in the rectum with impossibilities of evacuation, and often a faintness when it has been emptied, are well known. For treatment are mentioned course foods, exercise, bathing, draughts of hot water, regular massage, and the removal of the cause. Purgatives as a routine are not recommended. The following nervomuscular tonic is serviceable:

R	Aloin	.	.	.	.	.	gr. ii
	Strychnin	.	.	.	.	.	gr. $\frac{1}{60}$
	Ext. belladon	.	.	.	.	.	gr. $\frac{1}{8}$
	Ipecac.	.	.	.	.	.	gr. $\frac{1}{2}$

M. Ft. pil. Sig. One pill night and morning.

Small injections of cold water, small injections of glycerin, or a glycerin suppository may be used; or the following mixture may be injected:

R	Rhatan	.	.	.	.	.	ii
	Rect. spts.	.	.	.	.	.	ii
	Water	.	.	.	.	.	ii.

M.

It may be necessary to empty the distended rectum mechanically, and afterward to employ an antiseptic douche.

A New Method of Treatment of the Umbilical Cord.—

PEAUDECERF (*Rev. de Therapeut.*, September 1, 1897) describes a procedure recommended by Bar, which consists in the application of a small pair of clamps to the umbilical cord in place of a ligature. The clamp is placed squarely across the cord as close as possible to the abdominal surface. The cord is cut off next to the clamp and a light dressing applied beneath and above the instrument. On the following day the clamp is removed, and the portion of the cord which was compressed in its jaws is cut away. A small sterilized dressing is applied which does not require changing until the fifth day, when the fragment of the cord remaining will be found dry and already separated from the body. A bath is not given until cicatrization is complete.

Effect of Urotropin upon Cystitis.—NICOLAIER (*Der Arzt. Prakt.*, No. 12, 1897) has been using for two years a combination of ammonia and formalin, called urotropin, in the treatment of uric-acid concretions, and bacterial diseases of the urinary passages. He has been especially pleased with its effect in cases of cystitis accompanied by ammoniac fermentation of the urine. The daily dose should not exceed 20 grains, as larger amounts, especially if continued for some time, are likely to cause some burning in the neck of the bladder and urethra, and frequency of micturition. From 5 to 8 grains dissolved in a glass of water and taken after meals, will rapidly change the character of an ammoniac urine, and after two or three days it is not necessary to administer the drug more than twice daily. Gastric symptoms do not occur even if

the administration is continued for months. The first effect of the remedy is to diminish the intensity of the ammoniac odor of the freshly voided urine. Then the reaction of the urine quickly becomes acid. The urine once more becomes clear, the crystals of triple phosphate, and ammonium urate disappear, pus diminishes, and the associated symptoms vanish. Experiment proves that urotropin does not kill the germs which cause the ammoniac fermentation, but merely prevents their development. This statement is borne out by the clinical fact that if the drug is discontinued, the fermentation reappears after a short interval. If taken for some weeks or months, however, there may be no recurrence of the fermentation when its administration is abandoned.

Massage in Chorea.—FEDOROV (*La Semaine Méd.*, September 8, 1897) is well pleased with the results obtained in ten cases of chorea by the use of massage. The patients were children from seven to fourteen years of age. The movements were at first light, then gradually increased in force until the whole body was thoroughly handled. Passive motions followed as soon as the patients were sufficiently calmed to permit them. The beneficial effects of this treatment were evident on the third or fourth day, and at the end of a week an improvement in the general condition was manifest. Fedorov believes that the massage exerts a sedative action on the central nervous system, stimulates the circulation, and so facilitates nutritive exchange, and the elimination of toxins which have accumulated in the organisms.

Treatment of Soft Chancre by Prolonged Irrigation.—Two Italian physicians, MALUSARDI and BONADUCI (*La Semaine Méd.*, September 8, 1897), have been treating venereal ulcers with prolonged irrigations of hot water at a temperature of from 47° to 52° C. (108°–117° F.). The irrigations are commenced at the former temperature, which is then rapidly raised by heating the irrigator with an alcohol lamp, or more simply, by the addition of some boiling water to that in the irrigator. The irrigation should be interrupted from time to time to give the patient a chance to rest, and the whole *séance* lasting a half-hour, should be repeated daily. Under the influence of the heat, the ulcer becomes very red in a few minutes, and there is a sensation of heat all over the body, accompanied oftentimes by profuse perspiration. The ulcer is finally dusted with iodol powder, and a light dressing of absorbent cotton applied. This method causes the induration on the border of the ulcer to rapidly disappear, and transforms it into a simply wound which heels readily. In the forty-one cases in which the writers employed this plan of treatment from two to eleven irrigations were all that were necessary.

Normal Blood as a Hemostatic in Hemophilia.—BIENWALD (*Wien. Med. Blät.*, July 15, 1897) has found that the application of blood obtained by aspiration from a healthy person will stop the bleeding in a hemophiliac, if brought into contact with the wound. He explains this action by saying that the normal blood contains the necessary ferment to produce thrombi in the capillaries.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, NOVEMBER 20, 1897.

THE MEDICAL NEWS AND THE CHARITIES COMMISSIONERS.

THE MEDICAL NEWS has scored another triumph in correcting abuses in the Department of Public Charities of New York City. The exposure in our columns of the disgraceful exploitation of a "drink cure" in Bellevue Hospital during the summer of 1896 resulted, after bringing the Commissioners to a realization of their insulting action, in routing an intolerable invasion of quackery. This was accomplished only after a most persistent fight. The principle, however, was permanently established that in the management of the medical and surgical affairs of the hospital the best and only safe guide is inherent in the profession itself.

The present triumph to which we allude consists in restoring to the profession, as represented by the Medical Board of Bellevue Hospital, the power to nominate appointees to fill vacancies in the visiting staff as they occur from time to time. In a recent editorial (THE MEDICAL NEWS, October 30, 1897) we said: "In anticipation of such a result (the domination of hospital appointments by political influence), we respectfully call upon the

Board of Charities Commissioners of the City of New York to reconsider its action and restore the just and equitable mode of accession to the visiting staffs of the various city hospitals." The response has come promptly and definitely, as indicated by the following letter, which has been received by the secretary of the Medical Board of Bellevue Hospital:

"DEAR SIR: By direction of the Board I have to inform you that the resolution of September 25, 1897, has been rescinded, and paragraph 3 of the organization of the Medical Board of Bellevue Hospital, dated May 12, 1882, which provided that appointments to fill vacancies shall be made by the colleges or Fourth Division is restored to full force and effect as it was prior to the resolution of September 25th.

"A. G. WEAVER,
"Secretary of the Board of Commissioners."

THE RIGHT OF FREE SPEECH.

A CASE of interest and importance to medical men has recently been decided in the United States Court at New York City, in which a New York optician brought suit for libel against Dr. Frank Van Fleet demanding damages to the amount of \$40,000. The facts in the case are briefly as follows: The plaintiff had an advertisement in the directory published by the County Medical Society of New York, in the course of which these words were used: "Headache and neuralgia often proceed from latent defects of the eyes, and especially in cases of muscular asthenopia. If present, these defects are detected by our method of testing. Proper glasses give permanent relief, and physicians can have a report on the state of any patient he desires."

At a regular meeting of the Society, Dr. Van Fleet protested against this advertisement, as its insertion was sought for the ensuing year, on the ground that printing such advertisements in the official publication of the Society led the public to believe that its appearance there was equivalent to the Society's endorsement. He went on to say that "anybody, not a physician, who undertook to cure headache or neuralgia with glasses or anything else and accepted remuneration therefore, violated the medical laws of the State and was a quack; that the Society would not allow him to advertise in that way and it should not allow any one else to do so." It so happened that his words

found their way into the public press, and the optician sued him as above.

In answer, Dr. Van Fleet pleaded the truth of his spoken words and the protection of the Court, because of the circumstances under which the remarks were made. In this the County Society not only sustained him but agreed to bear the principal cost of the suit. The optician being an alien, a British subject, the action was brought in the United States Court, Judge Wallace presiding. The theory upon which the defense proceeded was that every person has a right to seek redress before a proper tribunal in a proper manner, and that language used upon the occasion of seeking redress is privileged. Dr. Van Fleet was supported in his position by Drs. Landon Carter Gray, Andrew H. Smith, and D. B. St. John Roosa.

At the close of the case the counsel for the defendant insisted upon his motion to dismiss the complaint and for a direction of the verdict, and Judge Wallace said in effect, that since the defendant had brought forward such eminent medical authority to sustain his view, he was bound to believe that Dr. Van Fleet had ample ground for believing what he had said to be true even if the evidence did not justify him (the defendant) in finding that it was true, and that it was, therefore, his duty to direct a verdict, because if the jury should find a verdict for the plaintiff he would be obliged, under the circumstances, to set it aside.

Naturally this verdict is extremely gratifying on every account, for it settles once and for all that a member of the Medical Society of the County of New York has a right to attend the meetings and speak as his sense of duty to the public dictates without fear of suits for libel. The Medical Society itself showed its gratification by a vote of thanks to Dr. Van Fleet for the plucky fight he had made.

INTERNAL MEDICINE AS A VOCATION.

THE recent address by Professor Osler on the above subject, at the New York Academy of Medicine, which we publish to-day, offers much material for reflection. It is in brief the essence of the ratiocination, the conviction, and the anticipation of one who graces the vocation concerning which he discoursed so felicitously. As the result of much thought we have his modern Lydgate; of his con-

viction, we have an expression of his belief in the evils of early specialism; and of his hope, his scheme for enlarging the field of medical teaching.

If we do not coincide with him as to the disciplinary and preparatory years of his exemplar, it is perhaps because we construe the title of his address more literally than he, and do not use the terms Consulting Diagnostician as interchangeable with General Practitioner. The plan of training which Dr. Osler has outlined in such detail will undoubtedly facilitate the development of the former, but we are not all convinced that it will develop the highest or most useful type of the latter. In the first place, the ideal Esculapian, who spends the larger part of the first ten years of his professional life in the dispensary and the dead-house, sees very little, if any, acute disease. He is allowed to take a case of typhoid fever, or pneumonia, now and then, if they come with the "crumbs," alluded to by the speaker, but he is admonished that they lie on deflected courses between him and his goal, and it is not absolutely necessary to include them in order to reach the latter in the possession of full vigor.

Naturally, Dr. Osler does not intend that his model shall not have experience with acute diseases, he anticipates that this will be forthcoming with the transition which shall carry him from the dispensary "to hospital wards," but here he reckons with conditions which do not exist, at least for the city of New York with which we are most familiar. Those who hold hospital appointments, as well as aspirants for such appointments, are painfully aware that there is practically no "reward-of-merit" system in the hospitals of this city, and the dispensaries connected therewith. Let us take for instance, three of our largest hospitals, representing three different "social grades": Bellevue Hospital, Mt. Sinai Hospital, and New York Hospital, and inquire what proportion of the constituents of their respective staffs served in the dispensaries of these hospitals, and received their appointment as a reward for faithful or brilliant service. We feel sure that we are quite within the mark when we say that less than one-tenth of the entire number were at any time on the dispensary staff. Under such circumstances it would be necessary for our physician, developing along the lines laid down, to "look sharp" or he would find himself well along in the second decade of his pro-

fessional life without any considerable training in the recognition and handling of acute diseases, and without great prospects of getting it.

After all it is with the physician as it is with the mariner. Our admiration is greater for the pilot who can bring a strong, seaworthy craft safely through tempest, storm, and the unavoidable exigencies of the voyage, than for him who guides a weak disabled vessel from one shore to another. And so it is with the physician. He who steps in when the ravages of acute disease are overpowering the vitality and jeopardizing life, and with a little help here, or some guidance there, succeeds in influencing the scales toward Nature's side, is more worthy of our emulation than he who diagnosticates a degenerative disease, and is able to tell to within a few months when it will terminate the patient's life.

To gain this experience and to stand ready with such aid it is necessary that one should from the very beginning become familiar with acute disease and acquaint himself intimately with its every phase and variation. This experience is not to be had in dispensaries, for nine-tenths of all the cases to be observed there are of a chronic nature, and it is the diagnosis of such conditions and incidentally their prevention and treatment that the dispensary physician learns. We are constrained, therefore, to contend that in a vocational sense the general practitioner must needs depart far afield from the restrictions made by our worthy mentor.

The suggestion made by the speaker, that the time is at hand for an extension of facilities for giving practical instruction to medical students, by the adoption of the system which has operated so advantageously in Edinburgh for many years, the so-called extramural system of teaching, must strike every one interested in elevating the standard of recruits to the ranks of the profession as an extremely important one. In this city not more than one-fourth of the large hospitals are utilized for bedside teaching and this because the visiting physicians are not of the faculties of the medical colleges. If Dr. Osler's suggestions were adopted the rich material which these hospitals afford might be utilized for the advantage of the student, while the increased attention which the visiting physicians who essay to conduct courses must need give would redound to the advantage of the patient. There is no denying the fact that to-day

Edinburgh maintains her preeminence as a medical center in Great Britain, and this is largely due to the extramural system of teaching which has been developed there to such a commendable degree. We believe that the reputation and material prosperity of the medical college which first adopts this suggestion of Dr. Osler will be materially enhanced. We respectively commend his suggestion to the serious consideration of the governing bodies of American medical colleges.

ECHOES AND NEWS.

Obituary.—Dr. Charles R. Bourroughs, President of the Mercer County Medical Society, died suddenly on the 10th inst., at his home in Trenton, N. J.

The Philadelphia Medical Club tendered a reception to Dr. Howard A. Kelly of Johns Hopkins Hospital on Friday, November 19, 1897, at the Aldine Hotel, Philadelphia.

The Trachoma Bacillus.—Dr. Leopold Müller of the University of Vienna is said to have discovered the bacillus of the so-called "Egyptian ophthalmia," or trachoma.

Appointment of Dr. Ophuels.—Dr. W. Ophuels of the Pathological Institute of Goettingen, has accepted a call to the chair of Pathology in the University of Missouri.

Plague Attacks Monkeys.—The bubonic plague which is still raging in British India has attacked a colony of monkeys near Hardwar. The local authorities are trapping and isolating the diseased animals.

Lavoisier's Memory to Be Honored.—The Municipal Council of Paris has voted the sum of 3000 francs toward a statue which is to be erected to the memory of the distinguished chemist Lavoisier.

Doctor's Life Worth \$30,000.—A New York Supreme Court jury recently gave a verdict of \$30,000 against the New York, New Haven and Hartford Railroad Company for having caused the death of a doctor.

A Physician Shot while Gunning.—Dr. E. O. Cummins of Jersey City, N. J., was shot and badly injured on the 11th inst., by the accidental discharge of a gun carried by a friend who accompanied him on a hunting-trip.

Addition to St. Vincent's Hospital.—An extension to St. Vincent's Hospital, New York, is to be erected at a cost of \$250,000. It will be devoted exclusively to charity patients. The ambulance service will also be enlarged and improved.

University of Berlin Laboratory.—A new building for the chemical laboratory of the University of Berlin is now being erected at a cost of \$250,000. It will contain four large laboratories, desks for 250 students, and twenty-five research-rooms.

Strange Epidemic in Omaha.—More than 10,000 of the inhabitants of Omaha, Neb., have been suffering during the past three weeks from an unusual skin disease. The affection is not serious, but its etiology remains a mystery.

The Sterilization of Books.—Dr. John S. Billings, who is the director of the New York Public Library, recommends that when the library becomes a circulating one each book upon its return shall be disinfected by formalin before being again issued.

Famine in Archangel.—A terrible famine is ravaging the Province of Archangel, in the extreme north of European Russia, extending from the Ural Mountains on the east to Finland on the west. The province has a population of about 300,000. Many deaths from starvation have occurred.

Ophthalmia in Prussia.—Owing to the fact that ophthalmia is prevalent in East Prussia, the eyes of all school children in Königsberg were recently examined, with the result that thirty-two per cent. were found to be suffering from the disease, and of these more than one-third have trachoma.

Insane Asylum Destroyed by Fire.—The State Lunatic Asylum at Milledgeville, Ga., was totally destroyed by fire on the afternoon of the 9th inst. The thousand patients were gotten out and housed in another building after the most heroic work on the part of the staff and employees, and not a life was lost.

Phrenologist as an Expert.—For the first time in the history of the criminal courts of the State of Missouri, or probably of any State, phrenology had been recognized as a science in determining insanity. On the 13th inst., in a murder trial before Judge Zachritz, a phrenologist was permitted to qualify as an expert and testify as to the insanity of the defendant.

The Lynn Typhoid Epidemic.—The epidemic of typhoid fever at Lynn, England, is still progressing. Up to the 6th inst. there had been 300 cases, and about ten new ones are reported each day. It now appears that a similar epidemic prevailed at this place in 1892, which, like the present one, was traced to the washing of filth into the Gaywood River, from whence the water-supply is obtained.

Strange Surgery.—The medical officer of an English almshouse was recently called to account for having amputated a gangrenous foot by incising the soft parts with an old razor and dividing the bones with a worn-out rusty saw which had been thrown away as useless. The explanation offered was that if proper instruments had been used it would have been necessary to destroy them in order that they might not carry infection.

The New York Medical Journal and the Marine Hospital Service.—The *New York Medical Journal* of November 13, 1897, in commenting upon a recent editorial in the columns of THE MEDICAL NEWS, advocating the enlargement of the power and scope of the Marine Hospital

Service, says: "We are glad to see an editorial on this subject in THE MEDICAL NEWS for October 30th. The stand taken in the article is, we think, perfectly right."

Scarlet-Fever Epidemic at Norwalk.—The epidemic of scarlet fever which appeared at Norwalk, Conn., two weeks ago is still spreading. Nineteen new cases were reported on the 8th inst. All the cases have occurred in families supplied by a certain milkman, who has been arrested by the order of the Board of Health. This milkman is charged with having bought his milk from a farmer whose children were suffering from scarlet fever.

Accident Insurance for Students.—At the University of Heidelberg, all students doing laboratory work, and even those who attend experimental lectures in chemistry or physics, are required to take out an accident insurance policy covering casualties which are liable to occur in such institutions. Students who are unfortunate enough to be entirely disabled are to receive \$500 per annum, with a corresponding allowance for lesser injuries. The premium, however, is low—but two and a half cents for lecture courses per semester.

Obituary.—Dr. Harrison Allen, Emeritus Professor of Comparative Anatomy in the Medical School of the University of Pennsylvania, died suddenly on the 14th inst. of heart disease. Dr. Allen was born at Philadelphia in 1841. He was graduated from the University of Pennsylvania in 1861, and soon after entered the regular army. In 1865, when only twenty-four years of age, he was called to the chair of Comparative Anatomy and Zoology in the Medical School of the University of Pennsylvania, which position he held until 1895.

Damages Allowed for Prenatal Injuries.—The *Journal of the American Medical Association*, in its issue of November 13, 1897, mentions a very interesting decision which was recently given by Judge Chetlain in the Superior Court of Cook County, Illinois. The question was whether a child after it is born has a right of action for injuries sustained by it *en ventre sa mere* (in utero), and the judge held that there was a good cause of action stated in the case in question. Suit was brought for the child against a person who conducts a lying-in hospital, for injuries received by the plaintiff *in utero*, while it and its mother were going to the lying-in chamber.

The Typhoid Epidemic at Ligoniel.—The cause of the typhoid-fever epidemic at Ligoniel, near Belfast, Ireland, has been traced to an impure water-supply. In this instance the water rises out of limestone rock, from which it is piped into a large underground reservoir. In the reservoir there is a manhole, level with the adjacent ground, and not water-tight. Consequently, surface water from higher ground after a storm can enter the reservoir. It was discovered that in the same field with the latter was a house in which two persons were suffering from typhoid, and that the excreta had been thrown at the side and back of the house—about 120 yards from the reservoir.

Smallpox and Vaccination in Japan.—In 1870-71 Japan was visited by a terrible epidemic of smallpox, which made great ravages in Yokohama and in the small villages to such an extent that there were no well people to attend the sick. At that time every person who wished to be vaccinated was obliged to pay a small tax to the Government—a quarter of a *bu*, which is equal to nine cents of our money. Vaccination was made compulsory in 1876. This rapid stride is said to be largely due to the fact that pock-marked foreigners were rarely seen in Japan, whereas there was probably not one in a hundred of the adult population of Japan who had not had smallpox.

A Question of Priority.—According to the *British Medical Journal*, a medical lawsuit turning on a question of priority has attracted much attention in Berlin. Some time ago Dr. Casper demonstrated a cystoscope to the Berlin Medical Society as an idea of his own. Dr. Nitze claimed that he had previously constructed and exhibited an apparatus similar in principle and intended for a similar purpose, and alleged that he had shown and explained his instrument to Dr. Casper at the time. Many experts were called, among others being Professors Von Bergmann, Hahn, Wolf, and Posner, and, as is the custom of experts, their testimony was very contradictory. A verdict was finally given to Dr. Casper, and Dr. Nitze was fined.

The "Six-Penny Doctor."—Complaint is made in England against the "six-penny doctor," so-called because he accepts small fees from those who are unable to pay large ones. It is a question, says *The Medical Press*, whether he deserves the condemnation which is heaped upon him by members of his own profession. His patients undoubtedly belong to the great army of the poor who usually seek medical and surgical aid at dispensaries and the out-departments of hospitals, and who, in order to save the time spent in waiting their turn at these places, prefer to pay their six-pence, all which they can afford, perhaps, to consult a man who is willing and ready to attend to them. In this way he is certainly a benefit to the poor, and it can hardly be said that he injures the practice of his brother medical men whose patients are of a wealthier class.

National Board of Health Desired in England.—At a recent meeting of the Sanitary Inspectors' Association at Birmingham, England, a resolution was passed in favor of the establishment of a National Board of Health, its president to have a seat in the Cabinet. In commenting upon this, *The Medical Press and Circular* (Eng.) says that there is no doubt that a department of Public Health is much needed in England, and that, although the idea of having a Minister of Health is not new, the sanitary inspectors have done well to bring the matter again to public notice. The duties which should belong to a department of public health are at present undertaken by the Local Government Board. In pointing out the urgent need of such a department, the typhoid epidemic at Maidstone is referred to and the opinion expressed that

with a department of National Health in full working order, such an alarming epidemic could scarcely occur.

Health Reports.—Statistics of the United States Marine Hospital Service during the week ending November 13, 1897:

Corner-Stone Laid at Bellevue.—The corner-stone of the new five-story building of the Bellevue Hospital Medical College, which is being erected at the corner of First avenue and Twenty-sixth street, New York, was laid with appropriate ceremonies on the 13th inst. by Dr. Lewis A. Sayre, Emeritus Professor of Orthopedic Surgery. The conventional metal box was deposited in the stone, containing a history of Bellevue Hospital, copies of the daily papers, the alumni catalogue from 1861 to 1881, a full set of lecture-cards and alumni circulars from 1861 up to the present year, a bottle of antitoxin, and a glass tube containing spores of the bacillus aerogenes capsulatus, which was first discovered in April, 1896. The ceremony of laying the corner-stone was conducted in the presence of the members of the Board of Trustees and the Faculty, instructors, and alumni of the college. The invocation was delivered by the Rev. Dr. Roderick Terry, and Dr.

Sayre made an address. A procession was then formed which marched into the lecture-room of the Carnegie Laboratory adjoining, where addresses were delivered by Dr. Landon Carter Gray, representing the alumni; by the Rev. Dr. Terry, who spoke for the Board of Trustees, and Dr. John S. Billings, who represented the medical profession. The new college building will be one of the most elaborate of its kind in this country, and it is expected that it will be ready for occupancy in March.

Yellow-Fever Notes.—Dr. S. R. Oliphant, President of the Louisiana State Board of Health, Drs. Samuel H. Durgin of Boston, and A. Doty of New York, members of the committee appointed at the recent meeting of the American Public Health Association, are in Washington for the purpose of urging the President to recommend to Congress the appointment of a commission of expert bacteriologists to visit Havana, and make a thorough study of the cause, treatment, and prevention of yellow fever.

A telegram from Colon, Colombia, says that owing to the continued prevalence of yellow fever at Kingston, Jamaica, the Colombian Government is enforcing a quarantine against all passengers from that place to the Isthmus of Panama and Pacific ports. The mails are being detained for fumigation.

On the 9th inst., eight new cases and four deaths were reported in New Orleans. Six new cases were reported in Mobile, Ala., and but one new case in Montgomery. No new cases have been reported in Memphis, Tenn.

No new cases have occurred in Mississippi and quarantine has been raised in that State.

On the 11th inst., twelve new cases and six deaths were reported in New Orleans. The Board of Health on that day abolished all quarantine, both territorial and house, within its jurisdiction. In Mobile, Ala., one new case was recorded. No new cases in Montgomery, Ala. One new case was reported at Edwards, Miss.

President McKinley has detailed Past-Assistant Surgeon Eugene Wasdin and Past-Assistant Surgeon H. D. Geddings, United States Marine Hospital Service, for special duty at Havana, Cuba, for the purpose of making bacteriologic investigations into the cause and nature of yellow fever. These officers have been for some time engaged in laboratory work in New Orleans. Their investigations are to be carried on in Cuba until some definite conclusions are reached.

The oldest son of Sir George Duffey, President of the Royal College of Physicians and Surgeons (Ireland), died recently of yellow fever in Jamaica, West Indies, where he was stationed with his regiment.

The British steamer "Strathdon," which arrived at Bremen on the 16th inst. from Savannah, Ga., has been quarantined for five days. During the voyage one of the crew died of what is thought to be yellow fever.

Appointed State Medical Examiner.—The Board of Regents has appointed Dr. Walter Suitor of Herkimer, to fill the vacancy in the State Board of Medical Examiners, representing the Medical Society of the State of New York, caused by the death of Dr. William C. Wey.

CORRESPONDENCE.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

AN EXPERIMENTAL STATION FOR THE STUDY OF BOVINE TUBERCULOSIS—PHILADELPHIA PEDIATRIC SOCIETY—PATHOLOGICAL SOCIETY OF PHILADELPHIA—THE MUTUAL-AID ASSOCIATION OF THE PHILADELPHIA COUNTY MEDICAL SOCIETY—THE STATE BOARD OF HEALTH'S NEW VACCINATION LAW.

PHILADELPHIA, November 13, 1897.

AN experimental station for the study of diseases of cattle is to be established at the University of Pennsylvania, under the control of the State Live-Stock Sanitary Board, and work upon a building to be used for the purpose will be immediately commenced. One of the first practical points to be determined by the Board is the influence of sanitary stabling upon the development and course of bovine tuberculosis, and to this end the following novel but simple procedure will be employed: Two stables will be built, one large, lighted, and ventilated, and having all arrangements conducive to the best sanitary conditions; the other small, aired, and ventilated with less care than the first, and representing as nearly as possible the ordinary cow-stables as seen on the average farm. Into each of these stables will be placed three healthy and three tuberculous cows, alternated, alternating in stalls between each other. The rapidity of the development and spread of the disease will then be watched in the two herds, and inferences drawn as to the value of sanitary stables.

At a meeting of the Philadelphia Pediatric Society, held on November 9th, the topic of intestinal intussusception occupied the greater part of the evening's scientific business. The medical aspects of this lesion were considered by Frederick A. Packard, who quoted a recent instance of intussusception which he had occasion to treat, and pointed out the indications for and against the use of injections as a therapeutic measure; the speaker emphasized the fact that after the third day, in such cases, the treatment referred to was useless, and he should be abandoned on account of adhesions and softening of the wall of the gut. Dr. Edward Martin, by invitation, spoke of the treatment of intussusception by surgical intervention, and thoroughly discussed the subject from the surgeon's standpoint. Dr. R. G. Le Conte related an interesting account of an instance of intussusception which he witnessed during the course of a laparotomy. In addition to the consideration of the above topic, two cases of congenital hereditary edema were presented by Dr. J. H. Jopson, who detailed the histories of the patients, and made general remarks upon the condition.

A stated meeting of the Pathological Society of Philadelphia was held on November 11th. Dr. Joseph Sailer exhibited a specimen of aneurism of the left ventricle, with myocarditis and pericarditis; there were a few partly occluded vessels with thickened walls, and much dense fibrous tissue scattered through the inflammatory lesion, and a number of cicatrices, suspiciously syphilitic in nature, in the kidneys and liver, although the patient had persist-

ently denied specific infection. Dr. Sailer also showed the lungs from a case of general septic infection; the patient first presented signs of a croupous pneumonia, which progressed to pulmonary abscess, and subsequently general pyemic infections, with collections of pus in the kidneys, spleen, and other organs, giving rise to grave constitutional symptoms, and a fatal termination. Dr. Judson Deland exhibited an appendix vermiformis, showing a common pin *in situ*. The appendix at the time of its removal contained fully six ounces of pus, and the pin occupied its lumen, which was tightly constricted in places from inflammatory processes. Dr. J. Dutton Steele read a review of the literature of Koch's "Tuberculin R.", and considered in detail Koch's early and later experiments with their disadvantages and advances, the dose, mode of administration, and by-effects of the preparation, and its practical bearing on the treatment of tuberculosis. The chief objections to the use of the new tuberculin are the danger of septic infection, the irregular strength of the preparation, and the uncertainty in the correct dose for different individuals. Results from the employment of "Tuberculin R." are as yet too indefinite to warrant a positive opinion as to its usefulness. Other communications at this meeting were made by Dr. J. H. McKee, who exhibited an umbilical hernia in a rabbit containing a portion of the round ligament which simulated a diseased vermiform appendix; and by Dr. David Riesman, who showed a specimen of cancer of the stomach, from a case which had during life presented irregular clinical symptoms.

At the annual meeting of the Mutual Aid Association of the Philadelphia County Medical Society, held on November 9th, Dr. Charles Hermon Thomas was elected president, Drs. James Tyson and Wilson Buckby vice-presidents, and Dr. John B. Roberts secretary. Four members of the Society were elected to the Board of Directors, who passed resolutions to make efforts during the coming year to add materially to the permanent fund of the organization by obtaining legacies and donations. The Directors' report showed that a slight increase might be declared in the amount to be paid as annuities to beneficiaries; that the membership had been increased during the past year by the addition of four life, and two annual, members; and that one addition had been made to the list of benefactors. A private room in the Polyclinic Hospital has been set aside for the use of those members of the Association who may require hospital treatment.

At a meeting of the State Board of Health, held recently, resolutions were passed declaring that certificates of vaccination should not be accepted by school authorities unless they specify the existence of either the typical vesicle, the typical postule, or the typical cicatrix of vaccination; and further, that children who have recently been repeatedly, even though unsuccessfully, vaccinated by competent operators should not be excluded from school, except in the actual presence of danger from smallpox. The most casual reader will notice the diametrically opposite tenor of the two parts of this resolution; the first clause, specific in detail, the second, allow-

ing the certifier an unlimited latitude of interpretation. Further comment on the subject seems unnecessary, except, perhaps, to draw attention to the fact that there are many unscrupulous medical pirates who will take prompt advantage of the second section of the rule, with the comforting assurance that no tell-tale scar will loom up to question their veracity, if queries should be made; and who, pray, will prove that they are not "competent operators"? In these days of antivaccination agitation, laws for the enforcement of this prophylactic cannot be too stringently observed; nor can their interpretation be made too definite.

The total number of deaths occurring in this city for the week ending November 13th was 381, an increase of 51 from the preceding week, and exactly the same number in the corresponding week of 1896. Of the total number 104 occurred in children under five years of age. Reports of contagious disease showed 151 new cases of diphtheria, with 26 deaths; 57 new cases of scarlet fever, with 0 deaths; and 50 new cases of enteric fever, with 12 deaths. The outbreak of diphtheria which occurred last week in one of the wards in the upper section of the city seems to be under control, and the city health authorities have taken active measures to suppress the epidemic, and to investigate its origin, which at present is obscure.

OUR BERLIN LETTER.

[From our Special Correspondent.]

TESTIMONIAL TO PROFESSOR LASSAR—PROFESSOR VIRCHOW'S SEVENTY-SIXTH BIRTHDAY—DEATH OF PROFESSOR HEIDENHAIN OF Breslau—PLEURAL EXUDATES AND THE TENDENCY TO ADOPT AN EXPECTANT TREATMENT—A NEW HOT-AIR TREATMENT FOR LUPUS—THE WINTER SEMESTER AT THE UNIVERSITY—ADMISSION OF AMERICAN STUDENTS TO THE GERMAN UNIVERSITIES.

BERLIN, November 6, 1897.

BEFORE the members of the Lepra Conference separated, a testimonial of their appreciation of Professor Lassar's services in the organization of the Conference was presented to the Professor and his wife. It consisted of a handsome silver service. The gift was the outcome of a suggestion of Professor Arning of Copenhagen, and was warmly seconded by all the members. It was to Professor Lassar that the Conference owed much that contributed to its success, and the interest shown in Government circles, as well as by the Emperor himself, is said to have been due to his well-directed efforts.

Professor Virchow celebrated his seventy-sixth birthday during the week of the Lepra Conference meeting. He was acting as president of the Conference, and the opening of the first-day's proceedings came in the nature of a surprise. On this occasion Professor Lassar presented a large bouquet to the old pathologist whose work on leprosy was done during the early sixties, and whose generous consent to act as president was much appreciated. Despite his age the veteran is still in the ranks. His opinion on disputed points was eagerly sought, and regarded with the greatest deference.

The death of Professor Rudolf Heidenhain of Breslau

means that German medicine has lost one of its greatest men. This distinguished physiologist was but sixty-three years of age, and his death was unexpected. He was once a pupil of Du Bois Raymonds here in Berlin, and succeeded Purkinje in the Chair of Physiology at Breslau during 1859. His work on glandular, muscular, and nerve physiology, and, during recent years, on animal heat, the vagus and hypnotism has given him a fame which is a common possession of the medical world. He is well-remembered for a strikingly ingenious expedient employed during the antivivisection agitation in the German Reichstag some years ago. Through the influence, it is said, of the Woman's Antivivisection Society of England, a bill was introduced in the Reichstag which threatened scientific progress. It is a difficult matter, as Americans know, to persuade legislators that under the guise of humanitarianism some of the proposed laws actually are inhuman, because they are calculated to stop the wheels of science by which so much has been accomplished for humanity. Professor Heidenhain, who was very well-known, took a prominent textbook on physiology, and marked with red ink the facts, the discovery of which was due to animal experimentation and which could not have been found out in any other way. The argument was so effective that Germany has not since been annoyed with serious attempts to prohibit vivisection.

While general lung surgery is advancing with rapid strides, it is somewhat surprising to find that certain points in surgical interference with the more simple lung conditions are not as definitely determined as they seemed to be some years ago. For instance, with regard to tapping in pleurisy, it was once taught that where an exudate remains unabsorbed for a certain length of time (about three weeks) it is better to remove it. The opinion has gradually gained ground that pleurisy is nearly always of tuberculous origin, and coincidentally, the advisability of tapping, unless it be for symptoms indicating serious interference with the lungs or heart, is being doubted.

The sudden relief of pressure would sometimes appear to have led to the absorption of tuberculous material by the lymphatics and to its deposit in other parts of the body. The danger of infection, and the well-known results of a mixed infection where tubercle bacilli are concerned, has also had its deterrent action. Finally, however, the results, when the disease is allowed to run its course undisturbed, and when absorption eventually occurs, are so much better than when tapping is performed, that it has been considered probable, theoretically, that there exists in the serum of the pleuritic exudate an anti-tuberculin with certain curative properties, and consequently it is decidedly better when possible to leave the exudate to Nature for absorption.

In the matter of empyema something of the same conservatism has replaced, in the medical clinics at least, the teaching that the maxim, *ubi pus avacua*, is especially applicable to the pleural cavity. Comparison of the results obtained under surgical treatment with those allowed to run their course, either to resorption or to rupture into a bronchus and evacuation by that route, has not always been in favor of the theoretically perfect surgical proce-

dure. Often enough, the pus in such cases is caused by the diplococcus pneumoniae, not a very virulent pus-producing organism, and one that the lungs, under ordinary circumstances, are perfectly capable of handling. In children, especially, empyemas often run a favorable course when untreated. Surgical interference usually means almost inevitable mixed infection, and this leads to a chronic suppurative process with the production of cicatricial tissue. In general, expectant treatment appears to be indicated whenever there are no immediately threatening symptoms.

Dr. Holländer's method of treating lupus seems to be a distinct contribution to the therapy of an extremely obstinate affection for which the gamut of therapeutic measures is often run without success. The principle is that of cauterization of the tissues, not in the usual way, but by means of heated air. The apparatus employed consists of an ordinary Bunsen-burner to which is attached a coiled tube in such a way that the heat of the flame is directed on the coil. Air is forced through this tube, and issues from a nozzle heated to any degree desired up to 250° C. The current of heated air is directed on the affected tissues until they become white, when the *séance* is interrupted.

In the process of cicatrization subsequent to the cauterization the lupus nodules disappear, and a much less unsightly scar results than usually succeeds lupus. The explanation of the effect seems to be that a certain peristaltic contraction of the fibers of all the tissues of the skin leads to the driving of the blood from the part, hence the intensely white color which follows the application of the heated air. After some days this intense contraction relaxes in the healthy tissues, and after the throwing off of certain portions of the epiderm the circulation is restored. The illustrated account of Dr. Holländer's cases in the last number of the *Deutsche Medicinische Wochenschrift* shows that this simple procedure seems to produce excellent results, especially in facial lupus.

The winter semester of the Berlin University was supposed to have begun last week, but will really be in working order about the first week of November. Not many changes will occur in the medical faculty. Professor Winter, as announced sometime ago, goes to Königsberg as Professor of Gynecology. Professor Rubner becomes Medicinal Geheimrath.

As to the question of American students and their exclusion from German Universities with regard to post-graduate work, the situation absolutely remains what it was despite the rumors to the contrary. Such rumors, by the way, usually find their way into print about this time each year. To matriculate at the University of Berlin for advanced work in medicine all that is necessary is to show a diploma or a license from a State medical examining board. For much of the post-graduate work matriculation is not necessary, and is often gone through with more for the civic privileges it involves than for what the University gives. Matriculants practically are outside of police control for ordinary offences, being responsible to the University authorities, and have certain theater and other privileges which are an additional consideration.

The rumor as to the exclusion of foreign students came from certain laws requiring examinations in all cases where students are applicants for a degree from a German University.

TRANSACTIONS OF FOREIGN SOCIETIES.

Paris.

THE PATHOGENIC ROLE OF DUST—CAN A DOG HAVE THE MUMPS?—OPERATION OF CHOICE IN INTESTINAL OBSTRUCTION.

KELSCH and SIMONIN reported to the Academy of Medicine at the session held October 5th, the results of a series of experimental researches, which show that just *as powerful agents of infection are to be found in the dust which collects upon floors, as in drinking-water.* They believe that with the exception of typhoid fever and cholera, the majority of infectious diseases, such as eruptive fevers, diphtheria, pneumonia, and especially tuberculosis, when they do not result from direct infection, are usually due to microbes existing in dust. Most of the contagious diseases which develop in barracks without having been brought in from the outside arise from the dust deposited in the course of previous epidemics or carried in upon the boots. In order to avoid such infection they recommend that the floors of such buildings be rendered impermeable by a coating of coal-tar.

LAVERAN said that coal-tar, even if applied in a satisfactory manner, is not as efficacious as it might be. "A good coat of coal-tar removes the danger arising from the floor itself, but it does not affect in any way the contagion contained in the dust existing under the floor. I am inclined to think, therefore, that the best plan would be to entirely do away with wooden floors in barracks, hospitals, and all buildings in which many people are living together."

LAVERAN reported upon *a case of mumps said to have been transmitted to a dog.* The animal became sick with parotiditis two weeks after its master fell ill with the mumps. It was by no means certain, however, that the dog had the same disease. The constitutional and local symptoms, it is true, closely resembled those which occur in mumps, the parotiditis rapidly subsiding, as is usually the case in human subjects. Still, it is worthy of note, that the swelling of the parotid region was limited to the right side, whereas mumps usually affects both sides. In addition, the lymphatic glands of the region were greatly swollen and tender, and they remained enlarged and indurated after the resolution of the parotiditis, a condition which is rare after mumps. Further researches are called for before the transmissibility of mumps from man to the dog can be accepted.

At the session of the Society of Surgery held October 6th, QUENU disputed the opinion of Broca, and claimed that *in certain cases of intestinal obstruction* which do not yield to electricity *an artificial anus is indicated.* In some cases a very small opening into the cecum permits the escape of gas and allows the intestine to resume its normal peristaltic action.

KERMISSON did not look upon celiotomy as a univer-

sal method of treatment in cases of intestinal obstruction. In numerous instances an artificial anus is the operation of choice. He is convinced "that we possess diagnostic points sufficient to distinguish the cases in which celiotomy is indicated from those which will be relieved by an artificial opening into the bowel. The decision depends absolutely upon the cause of the obstruction."

RECLUS, twelve years ago, was called to see a man seventy-seven years old suffering from intestinal obstruction and great tympanites. The formation of an artificial anus was quickly followed by the re-establishment of the normal course of gas and feces, and the patient is still living.

SEGOND said that in every case, whether the diagnosis was clear or not, it is necessary to spare the patient as much as possible; hence, an artificial anus is indicated. Thus, in post-operative obstruction, such as may occur after vaginal hysterectomy, celiotomy may possibly succeed in relieving the obstruction; but according to his experience the patients so operated upon all die. The establishment of an artificial opening, on the contrary, gives the maximum chance of recovery. In conclusion he would say that the establishment of an artificial anus snatches the patient from death, oftentimes produces a complete cure or at least puts them in a position, as in the case of tumors, to be cured by a later operation, and never, or hardly ever, causes immediate death.

NELATON gave it as his opinion that in the majority of cases it is impossible to determine the cause of obstruction. In these conditions celiotomy adds an unjustifiable risk. He performed it once and death resulted, while the production of an artificial anus has given him excellent results. If one can be certain that obstruction is due to a band, celiotomy is indicated.

MICHAUX thought that in acute cases in young patients celiotomy is the only rational procedure. If there is a great degree of tympanites, it is advantageous at the beginning of the operation to puncture the intestine and to allow the escape of fecal matter and gas. He has followed this plan successfully in several cases. It is only when the laparotomy gives no result that the operation should be terminated by an artificial anus.

ROUTIER said that if one does not know the site of the obstruction it is better to perform celiotomy if the condition of the patient warrants it. Moreover, an artificial anus is not as simple as some might think. In 1889, Curtis showed that this operation had a mortality of 48.7 per cent.

HARTMANN believed that celiotomy is the method of choice in the treatment of obstruction, and that the mortality which follows results rather from the duration of the condition than from the operation itself.

CHAPUT spoke of the difficulties of celiotomy for obstruction. The intestine is often enormously distended, and the manipulation which is required to inspect it and restore it to the abdominal cavity renders the operation particularly dangerous. Even in cases of obstruction due to a band the creation of an artificial anus may give excellent results, for it is the distention of the intestine which produces the obstruction, and if that is re-

lieved the normal course of the fecal matter may be resumed. It is only in acute cases without much tympanites that the celiotomy should be advised.

At the session of October 14th, the discussion of this subject was continued. LEJARS said that there is a mild variety of paralytic ileus which yields to electric treatment. In another form of paralytic ileus there are more obstinate symptoms, and these cases may prove as serious as those in which a volvulus or a band exists. It is impossible to lay down a hard and fast rule for the treatment of all cases. An exact diagnosis is often impossible, and if electric treatment is without result he inclines toward celiotomy. If nothing is found to explain the obstruction a fecal fistula should be established.

FÉLIZET said that in children the delicacy of the intestinal walls renders celiotomy especially dangerous. This and other reasons has lead him to the conclusion that an artificial anus, which can be easily established without general anesthesia, is the best form of treatment. Some days later when the abdomen has resumed its normal flaccid condition, there will be a reasonable chance of making a correct diagnosis, and the surgeon may then act in accordance with it.

PICQUE thought that in genuine obstruction treatment should depend upon the diagnosis. If, as often happens, this cannot be exactly determined, an exploratory laparotomy should be performed, and is the cause of obstruction is found, an attempt should be made to relieve it. If no cause is found, then either an artificial anus or an enteroanastomosis is indicated. Naturally, if the diagnosis is that of a lesion not amenable to operative treatment, an artificial anus should be performed to relieve the patient as much as possible.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.—SECTION ON GENERAL MEDICINE.

Stated Meeting, Held October 19, 1897.

DR. F. L. BISHOP in the Chair.

DR. WILLIAM OSLER of Baltimore read the paper of the evening, entitled

INTERNAL MEDICINE AS A VOCATION. (See page 660.)
DISCUSSION.

DR. WILLIAM M. POLK: I feel much indebted to the distinguished gentleman who has so kindly come a long distance to give us his impressions as to the right path to be followed to attain success in internal medicine. If the author were not present, it might not be out of place to draw attention to the enviable position which he himself has reached by following the lines so gracefully sketched in the paper of the evening. I do not know but that there is a good deal in the Doctor's intimation, that surgeons are perhaps excused from the possession of the amount of cerebral tissue, or the exercise of that tissue, which is essential to the success of him who confines himself to internal medicine. No man can practise any department of medicine unless he has a knowledge of

internal medicine. All, therefore, that Dr. Osler has said, as to the necessity for persevering work, we should take to ourselves quite as much as he intends the consulting physician to claim. There is no doubt that the surgeon takes up his work where he who gives his attention to internal medicine leaves off. This does not necessarily imply, however, that all bad and hopeless cases are turned over to the surgeon; for the practitioner of internal medicine, by reaching conclusions as to the limitations of his powers, is in a position to say whether he can continue the work, or whether it shall be taken up by the surgeon.

The poorest surgeon is he who begins his work as a surgeon; for he inevitably magnifies his field to the detriment of that of the physician, frequently when his comrade would have been able to bring the case to a successful conclusion. Often, if the surgeon has but the patience to withhold his hand, he will find that there are means and measures at his command, not strictly surgical, which will accomplish the purpose.

In reference to the way in which a good consultant is made, along the lines suggested by Dr. Osler, one of the first principles is to learn how to write. One must possess ideas if one would give expression thereto, and ideas cannot be obtained except as suggested by Dr. Osler. But, those who have followed some of the attending consulting physicians through the wards of the hospitals, not so very far away, remember full well how the men who wrote had the greatest reputations, but oftentimes the men who did not write could best tell what was the matter with the patients. No matter how much knowledge may be possessed, if we expect to win the confidence of those who are not merely at our doorstep, but in the adjoining towns and distant cities, the legitimate method of professional advertising must be learned and practised.

The curse of to-day is specialism. This may seem a broad statement to make; but it is, nevertheless, true. Specialism makes narrow, uneducated physicians. The human mind is so constituted, that given any problem to solve, it builds upon it, raises it up, magnifies it until every other idea is completely overshadowed. Thus, it occurs, that while specialism has accomplished great good, it is to-day demoralizing the profession by bringing it into contempt with the laity. Many patients are made to believe, perhaps honestly on the part of the physician, that conditions which are amply met by the ordinary rules of hygiene are of such vast importance that they must be attended to then and there or some dire calamity will result. This is perhaps presenting a low view of specialism, but it has its low as well as its high side. No man will be a good specialist who has not been a good general practitioner. In this respect the example of the carrier-pigeon should ever be borne in mind, which, when loosed to execute some special mission, rises higher and higher, ever circling upward and upward to obtain the broadest view, and then gathering its strength, starts and flies straight to the goal where it would be.

DR. ANDREW H. SMITH: I have been interested in observing how the two preceding speakers approached the question from two directly opposite points of view. Dr.

Osler's idea of a practitioner of internal medicine seemed to be that he should start from the very inception of his medical career with the distinct idea of making himself a consultant. Dr. Polk, on the other hand, has an idea to the main chance, and immediately starts off with a view to success by obtaining practice. Perhaps it would be best to choose a happy medium between the two.

With reference to the preparation of which Dr. Osler spoke, it would certainly require all the time that he had assigned to it, and it seems that the study of internal medicine would necessarily include a very considerable knowledge of the specialties. In order to attain the necessary erudition, all opportunities which open in the way of practice except such as are conducive to obtaining business as a consultant must be refused.

It is said of John Hunter that at one time when engaged in a very earnest study of some subject, in the midst of which he was interrupted by a professional call, that he put it off and put it off as long as he could until he thought the patient's patience would be exhausted, and then, throwing his work aside, said: "I suppose I must go and earn that damned guinea." This is the necessity which presses upon us in this utilitarian age to such an extent that, unless a certain number of young number of young men are determined to follow the lines indicated by Dr. Osler, it seems that the great consultants of the future will be about as scarce as the great statesmen of the present time. About the period during which Dr. Flint was so prominent here there were many great statesmen; they are gone, and we look in vain for their successors. Just so in medicine. There is a multitude of very clever men, but there are very few who stand head and shoulders above their fellows. Aside from a special training, it seems that to reach the place which had been attained by the men mentioned by Dr. Osler that there must be some peculiar attending circumstances.

Many young men have come to me and asked what they should do—where they should settle, and I have always told them to see much of disease, to put themselves in touch with it in any way they could, but at the same time to only handle as much as could be thoroughly and exhaustively studied; to keep themselves constantly occupied with sick people, and to treat every case, whether that of a tramp or a millionaire, with the same painstaking care. This character of work, continued year after year, without in any way seeking the plaudits of the world, simply plodding along day after day, always doing good work, with the interests of patients at heart more than personal aggrandizement, will almost invariably lead to success.

There is one point upon which I wish to touch in particular, and that is the distinction between a good diagnostician and a good practitioner. It is said of the French school that they first make a diagnosis and then are impatient for death to occur, that the diagnosis may be satisfactorily verified. It seems that many of our consultants have about the same idea. Frequently they are unable to assist us in therapeutics. I believe there is something in the therapeutic instinct. There are some men who, when you consult them, always give you an idea to fol-

low—something to do for the patient. This instinct, which teaches a man what may be done to relieve suffering, even though life may not be prolonged, is of immense value. I have often found this faculty to be remarkably developed in men whose field of labor is rural, where they have been thrown upon their own resources. I have often come in contact with such men, and have been surprised at their fertility in therapeutics, and how many times they "get there" when men much more thoroughly equipped halt by the way.

DR. ABRAHAM JACOBI: I am wholly unprepared to discuss this question, but will say a few words in favor of those who have made internal medicine their vocation, if only in the lower or middle walks of the profession. The practitioner of internal medicine has lost ground during the past ten or twenty years in favor of the specialist. Internal medicine has certainly lost in the opinion of the public. The practitioner of this branch of the profession does not spill much blood, does not crush bones, cannot be heard at work in the next room; the principal labor is accomplished in the brain, and is not very noisy. The surgeon removes a tumor which the general practitioner has diagnosed, and the result is that people say "Isn't he a brilliant surgeon? Doesn't he do fine work?" and it might be added, "Didn't he get your fee?"

Everything now goes to the specialist. If a woman has a pain in the head, she must go to a neurologist; if it is somewhere about the feet, she must go to a chiropodist; the nose must be blown by a rhinologist, and the laryngologist takes the case of catarrhal croup; there is the abdominal surgeon and the appendicitis man, so that now nothing remains for the practitioner of internal medicine; his vocation is gone.

I have been a general practitioner nearly all my life, and hope to live a few more years and die a general practitioner. I am quite satisfied with my position; because it appears that if there is any breadth in medical science, it is in the practice of internal medicine. Everybody deems the specialist very broad and deep, when, as a matter of fact, a great many of them do not know anything about medicine. "Internal medicine is a vocation where one deals, not only with every organ of the body, but with lives and hearts. Such a practitioner must care for, not only existing diseases, but for such diseases as may be developed; he naturally is the hygienist of the family. If a good sanitarian is wanted, it will be necessary to look for him, not among the surgeons, the laryngologists, or even among the bacteriologists, but he will be found among broad, well-educated internal practitioners, and if the accomplishments of the general practitioner are compared with the dexterity of the ever so good specialist, it will be found that there is more breath, more impressiveness, and more influence, privately and publicly, in the accomplishments, achievements, and actions of the general practitioners, take them altogether, than specialists can ever acquire.

From Hippocrates all the way down to modern times, there have been those who have made internal medicine their vocation. The surgeons of olden times have disappeared from history and from the memory of the profes-

sion. It is always the memory of the internal physician which survives. I believe that specialism is now at its height, not at the top of the ladder, but at its height, and we shall have fewer specialists in the future. It is my certain conviction that whatever there is that is good and useful for the common weal, will have to be searched for in internal medicine, which will then be the vocation of the profession.

DR. OSLER: I have listened with a great deal of interest to what has been said, and do not wish to be understood as reflecting seriously upon the surgeon. I only intended to say that with the surgeon success comes earlier, and that with him, in many cases, it is very much more a matter of hands than of head. In reference to a young man starting out in general practice, I believe that the plans followed by the young men in London could be followed with profit in our large cities. In London the young man who aspires to consultant-work does the junior duties about the hospitals and dispensaries, in many cases until he is forty-four or forty-five years old, before he reaches the wards. The young man, in the large cities of this country, who aspires to be a consultant should probably do more or less general medical practice, but the main work upon which reputations are to be built, should be in the hospitals and dispensaries. I am quite sure that the London method has proven successful, and that many of our best men in this century have never been in general practice; that is to say, in a large general practice, but have directly developed from dispensary and hospital work. There is no reason why a young man, during the first five or six years, who is looking forward to be a consultant, should not learn to use the ophthalmoscope, just as well as the microscope. He is sure that if Dr. Flint did not know much about bacteriology he took care to have a young man about him who did. There is one thing which always impressed me in regard to Dr. Flint's character, and that is, he retained to the last a remarkable degree of receptivity.

In regard to diagnosis, I believe it is a very important matter in consultation. In a large proportion of cases it is the only important function of the consultant. Everything rests with the diagnosis. Of the last three cases he had seen within twenty-four hours, one had pernicious anemia which was not recognized—the patient had been treated for malaria and the diagnosis would give him a few months or years, and possibly give him life; the second case, being cancer of the stomach, it did not make any difference; in the third case, the diagnosis may or may not save life, depending upon the surgeon into whose hands the patient falls. One trouble with the consultant is that their visit usually precedes that of the undertaker, and that they sometimes do not reach the door before the black flag is out. This is one of the saddest things in the life of a consultant; he is simply an attendant upon deathbeds.

In conclusion, I believe the position of internal medicine in this country will grow better and better. I feel confident that the younger men will devote themselves to internal medicine in the broad sense of the term—in the sense of being hospital physicians, clinical investigators,

and clinical teachers. After all, the chief prizes of the profession do not fall into the hands of specialists, but into those of the men who have had a long, hard, uphill struggle, who have worked and toiled for years as surgeons and as physicians.

HARVARD MEDICAL SOCIETY OF NEW YORK.

Stated Meeting, Held Saturday, October 23, 1897.

THE President, DR. JOHN WINTERS BANNAN, in the Chair.

DR. FOLLEN CABOT, JR., read the paper of the evening, entitled

RABIES; SOME EXPERIMENTAL WORK ON A NEW METHOD OF IMMUNIZATION.

The author exhibited a trephine such as is used in Paris for making subdural inoculations in rabbits and guinea-pigs. He also showed an apparatus devised by himself for holding an animal during inoculation, thus avoiding the necessity of tying it to a board, and the consequent fright and struggle. The animal is chloroformed previous to the trephining.

The paper gave in detail the results of experiments made upon guinea-pigs and rabbits at the research laboratory of the New York Board of Health and described at length the process of preparing the immunizing solution. The dry-cord method, which is employed by Dr. R. J. Wilson, is the one used by the author. This consists of a dilution made from fresh medulla or brain taken from a rabbit which has died of rabies. A stock solution is made and kept on ice in varying amounts of sterile glycerin, and each day dilutions are made from it for immunizing purposes. Such a solution is kept and used ten days. The advantages of this method are: (1) it can be tested for impurities before being used; (2) it is more exact and saves much time; (3) the stock solution may be sent to distant places and used by physicians in general.

DR. HOWARD LILIENTHAL said he possessed little knowledge of the subject, but it seemed to him that the author's work is valuable, and that he deserves to succeed in his very worthy object of furnishing an immunizing solution which will be within the reach of practitioners all over the country. As it is now, it is only in a few of the large cities that the antirabid serum may be obtained. Personally he has never seen a case of rabies, but the results of the author's experiments would seem to show that such a disease really exists.

DR. JOHN H. HUDDLESTON expressed surprise at the hesitancy of the preceding speaker in admitting that there is such a disease as hydrophobia, and said it had always been his opinion that the existence of the disease is generally accepted. Personally, he has no doubt of its reality because he has seen three cases occurring in human beings, all of which were fatal, and approved to be genuine by subsequent inoculation of animals. Nothing was done for the patients because nothing could be done. If an immunizing agent has at last been found, we will have to thank the author of the paper for it.

DR. REYNOLD W. WILCOX confessed to an even

greater skepticism on the subject than that shown by the first speaker, and said he had never seen a case of hydrophobia in a human being. A number of alleged cases of hydrophobia have come under his observation, and he has seen one or two dogs which were said to be suffering with rabies, one of which he personally watched for several weeks; but he is still to be convinced that the disease exists, even in dogs. He brought forward the fact that in Constantinople, which swarms with dogs, rabies is unknown, and, in other countries where conditions supposed to be equally favorable to the development of the disease are found, it has not been heard of. He thought the author deserved credit for his work, but added that the best result which can be obtained from such a line of investigation will be the determination of the non-existence of rabies.

DR. ARTHUR B. DUEL said that the belief that such a disease as rabies does exist is firmly planted in the public mind, and is shared by many physicians. If it can be proved that there is such a disease, too much cannot be said in praise of the work of the author in an endeavor to discover an immunizing serum, and one which will be accessible to physicians far removed from large cities.

DR. EDWARD F. FOOTE remarked that in experiments on animals it should be remembered that one cannot always reason by analogy for the same agent does not affect human beings and animals alike. This fact has been a block against which many men have stubbed their toes. Even the great Koch himself made this mistake, as shown by the disappointing results obtained when his tuberculin was tried on the human subject.

DR. CHARLES SCHRAM said that those who are familiar with Pasteur's work and that now being done at Budapest can hardly doubt that the human being is subject to hydrophobia.

DR. FRANK H. DANIELS expressed himself as being skeptical as to the existence of rabies either in animals or man. He is of the opinion, however, that it is sometimes best to treat patients when they think they need treatment, and in such cases it would be well to have some immunizing agent administered to persons who have been bitten by an animal and who fear they are going to have hydrophobia.

DR. DILLON BROWN declared that he is thoroughly convinced that there is such a disease as rabies, and that it may exist in the human subject. No one who has witnessed it in the rabbits and guinea-pigs which have been inoculated at the Health-Department laboratory can possibly doubt its existence. He said he had seen one case of hydrophobia in practice. The patient had been bitten on the cheek by a supposedly mad dog, and was sent for treatment to the only institution in this city where the antirabietic serum is employed. A certain number of injections were given and the patient promptly died on the sixteenth day after developing a classic case of hydrophobia. Unfortunately no autopsy was obtained. Whether the disease was due to the bite of the dog or to the inoculations is a question. Taking all things into consideration, it is not unlikely that it was caused by the latter.

DR. FOLLEN CABOT, SR., said that during his long

residence in New York he has observed two cases of hydrophobia, both of which resulted fatally within four days of the appearance of the first symptoms. Both cases were carefully watched, and no hysteric element was present. In one the disease was the result of the bite of a dog, in the other it was caused by the bite of a cat.

DR. FOLLEN CABOT, JR., said he was surprised at the skepticism displayed by some of the members present. After the work of Pasteur he thought no one could doubt the existence of rabies. The guinea-pigs and rabbits which have been inoculated at the laboratory of the Health Department all developed the disease, presenting the same symptoms and invariably dying within a certain number of days.

DR. WILCOX remarked that skepticism has been growing year by year, and is made stronger by the reports issued by the so-called Pasteur Institute in this city, which prove, if they prove anything, that the patients treated there all die within a certain length of time after receiving the inoculations. The speaker said that from a report of the Pasteur Institute of St. Petersburg, which he had been reading recently, it seemed that the patients which died after the antirabietic inoculation really died of septicemia. He also said that there is no known inoculable disease which has an incubation period of from one day to twenty-five years, which is the limit claimed by the believers in hydrophobia.

THE PRESIDENT asked the author if any definite lesions are found in animals who die after experimental inoculation, and, if such exist, whether they have ever been found after death in persons who believed they had hydrophobia.

DR. CABOT replied that some definite lesion has been found in pathologic work on animals, although it has not been clearly determined. He also took exception to Dr. Wilcox's remark in regard to the incubation period of rabies being from one day to twenty-five years. He thinks that no one nowadays makes such a claim. The disease generally appears within fourteen days, and always within a month. Every animal inoculated with the serum at the Health-Department laboratory developed symptoms of rabies in from three to sixteen days, and died within a month. The disease begins with gradually increasing paralysis of the hindquarters, paralysis of the jaw, progressive weakness, and in the *dumb* form the animal becomes weaker and weaker, and finally lies down to die. In the *furiosus* form delirium develops, the animal becomes wild and dies within a few days.

DR. WILCOX then said that the symptoms described by the author as occurring in the inoculated animals are precisely the same as those which appear in guinea-pigs after they have been injected with cod-liver oil, *i.e.*, symptoms of ptomain poisoning.

DR. CABOT replied that it is quite possible that symptoms resembling those of ptomain-poisoning may develop after the antirabietic inoculations.

DR. CHARLES SCHRAM then read a paper, entitled
PTOMAIN POISONING FROM EATING LOBSTER.

(See page 659.)

DR. WILCOX remarked that in the light of the subse-

quent events all would agree with Dr. Schram in his diagnosis, although many difficulties presented in the beginning. He also said that no internal preparation of bismuth is poisonous, although many curious effects have been noted after its administration. He cited the case of a woman who during four- or five-months' stay in a hospital received no bismuth whatever, and yet a mass of it weighing half a pound was found in her stomach after death. He also referred to a case of psoas abscess resulting from caries of the spine, into which one ounce of a ten-per-cent. emulsion of bismuth had been injected, and in which serious symptoms of poisoning developed. He stated that in all the cases of bismuth poisoning which have been reported the drug has been used externally in combination with glycerin. The speaker has taken 90 grains of bismuth internally with no bad effect except the resulting constipation.

DR. FOOTE said that the sudden disappearance of the fever might have been due to the large evacuation; in other words, that the temperature may have been caused by long retention of undigested food. He mentioned the case of a woman, suffering from fecal retention, who suddenly developed such serious symptoms that she seemed to be in danger of dissolution. All symptoms were immediately relieved by the discharge of a quantity of fecal matter through an artificial anus.

DR. DANIELS said he did not consider the case one of ptomain poisoning, because the symptoms were not sufficiently acute in the beginning. There would have been severe vomiting, diarrhea, and collapse within two or three hours, followed by great pain. He referred to an instance in which several members of a family suffered in this way from ptomain poisoning, due to drinking butter-milk.

DR. SCHRAM, in closing, remarked that retention of fecal matter would not explain the high fever which preceded the evacuation. The patient was a strong, healthy woman, not likely to be prostrated by such a movement. As against the theory of ptomain poisoning, of course there is the fact that two other members of the family ate of the lobster and were not in the least affected by it. He also expressed himself as not being sure that the naphthol did not play a part in causing the trouble. The drug was retained for thirty-six hours above the fecal mass, and was discharged with the latter. This he considers an important point.

REVIEWS.

APPENDICITIS AND ITS SURGICAL TREATMENT. By HERMAN MYNTER, M.D. (Copenhagen), Professor of Operative and Clinical Surgery in Niagara University; Surgeon to the Sisters of Charity Hospital in Buffalo, N. Y. Philadelphia: J. B. Lippencott Co., 1897.

THIS is a monograph of 303 pages submitted by the author to his alma mater for the degree of M.D., twenty-six years after his graduation. "The degree of Doctor of Medicine is not conferred in Denmark at graduation as in America," although the right to practice is given.

Aside from publishing the histories of seventy-five cases

of his own, the author has industriously conned the literature of the subject, and has given us a monograph at once scientific in conception and interesting in treatment. He has made it clear that appendicitis is a surgical disease, and in so doing accepts the verdict of American physicians. We believe that in no other country do surgeons and physicians agree more universally on any topic in the whole realm of medicine, than does the American profession on this.

The author has divided his subject into several chapters, dealing respectively with the history of the disease, the anatomy, histology, and function of the appendix, and the etiology, pathology, classification, symptomatology, complications, diagnosis, prognosis, and treatment, medical and surgical, of appendicitis. We wish he had not included Austria under "Germany," but this seems to be an inevitable failing of American writers.

The book is very readable and interesting, and will certainly meet the approbation of American surgeons. We hope it may do some much-needed missionary work in other parts of the world.

THERAPEUTIC HINTS.

For Asthma.—

℞ Tr. opii 3i
Ætheris sulph. 3ii.

M. Sig. Fifty drops at intervals of one-half hour until the spasm is relieved.

For Acute Infectious Gastritis in Infants.—

℞ Cupri arsenitis gr. $\frac{1}{80}$ - $\frac{1}{4}$
Sacchr. lact. gr. 3i ÷ i.

M. Div. in chart. No. XVI. Sig. One powder hourly, and when improvement begins give one powder every two or three hours.—*Krüger*.

An Excellent Vermifuge for Children Is as Follows:

℞ Benzonaphthol } aa gr. xxx
Santonice }
Sacchr. alb. gr. 3i ÷ i.

M. Div. in chart. No. XX. Sig. Two to five powders daily.

For Cephalalgia.—Pyramidon, related to antipyrin, is reported to be of great value for the relief of headache and all neuralgias of a rheumatic origin. The dose is 1 to 3 grains in water. Not more than 5 grains should be administered during an attack.

For Arterial Sclerosis.—A potion consisting of water and bicarbonate of soda, to which is added a sufficient quantity of lactic acid to neutralize the former, is advocated by Rumpf as a diuretic in arterial sclerosis. It also increases the elimination of the calculi-forming salts.

For Chronic Cystitis.—

℞ Methylene-blue gr. xxxii
Talcum gr. xlviii
Lanolin q. s.

M. Div. in pil. No. XXIV. Sig. Two to four pills daily.

ORIGINAL ARTICLES.

THE USE OF MANGANESE IN THE TREATMENT OF DYSMENORRHEA; WITH REPORT OF CASES.

BY CHARLES O'DONOVAN, M.D.,
OF BALTIMORE, MD.

IN THE MEDICAL NEWS of April 6, 1889, I published an article, entitled "A Plea for the Use of the Manganese Compounds in Certain Forms of Dysmenorrhea," in which I drew the following conclusions:

1. The manganese compounds are valuable additions to the therapeutics of dysmenorrhea, and in a certain number of properly selected cases, great benefit may be expected from their use.

2. Their use does not interfere in any manner whatever with the administration of iron or the vegetable tonics, but rather aids and is aided by them.

3. The best results from the employment of these remedies may not be obtained at once, and failure should not be confessed until after a continuous trial lasting three months.

4. So far as we know at present, the black oxid of manganese is the most convenient form for administration.

At that time the observations of Ringer and Murrell of London called attention to the benefit to be derived from the compounds of manganese in various menstrual disorders, and other clinicians had testified in their favor. Having enjoyed a certain vogue at the time, in the avalanche of new remedies which are being constantly exploited, manganese seems to have lost its prominence, and is now seldom referred to. I feel that this is a mistake, that a remedy, valuable in a number of cases, is being overlooked. That it is one which deserves to be rescued from oblivion and again presented for study and trial. I have been using manganese constantly since the appearance of the paper quoted, and am to-day as favorably impressed with it as when I reported my former observations. I hold it to be most valuable in the treatment of dysmenorrhea in unmarried women; and, until it has been faithfully tried during a period of not less than three months without intermission, I would use no other treatment.

Manganese will not relieve all cases; in some it produces no effect whatever, and in some few in-

stances women have complained that their sufferings actually seemed to have been exaggerated; but when it does act favorably, it is such a boon that it cannot be overvalued. Unfortunately, one cannot foretell in a given case whether or not manganese will be of benefit; I have known it to fail when I had most reason to expect success, and to relieve when I feared it would fail, so that its use is somewhat empiric, and apt to lead to disappointment. This does not, however, change the fact that a large number of cases of dysmenorrhea may be relieved by its use in a way that no other drug can approach, and often after numerous others have been tried and discarded as useless. Even in these days of manipulative and operative gynecology there are many young women who would prefer to be treated by medicines rather than by instrumental interference; who are very naturally frightened out of the office of a physician who suggests a digital examination as soon as a history of dysmenorrhea has been elicited.

In my experience the best results from the use of manganese have resulted when the history is of general malaise before the flow begins, with some pain, growing rapidly worse as the flow is about to commence, and pain more or less severe during the first day. A good color or a pale face seems to have no bearing upon the action of the drug; its action appears to be upon the nerves or nerve-centers concerned in the menstrual function, rather than upon the blood. It is no unusual thing to find a habit of dysmenorrhea, which had existed for years, yield at once to the exhibition of manganese.

The following case is an example:

CASE I.—B. J., aged twenty-five, unmarried, had always suffered from her menses since their establishment. Every month, for as long a period as she could remember, she had spent one day in bed, with severe pains, which she tried to deaden by taking whisky, about six or eight ounces being her ordinary allowance. Her sickness came on regularly every month, but always with a sense of weight and heaviness about the loins, and with excessive pain during the first day of the flow. The pain was no worse than it had always been; nor had the amount of the flow, nor the time which it lasted, changed during years of suffering. She had been a robust girl, taking a great deal of exercise out of doors. When younger she had been rather plump, with good development of bust and hips, but had at this time grown much thinner. Although she had

always been considered sensible and self-contained, she noticed that she easily lost control of herself and gave way to crying spells and fits of depression without sufficient cause, especially just before her menstrual periods. She became quite dyspeptic and constipated, and "colds," which she formerly disregarded entirely, were thrown off with difficulty. She did not blame her dysmenorrhea for any of these troubles, but found that she was less able to put up with these discomforts because of the weakening effect of the regular dysmenorrhea. Early in April, 1895, I prescribed black oxid of manganese, in combination with dried sulphate of iron and extract of nux vomica, in pill form, three times a day during the ten days previous to her menstrual period. On May 1st, she reported that her menses came on during the night, with none of the old feeling of discomfort, and so free from pain that she was not even awakened. This was a totally new experience, and incomprehensible to her, but she remained in bed during the first day of the flow, from force of habit, expecting every moment the return of the usual pain. On June 19th she reported a similar experience. She took the pills daily during the ten days before menstruation; again, she rested during the first day in anxious expectation, but had no pain. Before her period in July she took the pills daily during a week.

By this time, womanlike, she thought that she could act during menstruation just as at any other time, so she was quite imprudent regarding her exercise and clothing, but she experienced no ill result beyond a trifling amount of pain. I explained to her the limit of benefit to be derived from the medicine, and the necessity for care during menstruation even in healthy persons, and she promised to conform to my advice. I have heard from her several times since and she always reports favorably of the action of the pills, saying that she would not be without them for any consideration.

Inasmuch as iron and nux vomica as well as manganese were given, one might be inclined to attribute the resulting benefit to these drugs as well as to the last, but this I am not willing to do. The only improvement in the young woman's condition is that described; she is still as anemic as before; she has not gained in weight; she is still dyspeptic, and finds colds just as troublesome as formerly. The one function improved is that of menstruation, and in that alone does she see any change. She is not so depressed and inclined to the "blues," and she does not suffer pain during her periods. She expected to improve in all her other functions as soon as her dysmenorrhea ceased, but such a result has not followed.

CASE II.—V. K., aged twenty-one, unmarried, a very quiet, sensible girl, with no nervous symptoms whatever, consulted me March 6, 1897. She had a good complexion, was well developed, but not fat, had a good bust and fair hips, and seemed healthy in every way. She was a dressmaker

by trade, and formerly thought that the sedentary occupation and confinement to the workroom had much to do with her suffering, but during several months she had been out of employment, doing nothing but light work about the house, and had had plenty of time for out-door exercise. In spite of this, there was no improvement. Her menses began at the age of fourteen, and she had always had pain during the flow; this was bearable at first, but gradually grew worse until it became agonizing during the previous two years and was constantly growing worse. Menstruation was regular, and lasted six days, the pain continuing during the entire time, but being terrible during the first day, which she always spent in bed, taking large quantities of whisky or gin. This resulted only in somewhat alleviating the pain. Between her periods she was perfectly well in every particular. She had unsuccessfully tried various remedies recommended by friends, but had never been examined or taken any medicine prescribed by a physician. Her mother brought her to me for examination and local treatment, to which the girl was naturally much averse. Instead, I ordered black oxid of manganese in 1-grain pills, one to be taken after each meal until after her next period. On March 29th she reported that she had regularly taken the pills and had passed through a period. Although she still suffered a good deal, she felt much encouraged, as she was sick but four days, instead of the usual six, and with much less pain. On the first day of the flow the pain was distinctly less, and even then lasted a much shorter time, so that she was compelled to stay in bed only half the day. She was ordered to continue the same treatment. On April 26th she reported after another period. She had taken the pills, irregularly, until within a week before her time, but for the last week had faithfully taken them. Her period came on three days late, and lasted five days. For the first time in years she did not suffer pain; she was up and about every day, and was able to do her housework without any inconvenience. She was directed to take the pills regularly during at least a week before each succeeding period and report her experience.

From this girl's appearance and general health one would not have supposed that she experienced trouble with her menstrual function; from her history one would suspect the existence of some uterine malposition, most likely a uteroversion or flexion, producing the six-days' flow, with pain and congested feeling, and naturally some local treatment would be suggested after making the diagnosis by vaginal examination. Yet perfect relief was very promptly obtained without recourse to any instrumental interference or to anodynes. When I learned her symptoms I did not expect relief to follow so promptly, if at all; I thought she had some uterine displacement which would require treatment, yet on general principles, because I dislike very much to examine unmarried women unless it is absolutely necessary, I

decided to try first what could be accomplished by appropriate medical treatment.

I could never find out what remedies this girl had been given by her sympathetic friends, but I have often met girls whose drug-knowledge appeared to be quite extensive, either from their own experience or from what they had learned from others. The danger is that some anodyne may be tried, and in this way a craving for such drugs become established. Women are very clever and soon learn to read prescriptions. Already having a newspaper knowledge of morphin, antipyrin, phenacetin, and similar drugs they soon find out which acts most promptly and powerfully and have recourse to it without the formality of consulting a physician. Manganese, however, is an unknown quantity and does not appeal to the female imagination, nor, unfortunately, to the medical mind as much as it should.

CASE III.—S. G., aged eighteen, unmarried, consulted me June 18, 1895. She began to menstruate at the age of twelve, and always suffered. The flow usually lasted but two days. She always had excessive pain during the entire first day, so that she was compelled to remain in bed. She was a school-teacher and naturally rebelled against this suffering and loss of time. She had always been very irregular, menstruating at intervals of two, three, or four weeks. She had been treated by various physicians, with many different drugs, but none gave much relief. Antipyrin, in large doses, served to quiet her for a time to some extent, but left her very weak. She was seriously contemplating having her ovaries removed.

I prescribed the black oxid of manganese, in 1-grain pills, three times a day, during the next month. On July 15th she reported that menstruation came on after four weeks, that she was sick three days, and that she suffered some during the first two days, but that her suffering, though prolonged, was much less in the aggregate than at any period for a long time. I advised her to continue the pills regularly. She failed to report until October 10th, when she said that she had been very negligent in taking the medicine. During August she did not take it, and had had terrific pain. During September she took the pills with some attempt at regularity, and had had less pain. The manganese was then discontinued, and she was given fluid extract of viburnum prunifolium until December, when she asked to have the manganese again as the pains were not at all relieved by the other preparation. During January, 1896, she reported that she had worked all through her last period. She was seen again in February, having passed through two periods, which were very satisfactory, although not free from pain. She was advised to take the manganese regularly after each meal and report occasionally. I heard nothing more from her until May 15, 1897, when she reported that she had taken the pills regularly until Septem-

ber, 1896, and that during all that time each period had lasted three days, with pain of three- or four-hours' duration on the first day. The periods regularly recurred every three weeks, but with little discomfort. During September she lost the prescription, and did not take any medicine for eight months. She was under excessive nervous strain and mental worry at this time, but had very fair menstrual periods, although they gradually become more painful, until in April her pains were almost as bad as formerly. She was told to take the manganese pills three times each day during at least a week before each menstruation.

I asked this patient particularly about the drugs she had taken before I saw her, but she knew nothing of them, except that one was antipyrin, as all had been given her by different physicians, and all had been failures. Though the manganese was not as great a success as I had wished, still it was far more efficacious than anything else that had been prescribed.

This young woman was endowed with a great deal of good sense and perseverance, which had been put to a very severe test by the failure of so many drugs, one after another. Fortunately, she was not inclined to be at all morbid or hysteric, but had concluded that it was her fate to have such menstrual pains. There are many, however, who are not so placid; who rebel constantly at each recurring epoch; who brood over their sufferings, looking forward with dread from one period to the next. Such women are readily thrown into a true hysteric state, become peevish and fretful, and altogether disagreeable to themselves and to those about them. They are recognized as having high-strung nerves which are readily disordered, especially at or about the time of menstruation. In such women vaginal examination frequently does not reveal anything to account for the trouble, and local treatment is more or less empiric. I have found manganese very efficacious in many such instances, and always use it when such a history is presented before resorting to vaginal exploration no matter how severe the symptoms may be, or how helpless the case may seem from a therapeutic standpoint. Indeed, I consider these the most brilliant successes from this treatment. The whole train of nervous symptoms follows the pain, exciting reflexes in an individual already prone to develop such symptoms under the stimulus of pain, and rendering the system less and less able, with each monthly recurrence, to bear up against its disorganizing effect. The pain shatters the nervous equilibrium, which condition makes its endurance less possible; in effect this condition of the nerves increases the pain, from the sufferer's standpoint. This unfortunate sequence goes on month after month, with in-

creasing effect until the woman is reduced to a condition bordering upon insanity, and is ready to do anything for relief, even to sacrificing her ovaries at the suggestion of the operating gynecologist. I have seen a number of just such patients promptly and effectually relieved by the administration of manganese, so that the pain would never return as long as the drug was taken. The following case is an instance of this:

CASE IV.—M. M., aged twenty-five, unmarried, consulted me March 19, 1895. She was a very well-developed girl, who showed no apparent sign of illness. She worked at sewing of some kind, in a factory, which was not hard work, but confined her to a work-room, and to a constrained position at her machine. She had grown up in perfect health, and had been very strong and vigorous during her school days, being full of play and able to hold her own in any rough sport. Her menses began at the age of seventeen, lasted four or five days, and were at first entirely painless. About three years before I saw her she began to experience trouble with her menses, which began with slight pain, and fretted and irritated her. Gradually she had more pain each month until she felt as though death would be a welcome relief. During the previous six months she had been constantly at such a nervous pitch that it was almost impossible for her to work, and she felt that matters were rapidly approaching a crisis. She had not yet visited any specialist, but had been freely dosed with household remedies, chiefly whisky and ginger. From these she obtained a slightly stupefying effect, but no actual relief. I prescribed pills, each containing 2 grains of black oxid of manganese and 1 grain of dried sulphate of iron, one after each meal. I did not see her again until May 4th, when she reported that after the first few days she had improved. Her nervousness became less, and she was able to look forward to her menstrual epoch with less anxiety than formerly. She menstruated March 25th, and again April 19th. Both periods were perfectly natural and free from pain, even the nervous excitement which usually accompanied them being entirely absent. She felt just as she did formerly, before the advent of the painful experiences. She continued to take the pills during the month of May, and reported that her period at that time was painless. During June she neglected to take the medicine but had a very good period. She was warned of the imprudence of this neglect, and she began taking the medicine again, continuing it regularly through her July period, which lasted five days, and came on so painlessly that she was not conscious of it, and continued regularly and easily throughout. Better even than the absence of pain was the improvement in her general condition. Instead of the nervous, hysteric woman that she had become, she has again returned to her former excellent physical and mental health. She works regularly, and with little distress, and is in every way a different woman. She

feels that she has in her own hands a remedy which will keep her well if she uses it.

This is but one case taken at random from many which might be cited in favor of the use of manganese in such instances. The whole picture of the case of this girl is just such as gives pretext in the hands of advanced gynecologists to prolonged local treatment, often resulting in some serious operation; yet all the symptoms disappeared promptly and finally soon after beginning the treatment suggested, and never returned as long as it was continued.

I have had this experience too often to think it an accident. In equally trying cases I have again and again been able to give relief with manganese after many other drugs had been unsuccessfully tried. I do not pretend that manganese will relieve every case of dysmenorrhea, nor, indeed, that it is the only drug which will relieve it. I have often failed with it and obtained relief from the use of other drugs afterward, but I feel convinced, after years of patient and persistent study of the therapeutic aspect of dysmenorrhea as it occurs in young girls and unmarried women, that we have in manganese a remedy which, in many cases, will give relief from the severe and distressing train of symptoms usually accompanying dysmenorrhea, without recourse to any further treatment, thus sparing the woman, already nervous, perhaps hysteric to a high degree, the added anxiety of useless vaginal manipulation. With such a fact before us I feel that no unmarried woman who complains only of dysmenorrhea should be subjected to a digital or instrumental examination for the purpose of diagnosis until she shall have taken a full course of manganese during at least three months, taking 1, 2 or 3 grains of the black oxid three times each day during that entire period, the size of the dose depending upon the ability of the patient's stomach to retain and assimilate the drug. If such treatment could be faithfully carried out I believe that many women would find in the use of these harmless pills the relief which they do not receive from local procedures, and many more would be spared the necessity of any other treatment whatever.

In some instances the effect shows itself remarkably at the first succeeding menstrual period; in others, a longer time is required; in none would I feel that a fair trial had been given until three months had passed; not until then would I consider the propriety of making further examination. In cases of anemia or chlorosis it is well to combine iron with the manganese, but there are many cases in which a need of iron is not at all indicated by the appearance of the woman, and yet relief from severe menstrual pain is

obtained through the use of manganese. Such experiences teach that there is something in the latter drug which acts, apart from the iron, even in anemic cases. I believe it to be an excellent adjuvant to iron in the treatment of constitutional anemia, but in the treatment of the dysmenorrhea of anemic subjects I believe that the manganese plays the important part and that the iron is the adjuvant.

One word about the administration of the drug. Some women experience considerable difficulty in taking it because of a very delicate stomach, which rebels against it. For this reason it is well to begin with a small dose, say 1 grain at a time, and gradually increase it. I have given 5 grains three times a day during several weeks without any ill effect, but experience has taught me that 3-grain doses will do as much good as a larger quantity, and that failure with that much cannot be changed to success by increasing the dosage. Often it is unnecessary to give even that much, but it may be properly pushed to this limit in doubtful cases.

A NEW METHOD OF GENERAL ANESTHESIA.

BY M. L. MADURO, M.D.,
OF NEW YORK.

THE dangers of the administration of the general anesthetics now in use, *viz.*, ether and chloroform, have been too often discussed since their introduction, but up to now no one has succeeded in solving the problem whereby their disadvantages may be eliminated or lessened. With this object in view a new method has been given to the world which has stood the test of practical application, and has demonstrated, to the minds of many of our distinguished colleagues abroad, all that is claimed for it. The discoverer is best known to us through his original work in the domain of local anesthesia by the infiltration method. I refer to Schleich of Berlin, whom it has been my good fortune to meet recently, and thus be placed in a position to relate what he claims for his discovery.

It is now some two years since Schleich began making original investigations and experiments upon animals in the field of general anesthesia, and his results culminated in the production of a book which was published some six months ago, and was well received by the German members of the profession.

All anesthetics act in small doses as excitants, in large doses they induce sleep, and in the largest doses cause death. It is clear that a narcotic which rapidly evaporates is rapidly eliminated by the respiratory organs, and one which does not evaporate as quickly remains longer in the system and becomes more dangerous with prolonged inhalation. It is acknowledged that a body evaporates more rapidly

the lower its boiling-point, and *vice versa*. The question arises: What is the relation of the boiling-point of the various narcotics to the temperature of the organism by which they are absorbed? It must be admitted that a narcotic with a boiling-point of 15° C. (ethyl chlorid) or one which boils at 65° C. (chloroform) must act in different ways upon an organism the temperature of which is 38° C. Schleich, knowing that there ought to be an intimate relation between the boiling-point and the temperature of the body, undertook experiments to discover by a physical process a mixture which would satisfy this relation and materially lessen the dangers of general anesthesia. He found that when the boiling-point is higher than the temperature of the body the amount necessary to narcotize is less than when the boiling-point and temperature are equal. Again, when the boiling-point is higher than the body temperature the deeper the resulting narcosis. The boiling-point of chloroform is 65° C.; of ethyl bromid, 39° C., and of sulphuric ether, 34° C. Thus, it may be understood why less chloroform than ether is necessary to narcotize, and why chloroform narcosis is deeper than that of ether. Schleich has proved that anesthesia with ethyl bromid, the boiling-point of which is 39° C. (nearest the temperature of body), would be an ideal anesthetic were it not for the fact that the advantage of boiling-point is not sufficient to overcome the dangerous action of the bromin.

After making various mixtures of the different anesthetics, Schleich concluded that it is possible to change the boiling-point to the desired degree, and that the mixture will continue to boil without decomposition as long as its temperature is not considerably higher than its determined boiling-point.

Mixtures of ethers, the boiling-point of which closely approaches the temperature of the body, absorbed during respiration will boil when expired with the air in the lungs. It is possible to mix ethers having different boiling-points in various proportions and thus obtain a desired boiling-point; and further regulate it according to the proportion of each used.

After various experiments upon animals, Schleich succeeded in preparing the three following mixtures which constitute the new method:

Mixture I. (Boiling-point, 38° C.)
Chloroform, 45 parts.
Petroleum ether, 15 parts.
Sulph. ether, 180 parts.

Mixture II. (Boiling-point, 40° C.)
Chloroform, 45 parts.
Petroleum ether, 15 parts.
Sulph. ether, 150 parts.

Mixture III. (Boiling-point, 42° C.)
 Chloroform, 30 parts.
 Petroleum ether, 15 parts.
 Sulph. ether, 80 parts.

The mixtures may be prepared by the anesthetizer. The only thing to remark in preparation is that the petroleum ether should have a boiling-point between 60° C. and 65° C. Schleich uses petroleum ether because he found in his experiments upon animals that no other ethereal substance can be administered in such large doses without causing serious disturbances. It, however, seems to mitigate the action of the chloroform contained in the mixture and to dilute the other substances without interfering with their action. The method of administration differs little from that commonly employed in giving other anesthetics, inasmuch as the greatest care in the amount used should be observed. Small doses will lead to slow but sure results. Enough stress cannot be laid upon this point which, as we know, is the common mistake in the administration of anesthetics. With Mixture 1, 30 grams should be an average dose for an operation lasting twenty minutes or less. Schleich has manufactured a special mask; but he has now discarded it, to use with equally good results the practical American idea of the paper-and-towel combination.

If a more prolonged operation is undertaken, a higher boiling-point is selected (Mixture I. or II.); for then the small excess which cannot be immediately eliminated with the expired air will induce a profound sleep with a very small dose. With this method one can regulate the narcosis by the respirations alone. Schleich is enabled to have his patients who are only under a brief narcosis immediately awake after the completion of the operation; for if Mixture I. is used (boiling-point equals temperature of the body) only a few free respirations are necessary to awaken the patient.

After having witnessed quite a number of operations at Schleich's clinic, I was amazed at the rapidity with which the patients both succumbed to and recovered from the anesthetic. A response to a question could be elicited immediately after the mask was removed from the face. Laxity of the abdominal muscles was complete after an average of five-minutes' narcosis. The stage of excitement was generally absent, even in alcoholics. Cyanosis or nausea were never present. Vomiting occurred about as frequently, never more so, as with the use of chloroform. There was no salivation or bronchitis.

Schleich relates a case of bronchopneumonia in a child who previously had had diphtheria, and whom he had occasion to anesthetize. The child was not made worse, but recovered completely from the an-

esthetic within forty-eight hours. In febrile cases, narcosis has been induced without any resulting disturbances when the 42° C. mixture was used. The pulse was always of good tension, never increased, and sometimes decreased. After the employment of this method of anesthesia patients awaken more refreshed than after the administration of ether or chloroform.

Schleich has, up to the first part of this year, collected some 360 cases in which he has used his method of narcosis with uniformly good results. All that he claims for it has been upheld by many of his associates abroad. There is little or no doubt in my mind that this new departure in scientific up-to-date anesthesia will revolutionize the old methods, and will prove its efficiency by its general adoption in the near future.

A PHASE OF THE TREATMENT OF GOUTINESS.

BY REYNOLD W. WILCOX, M.D.,
 OF NEW YORK;

PROFESSOR OF MEDICINE AND THERAPEUTICS, NEW YORK POST-GRADUATE MEDICAL SCHOOL; VISITING PHYSICIAN TO THE
 NEW YORK POST-GRADUATE HOSPITAL, AND TO
 ST. MARK'S HOSPITAL.

THE subject of lithemia has been presented with thoroughness and vigor by many able internalists, and yet it has never received the attention which its importance demands. Those who have studied its literature during the past five years, and have intelligently applied the principles therein laid down are enthusiastic as to the real advances which have been made. Many hitherto unexplained and inexplicable symptoms and conditions yield as if by magic, and the result is not only a relief from long standing disability, but as well, the acquisition of clearly-cut ideas as to diagnosis and treatment on the part of the physician.

While we are not prepared to abandon the term lithemia, yet perhaps it is well, pending a more widely diffused knowledge of the significance of the term, to substitute for it the word goutiness, which is more suggestive to those who hold conservative opinions, and is supported by the authority of Ewart. Satterthwaite's classification divides lithemia as follows: the hepatic (dyspepsia), the neurotic (neurasthenia), and the arthritic (gout). Further, it must not be forgotten that uric acid, whose rôle in the causation of morbid conditions has been so convincingly proved by Haig, is not all of lithemia, nor of uric-acidemia: else leucocythemia must be included in the consideration of goutiness. Indeed, the fact cannot be safely ignored that many instances of what is popularly designated as chronic rheumatism are, properly speaking, forms of disease resulting from uric-acidemia. As for acute polyarticular rheumatism, modern

investigation warrants us in considering it to be of bacterial origin.

Then, making use of the term "Goutiness," as Ewart as defined it (as being synonymous with the conditions of imperfectly declared gout, not necessarily associated with definite structural change, although such may also be present in a minor degree, and usually consisting of varied functional disturbances of a general character which cause many clinical symptoms), we may differ with him in that uric-acidemia, although a declared pathologic condition, should come under the head of goutiness. After these considerations the title of this paper may seem to be appropriate, and more especially, as it is intended to cover but one aspect of the question, namely, the neurotic form so often discussed under the symptom-complex of neurasthenia. That this condition should be succinctly present is evident from the following instance which came under observation about five years ago:

CASE I.—An officer in the navy became incapacitated for duty. His habits were beyond reproach. He was emaciated, pallid, and appeared at least ten years older than he actually was. About every ten days to two weeks he would be absolutely incapacitated by violent attacks of headache, which continued from two to five days. During two or three days he would be depressed in spirits, suffer from inappetence, perhaps be constipated, and be disinclined to mental or physical exertion. Beginning with the afternoon he would suffer from slight vertigo, "crinkling before the eyes." Pain, resembling migraine, with pallor of the face, would assert itself, nausea would follow, and finally, he would be forced to go to bed. The whole gamut of migrainous symptoms would be run; pallor, later flushing of the face; temporary blindness, followed by throbbing temples; lightheadedness, with specks before the eyes; and, as a sequel, nausea, vomiting, and purging; heavy urine, diminished in quantity, with brick-dust sediment, would be followed by a copious flow of clear urine, resembling that of hysteria; forcible palpitation, precordial pain, dyspnea, and later, fluttering of the heart as a preliminary to tachycardia. During the first stage the patient would be melancholic, suspicious, jealous, and irritable. He would give way to fits of temper without cause. The future had nothing in store for him, the past was a failure, and present existence a torment. His heart was believed to be affected, and he underwent an operation for hemorrhoids without an anesthetic. He was believed to be dyspeptic, and his diet was limited until he became emaciated. Since mucus was a frequent and important constituent of his stools, he received cathartic medication in great variety. Finally, he was retired in the belief that his disability was permanent.

A careful physical examination revealed that the only disturbance referable to the heart was a slight hypertrophy of the wall of the left ventricle. The

pulse evidenced a high degree of tension. The liver could be felt below the free border of the ribs, the edge rounded and more than normally resistant. The abdomen was tender, somewhat distended, but otherwise normal. The urinary examination showed an acid urine of high specific gravity, a trace of bile, but no albumin, glucose, or casts. The relation of urea to uric acid was greater than thirty-three to one. A strict regimen of meats, green vegetables, excess of water between meals, regular evacuation of the bowels obtained by means of sodium phosphate, after preliminary purgation with calomel, resulted in relief of all symptoms within three months, save that his periodic headaches, although less severe, continued. The coal-tar analgesics administered at the time of an attack had little effect; the nitrites given during the spastic stage cut it short, but the secondary congestion was intolerable; opiates were out of the question. A weak convex glass for manifest hyperopia was worn with comfort, but did not relieve the headache. After several months, during which the condition remained about the same, the use of piperazin water was suggested. This was administered during an attack, and the patient managed to keep about instead of taking to his bed as formerly. The first time that premonitory symptoms appeared one bottle was taken each day three days in succession with the result that the attack of pain was the mildest he had experienced in many years. By giving this remedy as soon as the uric-acid elimination fell below the normal he was enabled to live in comfort, still, however, adhering to his diet and regular life. After some months he engaged in active business, and has so continued with success as to results and comfort to himself.

As this was the first of my using the "water" and as I had not obtained good results from the use of piperazin alone, I was led to quote Haig in my address upon lithemia before the Medical Society of the State of New York in February, 1893, in which I said that "it was not a powerful excretant and could not compare with the salicylates," adding that "I had only found it of use when, in the treatment of neurasthenia, it was combined with large doses of phenacol hydrochlorate."¹ The brilliant success achieved in this instance led me to continue my investigations and finally to believe that I had solved the problem of the management of neurotic lithemics, which hitherto seemed to present insurmountable difficulties. The use of a meat diet, then advanced in my paper, provoked adverse criticism. When, however, we consider, that the so-called vegetable diet is not only one of starches, sugars, and fats, but as well of vegetable albumins (gluten), it is apparent that the distinction between an animal and vegetable diet is one of terms rather than of facts. Further, when it is generally known that the

¹ *Transactions of the Medical Society of the State of New York*, 1893, page 321.

vegetable albumins are of far greater difficulty of oxidation than those of animal origin, and, since lithemia is largely dependent upon imperfect oxidation, the reason for the use of a meat diet is clear. The practice then advocated has been adhered to with the most satisfactory results, not only in affording relief to patients afflicted with goutiness, but to those with well-marked gout who had been treated, *secundem artem*, by the classic methods. While uric-acidemia is a constant factor in both gout and goutiness, we must, as careful observers, admit that there is something else of enormous importance. It hardly aids in the solution of the question to add imperfect oxidation; it simply advances the problem another step. Since it has been conclusively shown by Haig that migrainous attacks are associated with a diminished elimination of uric acid, and that the end of the vasospasm is followed by a largely increased output of this substance, and, inasmuch as *in vitro* piperazin is an excellent solvent of uric acid, we have a logical remedy for the pathologic condition. Inferentially, this drug should be of use in all conditions associated with deficient elimination of uric acid, and practically this is found to be a fact.

A striking example of this condition (neurotic lithemia) is shown in the following history:

CASE II.—A gentleman of middle age, somewhat corpulent, had spent two summers in Europe and two winters in the South for so-called nervous prostration. There was temporary relief following each vacation. He was a good liver but not a hearty eater. His habits were excellent with the exception that he smoked a number of cigars each day. He was prosperous in business and fortunate in his family relations. His sleep was disturbed by annoying dreams; he awoke in the morning unrefreshed, and rarely slept more than three to five hours. He was irritable, depressed in spirits, and unreasonable; the physical examination revealed an unusually healthy man as regards the respiratory and circulatory systems. The liver was slightly enlarged and tender; the abdomen somewhat distended, and tympanitic; conjunctivæ jaundiced. During January of this year a urinary examination showed absence of albumin, casts, and glucose. There was a trace of bile; acidity high, and the total amount of urine was 935 c.cm., and contained .312 gm. of uric acid, and 25.2 gms. of urea. Thirty grains of potassium acetate was given at 10 P.M., in the hope that the normal morning alkaline tide would be increased. Sodium phosphate was ordered, dissolved in hot water, at bedtime, in sufficient quantity to produce an easy evacuation of the bowels. The diet and the exercise were regulated according to the principles laid down in the address previously mentioned. Ten days later the urine was found to be 2825 c.cm. in quantity, which was exceptional, and it contained .334 gm. of uric acid, and 28.2 gms.

of urea. The sodium phosphate was continued and piperazin in 20 grain-doses was given at bedtime. On month later the amount of urine was found to be 1800 c.cm. containing .346 gm. of uric acid, and 29.3 gms. of urea. The patient's ability to sleep was somewhat improved and the morning exhaustion was not so much a subject of complaint. To the dose of piperazin 30 grains of phenocol hydrochlorate was added, and the patient spent nearly two months in the South, returning considerably improved. The urine was now 1920 c.cm. in amount, and contained .501 gm. of uric acid, and 25.1 gms. of urea. The constant dreaming was now lessened, and there was marked improvement as regards irritability and depression of spirits. He was directed to take one bottle of piperazin water during the evening. Five weeks later the urine was 1650 c.cm. in amount, and contained .572 gm. of uric acid, and 24.6 gms. of urea. He now went to his country residence for the summer, coming to town each day for business, and at present reports that he sleeps with but little dreaming, awakes refreshed; everything is bright and cheerful, and he feels able to attend to his business in a satisfactory manner. The last report of urinary condition was: quantity, 1810 c.cm.; uric acid, .629 gm.; urea, 24.2 gms. It is a curious fact that in spite of the low coefficient of uric acid during the earlier part of his treatment he never suffered from headache nor from neuralgia.

The following is an instance of a common error in diagnosis:

CASE III.—A young man engaged in a literary occupation became incapacitated. He was finely educated, brilliant, and cultivated. During May of last year he collapsed mentally and physically, presenting the symptoms generally ascribed to neurasthenia. He was treated in a sanatorium for eleven months, running the gamut of the rest cure, massage, electricity, baths, packs, and vegetable diet. At the end of this time he was just as unable to endure mental or physical fatigue as when he commenced the treatment. He had, however, gained considerable flesh. On examination, during April of this year, he was found to be sallow, and lethargic. He complained of constipation, and of but little appetite, abdominal distention, dull headaches, and inability to think or do anything requiring thought. The physical signs were those of an enlarged liver, gastro-intestinal dyspepsia, and the neurotic type of lithemia as regards heart and nervous system.

FIG. 1.

Pulse-tracing illustrating the circulatory condition. (Case III.)

The urine was 1120 c.cm. in amount, containing no albumin, casts, or sugar, but a trace of bile, and .336 gm. of uric acid, and 27.1 gms. of urea. A system of purgation was begun with $\frac{1}{10}$ -grain of calomel at hourly intervals until a free movement was obtained each day, and this necessitated the occa-

sional use of Kissingen water. This was continued ten days, during which time the movements would have recalled the older descriptions of inspissated bile. The usual diet was ordered, with a considerable amount of water between meals. A Turkish bath was taken every second or third day. At the end of this period the patient slept much better, and felt refreshed when he awoke. The skin had lost some of its sallowness, and the mental depression was less. During the next ten days gastro-intestinal fermentations were inhibited, first with resorcin and later with bismuth naphtholate. The piperazin water was prescribed in bottle doses, to be taken between dinner and bedtime. At the end of this time the urine was 1640 c.cm. in quantity, and contained .496 gm. of uric acid and 26.2 gms. of urea.

FIG. 2.

Pulse-tracing. (Case III.)

At the present time the patient sleeps six to eight or nine hours each night, and awakens refreshed. He walks several miles daily, reads the newspapers, and takes interest in his surroundings. For the next month the piperazin water was continued; a weekly series of calomel powders were insisted upon. His diet was now made more varied, and increased in quantity; bicycle riding was encouraged. At the end of five weeks the urine was 1725 c.cm. in quantity, and contained no bile; uric acid, .550 gm.; urea, 25.3 gms. The following pulse-tracing shows a distinct gain:

FIG. 3.

Pulse-tracing. (Case III.)

At the present time the patient can easily ride fifteen miles per day upon his bicycle, eat articles of food which he has not ventured to ingest for years, and can digest them better. He sleeps quite well, has regained his intellectual vigor, and is in a fair way to attain his former standard of physical strength.

The purpose of this paper is to point out that a very considerable number of so-called neurasthenics are really patients who are suffering from goutiness of the particular variety known as neurotic lithemia. It is a notorious fact that these patients are cured with difficulty, notwithstanding that they are curable. The clearing of the mental atmosphere of depression as soon as the stored uric acid is set in motion toward excretion is remarkable. Further, since it is not the excess of manufactured uric acid, but rather its deficiency of elimination to which the symptoms are due, and in addition, that a vegetable diet contains albumin of a variety which is difficult of oxidation, renders the prohibition of red meats an illogical procedure. Piperazin *in vitro* has been proven to be an efficient and harmless solvent for

uric acid. Administered with phenocol, better results are obtained than when piperazin is alone employed.

So far as my knowledge goes piperazin water is the method of choice for the administration of this drug, because perfect solution in proper dose and quantity of menstruum is obtained.

It may then be concluded: (1) That uric acid, as a causative factor in neurotic lithemia, a form of goutiness, should not be overlooked. (2) That a limited meat diet is productive of good results. (3) That piperazin administered in the form described in this paper is the remedy of choice for the elimination of uric acid, not only in this, but in other pathologic conditions dependent upon the same cause.

WATER PURIFICATION HYGIENICALLY CONSIDERED.

By C. G. CURRIER, M.D.,
OF NEW YORK;

ASSOCIATE OF THE AMERICAN SOCIETY OF CIVIL ENGINEERS, ETC.

(Continued from page 658.)

THERE are localities, notably in desert regions, where the available supply of good drinkable water is so deficient that the providing of distilled water in large or in small amounts is a hygienic necessity. Aden (steamer point), on the Arabian coast, affords an instance where large evaporators of American and other types are employed for supplying water. Especially when the apparatus uses an exhaust pump is it important to test for the presence of lead contamination or its probability. In our western mining regions and in certain grazing districts in the "Great American Desert," water is often so impure and unpalatable as to require distillation in order to be rendered fit to drink. When the supply is copious enough to permit an abundant flow of cold water for keeping condensing-coils or plates cool, use may be made of the common form of glass or tin spiral tube connecting tightly with a large closed kettle or vessel in which water is kept boiling. The resulting steam goes out of a small opening into a long pipe, which rises at first and then, like the coil into which it conducts the steam for condensation, descends gradually. The spiral tube or coil is fixed in a pail of freely wasted cooling water, and conducts its condensed steam as distilled water outside by passing through an opening on the side of the pail. By bending this distilled-water tube upward and then downward so as to form a siphon after it emerges, contamination by leakage of the cooling waste water is obviated. Such a primitive arrangement produces distilled water that is sterile if only the inside of the condensing-pipe be sterile beforehand. So too do tinned copper drums or pipes through which water is

condensed from steam in an automatic way, the air outside these large-surfaced conductors cooling them sufficiently to secure condensation. Attention is needed only to keep boiling water in the kettle. The joints should be quite tight.

During the last ten years the writer has seen various adaptations of this principle of using cool air for condensation, and those which he has tested have proved capable of yielding wholesome water, free from bacteria and mineral matters, except that lead has been evident when even a little solder has been used for the joints. This is especially the case when the apparatus is new. If such a faulty new condenser must be used, the first few gallons ought to be wasted, and also some after disuse. Tests show that it is safer to tolerate a small leakage of steam from a well-made condenser than to use solder, instead of tin and the blow-pipe, for stopping it. The accompanying illustration (Fig. 5) shows the appearance

FIG. 5.

Domestic condenser. Arrow indicates direction of inflow of steam. Distilled water flows out at base.

of a domestic condenser of the most effective kind. These are usually made as a series of drums communicating by short pipes with tight joints, as illustrated by Sears in the *New York Medical Record*, March 21, 1896. Practically the same idea is embodied in a subsequent model used for the "400" still, which has a cooling surface of over $1\frac{1}{2}$ square meters. These stills yield from a quart to a gallon per hour, according to their size, and somewhat according to the outside temperature and the way they are worked. The steam kettle may be heated on a stove, but a

more constant heat can be obtained from a central-draught "mammoth" lamp or an "oil-gas" stove or a gas-stove. When gas is supplied under sufficient pressure, and when water abounds for cooling the steam, a still of the Jewell pattern or the "Domestic" style can produce a gallon or more per hour. The writer has used the latter kind during the last nine years, and found it satisfactory. There are various American and foreign domestic stills employing a comparatively small tinned surface for condensing, and flowing water is used (and also ice) for cooling this. They are generally less satisfactory than the styles above indicated, although they produce distilled water of fair quality.

Chemicals, in which class may be included alcohol in beverages and also the employment of electricity in any form or adaptation, are not to be recommended or relied upon for ordinary practical sterilization of drinking-water. It is true that various reagents of this class if acting in sufficient strength and for a sufficient length of time are capable of destroying bacteria in water. We know that, by admixture of just the proper amount of certain chemicals, foul water and even sewage can be clarified and even sterilized. The importance of the skilful use of quicklime under certain conditions for the removal of organic matter or for lessening the amount of lime already present, is recognized. Like alum, iron, or similarly acting coagulants, it has a distinct utility when indicated for the purification of bad waters, but the use of these chemicals, or of permanganate of potash or such chemicals as bromin (urged by Schumburg), or any others in sufficient quantity to produce immediate sterilization of bad water in all cases, may make it anything but wholesome or palatable. Boiling is in every way more reliable and therefore preferable.

It is quite possible with time to produce, under laboratory conditions, the death of all the bacteria of a given sample of water, or at any rate cholera bacilli, if even so mild a natural acid as lemon juice is added to it. Stronger agents are of course more potent, but it is unwise to recommend that such uncertain means be relied upon by the masses in time of epidemic. Some abominably tasting and rather harmful drugs are at times thus advised without giving the authority and without retraction. Even in serious technical literature fallacious statements of assumed fact are encountered. Thus, Traube asserted that a minute amount of lime chlorid sterilized water. Although obviously erroneous, the statement attracted some attention because of the high character of the organ of publication. Various tests showed that at least thirty times as much as the amount specified was needed. To sterilize bad water in ten minutes one must use of lime chlorid no less than 15

parts to 100,000 parts of the water. Even more may be required if the water contains much organic matter, for that takes up the chlorin so rapidly as not to leave enough to act on the bacteria. The lime chlorid is not easy to dissolve and a sufficient quantity may make the water very hard as well as cloudy, thus necessitating filtration. So, too, the alum process urged by Babes was proved to be inadequate. Although in some cases 4 parts of alum to 10,000 parts of water prevent increase of bacteria, the writer determined from repeated experiments that under practical conditions even this considerable amount could not always be relied upon. Peroxid of hydrogen acting, like ozone, because of its contained active oxygen, if in the proportion of 1 part to 1000 of water, sterilizes it in twenty-four hours, but when organic matter is present this agent is not to be relied upon. All such agents act in too complex and uncertain a way to be comparable with boiling.

Electricity deserves mention chiefly because of the prominence which has been given to it. If conducted through water, a dissociation of the molecules into the component hydrogen and oxygen occurs, the latter being set free at the positive pole, and it can exert a destructive influence upon bacteria, especially in sunlight or strong daylight. This affords an interesting laboratory demonstration, but it costs too much for ordinary employment and is otherwise impracticable. Electrolysis of common salt, present in water, causes the salt to break up into sodium and chlorin. These tend to recombine and one of the products is chlorinated soda, just as chlorinated lime results from electrolysis of lime chlorid. By reason of their available chlorin, these resultant salts are powerful disinfectants and are known to be destructive of bacteria if enough of the fresh, powerful chemical be present, but this is merely a chemic action and no other and subtler force than the chemic products are operative in the process. Because of obvious uncertainty as to the exact quantity of these evolved chemicals when they are introduced in this indirect way, it is preferable that they be added in a precisely known quantity. This is also the more economical way, although the use of such chemicals cannot be regarded as a desirable means of sterilizing drinking-water.

It should be mentioned that when lime is used in the largest permissible amounts to clarify sewage, the effluent water is almost never free from bacteria, and in no case is wholesome even if used at once. If stored or poured into a river, its alkalinity favors the growth of algæ and other forms of water vegetation. The effluent from a properly managed sewage-farm is much more suited for admixture with water

of streams that further on are used for water-supply. Natural filtration by the soil or efficient artificial filtration must be considered—like boiling—as vastly superior to chemic and electric means of sterilizing water. Any insoluble substance in minute particles, which is clean and just heavy enough to sink slowly in bacteria-laden water through which its innumerable grains or flakes are diffused, will in settling carry down a considerable percentage of the bacteria. Even rapidly sinking particles, such as grains of sand, can experimentally be shown to produce this result to a certain extent although less completely than particles which settle more slowly. The gelatinous sediment resulting from the addition of alum or other coagulant is very effective in this respect. So, too, on adding fresh lime and also soda to reduce the hardness, the fine resultant precipitate in settling causes many bacteria to sink with it. But this removes only a portion of the bacteria, for it is a mechanical removal and not a chemic action, unlike the total destruction caused by adding an excessive amount of fresh lime or other strong chemic agent.

Hardness of water varies according to the amount of lime and magnesia salts present. Distillation of water, heavily charged with these or other salts, yield a product free from them, and is eminently necessary in exceptional cases in which not only these, but sodium and other soluble salts abound in the only obtainable supply. Ordinarily, however, it is too expensive, costing much more than a cent per gallon. Of the salts which render water hard, carbonate of lime is most common. This is kept dissolved by the carbonic acid present, which is driven off by boiling. Boiling, therefore, causes most of the carbonate to become insoluble, and to separate as a precipitate. This portion thus removable is called "temporary hardness." The same result is obtainable by adding water-slaked quicklime in proper amount, estimated according to the degree of temporary hardness. If there be 20 parts of this to 100,000 parts of water (which is more than can well be tolerated for all domestic and industrial purposes), about 11.2 parts of fresh quicklime are required to counteract it. This, the so-called Clark process, can be accomplished rapidly by the aid of several styles of more or less effective apparatus that agitate and aerify the treated water. Ordinary mechanical filters are also introduced into the process, or water may be allowed to settle in a tank for hours after the quicklime, wetted with four or five times its bulk of water and this still further diluted, is well diffused throughout the entire volume of the hard water. After a day or less of settling, the clear water may be drawn off, or the whole filtered. As above explained, the process reduces the percentage of bac-

teria and organic matter also, as well as the greater part of the lime (and magnesia) carbonate.

As a check upon the addition of an excess of lime, a solution of silver nitrite is recommended. If a little of this be added to a sample of the treated water and a brown precipitate results, it indicates that no more of the lime solution is needed. For each part of sulphate of lime and magnesia ("permanent hardness"), 2.86 parts of fresh sal-soda are required to counteract it.

Springs and wells are fed from the vast quantity of water, usually very free from bacteria, that is present in permeable ground underlain by impermeable strata. Artesian-well supplies have, in addition, an impermeable stratum overlying the water-bearing strata. This supply is derived from rain and snow precipitated upon and sinking into the earth, perhaps a great distance away, and is termed ground-water. It flows along several feet a day, seeking its level toward streams and bodies of water.¹

When intercepted by rocky or other barriers which are impermeable, or nearly so, it tends to flow out as a spring, which, if favorably situated, is free from bacteria, as the water flows from the ground, because of the slow flow through an immense mass of soil that furnishes the most perfect of filters. If into fine, porous soil, well situated, we drive a perfectly clean tube, water similar to that of a pure spring is obtained. The supply remains free from bacteria so long as they are not introduced by contamination from above. Practically the same result, or nearly as good, can be obtained from a carefully dug well in a favorable spot, yet if a well be not properly curbed, covered, and cared for, dirt and bacteria are certain to enter it, and altogether too often prove the source of disease. Unclean buckets, failure to conduct off overflow (waste) water, filth carried in by rain, wind, general carelessness, and especially nearness of privies, barnyards, and other obvious sources of filth, account for the most frequent unsanitary impurity of well waters. Topographic peculiarities, including flaws in the formation into which the well is sunk, account for some contaminations. All germs of disease ought to and by due care can be prevented from entering.

Wells may be regarded as large pipes surrounding an excavation in water-bearing ground and filled to a varying height with water from this cool source. If only unpiped holes in the ground, they are not hygienically complete. If, then, this pipe, covered on top, has an impervious wall tightly fitting in flawless soil and carried up at the top so that no surface washings can be introduced, unless filtered

by at least eight or more feet of fine, close soil, disease bacteria cannot enter. Then all water, however it may vary chemically because of lime, iron, nitrates, chlorids, or what not else, enters only at the bottom through the perfect filter of the fine soil, and so is practically free from bacteria. The immense majority of observers agree upon this point, although occasionally some one comes forward with a statement to the contrary. An eminent biologist has recently reported finding bacteria in deep-driven well waters, but fails to explain that they, like those found by others under such circumstances, were due to contamination from above. Care should be taken during construction to see that the bottom of a dug well has no flaw of the rock or soil to allow bacteria to enter in that unusual way. The well being dug in a place free from danger of contamination of this sort, attention should be paid to the absolute prevention of direct pollution from the surface, which is the source of infection in almost all the cases in which well water causes typhoid and other water-borne disease.

From the lowest part of the wall of the well-shaft, or at least from eight to ten feet below the surface of the ground, there should be a continuous, water-tight concreted casing, and this should rise from one to three feet above the ground. If concrete pipes, two or three feet in diameter, be employed for the purpose they must be well cemented at the joints and loam carefully rammed in around the pipe up to the level of the joint before setting and fixing the next length, all being supported so as not to settle. The top should be protected by a locked or otherwise fastened cover, asphalted, so as to keep out surface or other waste water, insects, and other things. Lead should not be employed for the purpose. The ground should be graded so as to slope away from the curb. Pails and buckets are not to be used. If a pump be placed over the shaft, provision should exist for conducting off waste water. It is much better that the pump be away from the well and the small (two-inch) pipe used for the pump-connection be carried through the casing at least several feet below the surface of the ground by a hole tightly cemented or asphalted about its periphery so that it allows no leakage into the well. The pipe may usually with impunity be of lead if the water be quite hard, but well-tinned brass or copper is better. Tin pipe, practically free from lead, could until recently be bought for a little more than 16 cents per pound, and ought to be used more frequently. The common form of iron suction-pump is preferable to the endless chain and wooden pumps which are used over very many wells.

As above indicated, wells which are properly con-

¹ See *The Am. Jour. of the Med. Sciences*, December, 1890.

structed and located many feet away from privies, barnyards, wash-water, and other sources of filth that in no case drain toward the shaft, afford healthful water, preferable to that from rain, storage, or any ordinary surface supply. It is usually from surface wash entering, owing to the lack of an impermeable curb, casing, and cover, that germs of disease enter a well and cause typhoid fever and other water-borne diseases. In this sort of pollution is included filth brought upon the boots of users to the cover of the well or to the ground near it and washed in, as by waste-water entering through a defective cover, or carried in by rain or by leaching in over the edge with puddle-water or drainings. Water from shallow, unprotected wells, which are not grossly faulty in this regard, is likely to be quite clear and taste better than that from deep waters which contain less oxygen, but which are usually much freer from bacteria. That deep protected wells receive much less of the only slightly changed organic and other chemic constituents of the soil which are carried down by heavy rainfall does not count for much hygienically, for it is particularly putrefactive and specific disease bacteria which cause shallow, unprotected wells to be dangerous.

Palmer of the University of Illinois, in a recent chemical report, has added to our great volume of instructive statistics concerning Illinois and other States, which show the unwholesomeness of water from such mere holes in the ground. He emphasizes the familiar fact that deeper wells in the glacial drift of the prairie regions are much less productive of disease, although the water is often unpalatable, not only because of lack of oxygen but also owing to presence of marsh-gas (due to decomposition of vegetable matters) and perhaps of sulphuretted hydrogen. Iron often adds to the unpleasant taste and appearance of such water, so that the senses are likely to mislead people to prefer an inferior product. This explains the slowness with which the unintelligent learn that it is of paramount importance to guard wells against surface contamination. In prairie regions where the ground lies perfectly level, the house well ought to be a hundred feet away from any privy or other filth, and slops and kitchen waste should be carried far from the locality of the well. When the ground slopes, it must be borne in mind that water seeks a lower level, hence the well should be so situated that the natural flow of the ground-water current is from the well toward any privy or other source of contamination and not in the reverse direction. The ground must be studied to prevent the location of all three of these near together in one common small basin or sink formed by impermeable underground barriers. Mere vicinity of well and house is not

necessarily dangerous if no privy or drain be near, and if no slops or other filth or surface drainage can leak into or upon the ground near by. The writer has made bacteriologic tests of carefully constructed wells adjoining, as also underneath houses with thoroughly cemented cellars, and found the water exceedingly pure and likely to remain so as long as no contamination entered; but it is invariably best to have such a source of drinking-water so situated that any one can always see that no carelessness ever introduces contamination.

Local inspection and survey always furnish the most important means of determining the absence of contaminating influence. The shaft of the well is best examined if illuminated, and when emptied the lowest parts can be inspected and flaws carefully searched for. Chemic and especially bacteriologic tests if repeated several times under varying conditions are of considerable value in this respect. For rough practical purposes an inexpensive test, substituting the lithium test, is afforded by throwing a suitable amount of saprol or some intense anilin red, dissolved in water, upon a neighboring filth pile or in the kitchen slop-water suspected of polluting the well. Common salt can be made to serve the purpose. Saprol is a low-priced coal-tar disinfectant of a very marked odor and taste suggesting illuminating gas or naphtholin and, if it penetrates to the water of the well, betrays its presence in a sample taken. To the taste it is perceptible when only one part is present in two million parts of water. The odor is evident when twice as much is present in the sample. If none of this substance be detected in the well after liberal application of it to the suspected filth, it is presumably safe to use the water. If saprol enters the well, further and more precise examination should be undertaken to determine the defect. When the water of a well is exposed to pollution which cannot be prevented, and the trouble is not remediable by the introduction of an impervious curbing and the other safeguards above recommended, the safest way is to fill up the well and make a proper new one in a good location. Koch's recommendation to convert a faulty well into a driven well by filling it up with sand and sinking a pipe in it is not practicable in most cases. At any rate, if this expedient be tried, thorough disinfection and cleansing should precede its employment.

In towns and wherever else it is available, steam driven in for two or three hours at a pressure of from two to four atmospheres is an efficient disinfectant. The leather valve of the pump is to be treated apart by soaking it for an hour in a 1 to 1000 solution of corrosive sublimate. After steaming has ceased, the water should remain in the closed well for nearly a

day and then be removed together with the dead frogs and other organic matter which, by subsequent decomposition, would become offensive, as would be the case after the use of lime or other chemicals. One portion of freshly slaked lime thrown in for every fifty parts of water proves an efficient disinfectant. It is cheaper than bromin or permanganate of potash and more satisfactory than the addition of one per cent. of sulphuric acid. Steam acts upon the entire well, while, when chemicals are added to the water, the walls have to be treated in addition. For artesian and other driven wells, Neisser recommends that steam be driven to the bottom of the tube by means of a small pipe sunk nearly to the bottom. Another pipe may also be introduced for the purpose of drawing out the water at the same time.

Ground water derived from carefully located gang wells and used promptly without being stored is usually very free from bacteria and other organic life. This is especially true when the territory which the driven pipes drain is reserved for a park and guarded from contamination. Such sources may in the end prove to yield less than the expected amount. If then, undue suction be employed to augment the flow of water, the results are unsatisfactory, and underground defects and partial stoppages of the pipes may be produced. When locating such a plant, bacteriologic tests are indispensable for preliminary determination of the quality of the water derived through sterile experimental tubes, samples being taken at different stages of the pumping. A chemic examination is also necessary for learning the amount of iron, hardness, chlorids, and organic matter.

Artesian wells usually yield water of great purity as regards bacteria, yet tests of the water from these deep borings sometimes show numerous bacteria other than those introduced from above ground through carelessness. The character of those found aids in determining their source. There are cases in which various forms of water-life have been carried long distances through coarse strata, and the possibility of contamination from the remote outcrop of the water-bearing strata, must be borne in mind. In those regions in which these deep wells have most frequently been bored, the distant outcrop is usually so situated as to preclude the likelihood of infection entering the water there. Considerable salt occurs in artesian well water in some districts.¹ With all their usual excellence as regards absence of bacteria, deep ground waters, even if the yield continues ample, proves at times too hard and contain too much iron to make them satisfactory, unless they undergo treat-

ment. Moreover, the sieves introduced on the lower end of the driven tubes for the purpose of keeping out sand, tend to become incrustated and thus greatly retard the flow. To remedy this obstruction, hydrochloric acid, diluted with nine times its volume of water, may be carried down to the bottom of the tube through a small pipe, and allowed to exercise its solvent action for nearly fifteen minutes, after which time it is pumped out.

Iron, so common in water from deep wells, may in some cases occur as phosphates of iron in part, but is usually in the form of free ferrocarbonate dissolved in the carbonic acid of the water. If this be driven off in the presence of air, or, if the iron water merely comes briefly into contact with air, the iron carbonate is thereby changed into insoluble ferric compounds; consequently, according to the amount of iron present, and the length of time that the oxygen of the air has worked, the water becomes opalescent, then gradually yellowish-brown, because of the innumerable minute particles precipitated, and which can be filtered out, leaving the water clear. Earthly alkalies present favor the separation of the iron. Any contrivance, such as a spray or an aerified filter, which causes the water to be exposed to the action of air will remove nearly all of the iron from a water.

Filtration, through from seven to ten feet of pieces of coke, gravel, or broken rock, one millimeter in size, with the utmost possible exposure to air, has been found in German experience to remove iron successfully. The slimy precipitate collects and the upper layer of the filter has to be cleaned every fortnight or so, and the entire mass needs renovating, or renewing every few months. Dunbar² has indicated a suitable mechanic sand-filter for use on a small scale. The Krölinke process for removing iron calls for the addition of ten parts of ferrosulphate of iron to one million parts of the iron water. Then from fifty to a hundred parts of lime (with water) are stirred in and the whole allowed to stand for twenty minutes before filtering. Hardness, as well as organic constituents, is also greatly lessened by this process, which at the same time separates most of the bacteria. Steckel's process, used in connection with an ordinary well, consists in packing a layer of lime, or, preferably, tribasic phosphate of lime, on the bottom and sides of the well, and fixing it in place so that the entering ground water passes through the lime, which remains efficient for years without removal. It greatly increases the hardness of the water, but removes iron.

For domestic use a bone-charcoal filter will attract and separate iron, lead, or other metallic impurities,

¹ An excellent monograph on "The Artesian Wells of Dakota," by Gilbert, is contained in the report xviii, 2d part, of the U.S. Geological Survey.

² *Ztschr. für Hyg.*, xxii, 68.

present in small amount in water which flows slowly through it. Even the ordinary carbon cylinders sold for filtering have some value in this way, although it must be remembered that they have the defects of all ordinary filters. If such filters become clogged by the iron slime, they may be renovated by soaking them in dilute hydrochloric acid. If such a filter be used as a makeshift, the cylinder may be covered with coarse sand, and the water aerified by dropping upon it from a height. Whether any of these or a mechanical filter be used for deferrating water, the main thing is to see that abundant exposure to air takes place.

Rain water, being precipitated moisture of the atmosphere, is very pure as regards the presence of lime salts and other things taken up by surface and ground waters. As ordinarily obtained from a roof, through a gutter and pipe, the first portion that falls takes up not only the soot, dust, and grass which may be in the air, especially of cities, but the washings of the roof and gutters as well. It is best that the first portion which falls be allowed to flow off, carrying leaves, bird droppings, and other dirt, the following portion then proving much purer. Automatic contrivances exist to effect this separation of the unclean first flow, but are not likely to prove popular. They are apt to work badly when leaves or other coarse dirt are washed in. When rain water is of necessity depended upon for a supply, the water-conductor should be kept shifted so that the water running down after rain has begun to fall will be diverted until after the dirt has been washed off, then the following water may very easily be guided into the cistern. In many cases this water contains very many bacteria, which thrive in the darkness and abundant organic matter. Boiling renders it fit to drink. The cisterns or tanks employed to hold water become foul if of wood, and should never have lead in any part, even for piping or cement. Bricks, well coated with hydraulic cement, are approved for cistern construction. Reservoirs of any sort need cleaning from time to time. Chemicals, such as above indicated for porcelain filter-tubes, serve the purpose of disinfecting these also. Steam is excellent when it can be applied.

SUMMARY.

Water may be very clear and palatable, yet at the same time may chance to be impure. As precipitated by condensation of vapor it is pure. Precipitated from the clouds and sinking into the earth's surface and other natural reservoirs it remains wholesome so long as bacteria capable of inducing disease do not enter it. Bacteria present in almost all natural surface waters remote from habitation are presumably harmless. Harmful micro-organisms tend to perish

or become innocuous in course of time after entering ordinary water, yet complex conditions may make the operation of this principle uncertain. If harmful bacteria are known to be present more or less regularly in a given supply, or if the entrance of sewage or other obvious pollution near an intake make its presence probable, it is most necessary to employ adequate filtration or other means of purifying water taken from that place. Distilled water is wholesome if it contain no lead. The receptacles in which this and various originally pure bottled waters are stored and transported are often bacteriologically unclean. Boiling, even for a moment, destroys the causative germs of typhoid fever, cholera, and other diseases known to be likely to occur in polluted waters. Ordinary small filters are usually quite inadequate to hold back disease bacteria or any others. All of them allow bacteria to multiply in the filtering substance and to pass through into the filtered water. Reported cases show that ordinary filters can harbor disease germs and cause disease. Small filters of very dense texture, such as the best porous porcelain and also the material used in the Berkefeld filter, can hold back all micro-organisms and thus yield absolutely sterile water for a limited number of days if intelligently cared for. None of these are permanently "germ-proof."

The only permanently germ-proof filter is the natural one formed by immense quantities of fine porous earth, through which "ground water" slowly flows. Filtration by well-managed large gravity filter-beds of fine sand approximates this natural process in efficiency, being capable of rendering the water practically pure. Mechanical filters can accomplish the same result, but are less likely to be maintained constantly in a condition of the highest efficiency.

Ground water, uncontaminated, is hygienically pure, under the conditions indicated above. In very many cases it is the best available source of supply. Free from bacteria as it issues from favorable ground, it frequently becomes contaminated because of carelessness. An outlay of effort and of money, usually much less than would be required for securing a pure surface supply, will eliminate the defect, which is commonly a local one. Open, shallow wells, unprotected from direct pollution by surface washings from privies and other filth, are a notorious source of pollution by, and dissemination of, the germs of typhoid fever and other diarrheal diseases, including cholera whenever and wherever that occurs. If properly located, and provided with a continuous water-tight casing and curb tightly covered, and if it has a good pump which does not necessitate an aperture above ground, even a shallow well can furnish wholesome water.

CLINICAL MEMORANDA.

REPORT OF TWO CASES OF GANGRENOUS PERFORATIVE APPENDICITIS.

BY F. SHIMONEK, M.D.,
OF MILWAUKEE, WIS.

CASE I.—George W., aged eleven years, was perfectly well up to the time of the present illness. December 3, 1896, he was taken with a pain in the abdomen which did not seem to be localized. There was some tenderness over the entire abdomen. The temperature was normal, but the pulse was somewhat exaggerated, being about 100 per minute. During the first day of the attack the condition remained the same. The next day pains were somewhat worse; temperature, 100.4° F.; pulse a little more rapid; bowels constipated, and there was some nausea and vomiting. Slight tenderness was present to the left and below the umbilicus, but no tympanites could be discovered. The bowels moved freely, which, however, afforded little if any relief. Early on the morning of December 5th, after an evacuation of the bowels, intense and cutting pain developed in the region of the bladder and to the left and below the umbilicus, following which the patient collapsed, but reacted within about twenty minutes. The temperature then rose to 102° F., the pulse to 130 or more. There was much pain and tenderness, and tympanites developed. The recti muscles were contracted. The facial expression became very anxious. The pain and tenderness were not situated over the appendical region at any time, but were rather to the left and below the umbilicus, which made the exact pathologic condition somewhat obscure. The subjective symptoms pointed to appendicitis with perforation and peritonitis.

During the evening of the third day of the attack abdominal section was performed. Because of the impossibility of locating the disease externally it was decided to make a median incision. The moment the finger was introduced into the peritoneal cavity it came in contact with a mass about the size of a chicken's egg, attached to the abdominal wall to the right of the median line, and before I was aware of it about two ounces of extremely fetid pus welled up in the wound. The small intestines were coated with a fibrinopurulent exudate, showing that there was present a progressive diffuse peritonitis. The omentum with which Nature had surrounded the appendix to protect the general peritoneal cavity formed the wall of the abscess, but it was scarcely sufficient to carry out this life-saving purpose. The appendix and omentum were separately tied off and removed. The peritoneal cavity was most thoroughly irrigated with about six gallons of sterilized normal salt solution, and carefully drained with long strips of iodoform gauze, reaching down into the cavity as far as possible. The appendix showed small perforations near the apex, and contained a hard concretion. The iodoform drains were withdrawn and the incision closed four days after the operation. Convalescence was uneventful.

CASE II.—Mrs. S., aged twenty-five years, nullipara, a hard-working woman who had always enjoyed excellent health. When first seen by me, thirty hours after

the beginning of the attack, she presented the characteristic symptoms of appendicitis. The temperature and pulse were both above normal; general condition good; very little or no tympanites; excessive tenderness over the region of the appendix, but no tumor could be discovered, either by abdominal or vaginal examination. The right rectus muscle was very rigid.

She was given a cathartic dose of calomel, and immediately after the resulting evacuation, excessive, cutting pain was felt in the hypogastric region, immediately above the mons veneris. The temperature suddenly rose to 103.8° F., and the pulse to about 130. Laparotomy was performed during the evening of the third day of the attack. A large quantity of very fetid pus was evacuated, and the gangrenous and perforated appendix with surrounding omentum removed. A large and hard concretion was found in the appendix. General fibrinopurulent peritonitis was present, and the small intestines were extensively covered with exudate. The peritoneal cavity was very thoroughly and carefully irrigated; it was necessary to use ten gallons of sterilized normal salt solution before the return flow became clear. Iodoform gauze was passed down to the bottom of the pelvic cavity, and the resulting drainage was excellent. The temperature and pulse rapidly dropped to normal.

On the fifth day the gauze was found dry, and therefore was removed, and since everything was found to be progressing favorably the incision was closed. Patient progressed nicely, temperature and pulse being normal until the fourth day, when on account of a slight rise of temperature it was deemed necessary to remove the stitches, fetid pus having escaped through the stitch-holes. The entire incision was reopened and a large quantity of extremely fetid pus washed out and a drain reinserted. The peritoneal cavity was now, however, found to be thoroughly walled off. The patient after some ups and downs finally made an excellent recovery.

These two cases prove that diffuse peritonitis is not always a bar to prompt and complete recovery. It has been stated that the presence of peritonitis complicating an attack of appendicitis is a contraindication to operation.

A CASE OF HYDATID TUMOR.¹

BY S. J. McNAMARA, M.D.,
OF BROOKLYN, N. Y.

A DESIRE to lend assistance to the keeping of accurate statistics of a rare disease prompts me to report the following case of echinococcus. But one hundred cases of this disease have been reported as having occurred in the United States, for the statistics of which we are indebted to Mr. H. O. Sommer of the Government Agricultural Department. In sixty-six of the hundred cases the echinococci had their habitat in the liver, in seven in the lungs, and in six in the bladder, the remainder being distributed through various other organs and tissues of the body. In one instance they were found in the tibia, and in another in one of the ventricles of the brain.

Mrs. P., Italian, aged thirty-one years. During the

¹ Read before the Kings County Medical Association.

past nine years she has resided in the United States, and for the last six years has been subject to epilepsy. Is the mother of five children, the youngest being two and one-half years old. Enlargement of the abdomen was first noticed sixteen months ago, until which time the general health had been good. She then became emaciated and gradually grew weaker, while the abdomen continued to enlarge until, just previous to operation, it equaled in size that of a pregnant woman at term, but with greater fullness at the sides. Fluctuation was marked. On opening the abdominal cavity, which was accomplished through the usual median incision, a large cyst presented. A trocar was unsuccessfully employed to draw off its contents. An incision through the wall of the tumor revealed the echinococcic character of the cyst with which I had to deal. It is not an exaggeration to say that thousands of smaller daughter cysts, light yellowish, limpid, and with very thin walls, rolled out until a foot-tub was three-quarters filled. The woman was relieved of twenty-six pounds of these daughter and granddaughter cysts, all of which had been contained in a single large cyst. The tumor had its attachment in the upper portion of the abdominal cavity, although it was impossible to determine its exact point of origin. A large portion of the omentum, which was studded with secondary deposits, was removed. As much of the main cyst as possible was also removed, and that remaining was sutured to the abdominal wall and a drain inserted.

The operation took place on the 26th of June and one month later the patient left the hospital. Four days afterward she had a miscarriage which, though not severe or dangerous in itself, in her weakened and already exsanguinated condition, proved fatal. During the last two weeks of life the hydatids multiplied to such a degree as to be detectable through the abdominal wall. After the operation and up to the time of the fatal issue the cyst remained open, and occasionally it was necessary to change the dressings five or six times a day.

AN ADDRESS.

SUGGESTIONS FOR THE FUTURE WORK OF THE SOCIETY.¹

BY ARTHUR MIDDLETON JACOBUS, M.D.,
OF NEW YORK.

FELLOW MEMBERS OF THE MEDICAL SOCIETY OF THE
COUNTY OF NEW YORK:

During a membership of more than twenty-one years I have received many honors at your hands, such as appointments on special and standing committees, and election to the office of Censor and of Vice-President, but it now remains for me to thank you for having received the greatest honor in your gift, that of President of the Society. This is especially gratifying since it came to me with absolutely no personal seeking, and after a spirited contest on pending issues. Words fail me to express due appreciation of this evidence of esteem and confidence on

the part of so large a body of my professional brothers, and which, without disrespect to the society, is appreciated even more than the honor of holding the office conferred. In return, I pledge myself to fulfil the duties of president to the best of my ability and judgment, absolutely independently and impartially and with a due regard to all the rights and interests of each and every member. In so far as the influence of the president may control the policy for the year, it will be aggressive yet conservative; aggressive as to the rights of the profession and of this society in particular and conservative as to rights of others.

This will undoubtedly be a very active year for the society and its work for good, it is hoped, will be of lasting value. On January 1, 1898, we will pass from a county society, occupying the entire area of the largest American city, to one limited to but two boroughs out of five—though of the same area, the boroughs of Manhattan and the Bronx—in the third largest city in the world, the so-called "Greater New York." By this change, three other county societies will be entitled to share with us the consideration of medical matters pertaining to the enlarged city. With this transition, there will be great changes in the public departments; for instance, in the Departments of Public Works, Schools, Charities, Health, and Street Cleaning, the efficient and proper management of which we have so much at heart. It is, therefore, suggested that it would be of mutual advantage, and of public benefit, if the elective officers of this society were empowered to invite a conference during the coming month with the officers of the other county medical societies located wholly or partially in our sister boroughs (those of Kings, Queens, and Richmond), for the purpose of cooperation in the supervisory functions which we all should have, and are justly entitled to, over all medical matters arising in the said public departments of the enlarged city of New York. If mutually agreeable, these conferences should be held at least quarterly for the consideration of all public medical questions pertaining to the city departments, which from time to time may arise and which should be submitted to at least some competent representative medical body before any department or public official shall be permitted to promulgate rules affecting the medical profession or its practice, or the conduct of medical charities.

In a representative sense this body might be called the Medical Society of the City of New York, and will be the spokesman of some 2500 reputable physicians who are members of the four county medical societies previously referred to, also acting in the interests of several thousand others. Public officials, either through laxity, ignorance, favoritism, or partisan or vicious tendencies, often err in making appointments or in the line of department work, and consequently a watchful body such as has been suggested, zealous not only for the public weal but of that of the profession also, would have lasting controlling force and effect. Indeed, considering the gradual and insidious encroachments which by legal enactments and otherwise, at least one of the great public departments of the city is surely exceeding its functions as a public servant and tres-

¹ President's Inaugural Address, delivered before the Medical Society of the County of New York, November 22, 1897.

passing upon and usurping the duties, rights, and privileges of the medical profession and the public. We cannot too soon call a halt and demand a surrender of such autocratic and unwarranted powers.

I refer to the Health Department of this city and, in doing so it must be distinctly understood that there is no intention to reflect on the personnel of the commission. I refer to it in order to condemn the autocratic rules and unrestricted and increasing practices of the department and its officials; more specifically, to condemn the free vaccination, and the inspection and examination of school children for contagious diseases, defective vision, etc., regardless of the wealth of their parents or the rights of the family physician or other practitioners; to the ever-increasing control, segregation, and free treatment in public institutions and elsewhere of patients suffering from even the ordinary infectious diseases, which any physician of to-day is fully competent to quarantine and treat at home, in most instances, and that too, without the frequently officious visits and criticisms of the Department Inspector or other employee. In justice to the present commissioners it should be stated that since last spring, when a committee of this society, consisting of the retiring and present president and the chairman of the Committee on Hygiene, had a conference with them, they have issued more stringent rules for the guidance of the inspectors and other employees in their relation with practitioners, and the patients of such, and fewer complaints have come to the ears of the officers of this society. The commissioners at that time promised to eliminate the cause of such complaints of discourteous or unprofessional treatment of practitioners, even if it were necessary to discharge each and every employee of the department, high or low, and they desired that physicians with such grievances should write to them at once, giving full particulars, when the inspector or other employee involved, if guilty, would be reprimanded or discharged, as the offense warranted. If the members of the society would bear this in mind, and act accordingly, there would soon be little cause of complaint on this score.

To return to the main question, it may well be asked: By what right in law or equity does the Health Department, or its physicians, presume to treat disease in public institutions, or elsewhere, and in some instances attempt to dictate or to discredit the diagnosis of the condition, or the treatment, of patients under the care of a licensed practitioner, not only in private life but in public institutions? If the afflicted persons are poor and in need of hospital care they should be treated like other poor patients, by the physicians of the various public institutions under the care of the Commissioners of Charity. If they are well-to-do, then they should be treated by the private practitioner, at home or in a secluded public or private hospital if need be, and pay for the services rendered.

The same rules should apply to the vaccination and examination of school children or others in so far as may be possible. With the gradual extensions of the arbitrary rules of the Health Department, made without consultation with the medical profession as a body, or only, perhaps, with committees of their own appointment or

suggestion; by its yearly addition to the list of so-called infectious diseases which it desires to bring under its control; and by its almost unlimited power over persons, patients, and property, and the too-frequent abuse of power by its employees, it seems that the time has arrived when the medical profession should awaken from its lamb-like complacency and assert its rights as well as those of the public and enforce recognition of them.

Where shall the line of demarcation between the proper functions and duties of the Health Department and its inspectors and other employees, and the rights, privileges, and duties of the licensed practitioner be drawn? I would suggest that this question, which also gives utterance to the feeling of many members of this Society, be referred to a special committee, or to the Committee on Legislation, for an impartial and thorough investigation, and that the committee be directed to report back to the Society, with any recommendations deemed advisable, at the earliest possible date, in order that we shall be in a position when the new civic administration comes into power on January 1st next, to advise it concerning the matters herein referred to, and if necessary, to appeal to the Legislature for the desired relief. The Society should also, with the cooperation of other interested societies, make an earnest effort and use all possible legal influence to induce the Legislature to amend the law which disfranchises and excludes the members of the medical profession from the chief executive position in the Health Department. The only open excuse for excluding physicians from this office has been that they are claimed to be poor business men or executive officers. This is absurd, and especially so when we recall that members of this and other medical societies throughout the city and country who have been, or are, speakers or members of different State Legislatures, or of the United States Congress, or governors, mayors, presidents, managers, trustees, or directors of some of our largest life insurance, telegraph, railroad, or real-estate companies, or of colleges, banks, or various other large corporations, and in which several positions great executive ability is required and rendered. It is an anomalous condition, and as well might a lawyer be disfranchised and debarred from the office of district attorney or counsel to the Corporation of the City of New York, and a physician only eligible and appointed instead.

Among the questions already under consideration by the Society, the correction of the abuses of medical charity is the most important, and in consequence of these well-known abuses, the increased departmental physicians, and the matters previously alluded to, we are as a profession sorely beset. The time seems to be coming when the calling of a physician, as such, outside of public institutions and departments, will become but the luxurious pastime of the wealthy sons of the fashionable set. The abuses of medical charity have been so generally recognized and admitted by the laity, as well as by the medical profession, and have been so thoroughly written up by so many of our members and others, for instance, by Drs. Stephen Smith, George F. Shrady, Landon Carter Gray, F. H. Wiggin, Charles Phelps, J. B. Huber, T. J. Hillis, Douglas H. Stewart, and others, and by

almost the entire medical and secular press of the city, and finally by your Committee on the Abuses of Medical Charity, that were I able it would be superfluous for me to go into the subject further, for the abundant evidence is all one way and is admitted by everybody. It is significant also that in all the medical societies of this State, from Buffalo to Montauk Point, in which the subject has been discussed and committees appointed, the general sentiment has been the same, namely, that grievous abuses of medical charity exist and are rampant, and that they must cease; and that free treatment, or other medical charity, must be limited absolutely to the deserving poor. It only remains, then, for this and sister societies to determine upon satisfactory measures of relief, and to see that they shall be enacted and enforced.

It will be recalled that on May 24th last, your Committee on the Abuses of Medical Charity, which was composed of men representing various interests, rendered a report of its investigations and work, with a copy of a bill, which had passed the Legislature unanimously. This report, after considerable discussion, was accepted, the recommendations therein contained were adopted, and the committee continued, with power. The bill, as you know, failed to receive the signature of the Governor. That bill, with a few minor changes as to details of enforcement and penalties, has my hearty approval, but as I understand that the Committee on the Abuses of Medical Charity proposes to make a supplementary report to-night, which will include a bill amended to suit the objections made last spring by the Governor and a few members of this Society, it will be left for the committee to tell just what legislation is proposed and deemed necessary. In attempting by legal enactment to bring about the necessary relief—and no other means under the circumstances can possibly cope with the abuses,—due regard should be given to the interests of all concerned, for instance: the medical profession as a whole, the public philanthropists, and the incorporated colleges, hospitals, and dispensaries. No “vested right” of any existing legitimate, *properly conducted* institution, or corporation, should be interfered with or abolished so long as such institution shall truly and honestly endeavor to conform to such reasonable laws as may now exist, or shall hereafter be enacted, to correct the abuses referred to.

Let us all get together, give here and take there, acting unselfishly for the general good and combining the harmonious and unanimous action of the members of this Society with the increasing number of other societies ready to lead or assist in the movement. The result will be sure and certain, and will redound to the credit and prosperity of all concerned. If the members of the medical profession as a whole would stand by each other as individuals, unselfishly and honestly as men, the same as lawyers and members of other professions do, there would be little necessity for legislation for the relief of evils which physicians themselves are largely and almost wholly responsible for.

Another question which should engage the serious attention of the Society this winter, and be settled if possible, is whether midwives shall be permitted to exist, be

educated, regulated, and licensed, or shall be abolished as a profession. As a Society we are bound, if only for the public good, to insist that either one or the other of these propositions shall be adopted. As the state of affairs exists to-day, it is a horrible stench and crime in the nostrils and eyes of every civilized community. The name of midwife in this city to-day is synonymous with feticide, infanticide, and homicide. Proof of this may be found in the glaring advertisements and in the startling accounts of criminal abortions which are published in the daily papers or in the coroners' or criminal court records, or in the reports of deaths from septic peritonitis, filed in the Health Department, of many victims who have passed through the hands of midwives. But even such abundant evidence, as the members of this Society well know from what comes to their ears or eyes almost daily, does not tell one-thousandth part of the horrible tale. Only recently have we seen the spectacle of a miserable fiend of this character, who, if but a fraction of the rumors and stories are true, is deserving of punishment far beyond that of electrocution, and who, to save her own miserable, cowardly life, turns State's evidence and thus ensures another death—that of her foolish paramour and tool.

In this city, where midwives have even no legal status, it seems only requisite, in order that they may qualify for such a calling, that, first, from the necessity of widowhood, poverty or sordid gain, they shall have attended one or more cases of confinement, perhaps their own, obtain a certificate from two physicians, and file the same at the Health Department, when the trifle of a little thing like fitness and education is accomplished and they are graduated to go on their errand of mercy, and, not unfrequently, death. As physicians, we have even a more serious personal reason why something should be done to abolish the abuses or crimes of midwifery. It too often happens that after the criminal or ignorant malpractice of a midwife, we are, as a last resort, called in to assist in saving the life of a victim, and as a result of our errand of mercy we are often haled before a court of law, or worse, that of the public press, and there stand charged as the prime mover or abettor of the crime, a stigma which, however innocent we may be, we can never efface during life from the memory of some. I regret to say that the press, in a few instances, for the sake of notoriety, or other reasons, devotes columns to the purpose of parading the physician's innocent connection with the case, rather than to an effort to assist the authorities in apprehending and punishing the real criminal.

The Society of Medical Jurisprudence, at a meeting held in this building on November 8th last, after listening to a very suggestive paper, entitled “Midwifery and the Midwife,” by Dr. C. A. Von Ramdohr, appointed a committee to consider the question of the enactment of proper laws to regulate the practice of midwifery, with power to cooperate with committees of other societies working to the same end. I would suggest, therefore, that our Committee on Legislation be directed to make an investigation of the subject, and to confer with the said committee, and to report back to this Society, with such recommendations as it may deem necessary.

There are other matters of public interest, which the Committee on Hygiene should undertake to study and report upon to the Society, such as the deleterious effect, if any, of the terrible, almost volcanic eruptions which the city has been subjected to on almost all of the avenues running north and south, and particularly below Fifty-ninth street, during the past two years, and which will probably continue another year, and the remedy for the same; also, as to the advisability and methods by which inexpensive public lavatories and toilet-rooms may be established at reasonable intervals in connection with drug-stores or respectable hotels, etc., on or adjoining public thoroughfares, for the convenience of the citizens, men and women; also, as to whether the advantages of the asphalt pavement, now so generally being put down in the city, outweigh the disadvantages, as it is claimed by some that they do not, and particularly as to whether the air-tight pavement is injurious to adjoining houses and residents by forcing the noxious gases, as some claim, to enter the houses; also, as to the injurious nervous effects of long school hours, and the excess or forced instruction of young children, particularly girls, in the public grammar schools, where they are often graduated a year or two before they are old enough to enter the Normal College; also, as to the physical injuries, if any, to the smaller children in the primary grades, who are forced to sit and study during several hours daily over non-adjustable writing-desks, with seats so high that the feet of but a few of the pupils can touch the floor.

These and other matters in connection with public institutions, such as street railway accommodations, milk, water, and other foods, the disposal of manure, garbage, and slaughter-house refuse, etc., are of vital importance, and this society should endeavor to study and correct them in so far as possible; but for fear that your patience is already taxed to the point of endurance, further reference to the questions of this character will be left to the Committee on Hygiene.

Before closing, permit me to refer to one more topic, namely, the question of enlarging our membership for offensive and defensive purposes, by encouraging and inviting all non-sectarian, well-qualified physicians of known respectability to enter our ranks. This society certainly represents, to a greater degree than any other in the city, the pulse, welfare, and wisdom of the profession as a whole, and since the society during generations has been the faithful bulwark which has stood between charlatanism, bigotry, and ignorance on the one side, and the rights and privileges of the public, as well as the profession, on the other, it ought to receive the homage and support of the entire profession of the city, instead, as has sometimes been the case, of unmerited criticism, censure, or revilement from many who ought to and do know better.

This is often called a "fighting society," and only recently have I heard more than one medical man of standing exclaim: "Oh, you are always fighting down there." Well, that is true, and we also have a little skirmish occasionally over the election of officers, or about questions of public and professional policy. But, as to

that, a man or woman or a society which has not some fighting blood is not of much consequence or worth existence excepting perhaps as a missionary to the cannibals. Even a "fighting chaplain" is the more valuable, like famous Parson Caldwell, one of New Jersey's Revolutionary heroes, who, on the battle-field of Springfield, on the appearance of the "Red Coats," gathered an armful of hymn-books to be torn into gun-wads, and, while he probably wanted to say, "Give 'em hades, boys!" shouted, with electrical effect: "Give 'em Watts, boys! Put Watts into 'em, my men! Ah! I see they're out of wadding. That's the tune! We'll all join in!" Let the cause be just, the means of warfare fair, and the motto "Right Makes Might," and we need not fear to have the name of being fighters; rather may we be proud of it.

But, seriously, what has the Society fought about or for? It has fought against bigotry, charlatanism, ignorance, illiberalism, and selfish or unprofessional conduct on the part of members of the profession, as well as against the autocratic or unjust treatment by public officials or departments of the profession as a body, and particularly for the rights and privileges of the latter. It has fought for non-sectarianism in medicine; for a higher and better medical education; for a "golden-rule" policy or guide of ethics, and one by which we can and do discipline the guilty, whether high or low; for a liberal policy toward women who desire to take up the profession of medicine, and, in this, as in most other matters, it has been in the van; for the protection of the public health; for the protection of its members when sued for reporting supposed contagious diseases under a penalty rule of the Health Department, whose inspectors ought to have been held responsible, as for instance, the case of Brown *vs.* Purdy; and for many other questions too numerous to mention. Its steady work during the past seventeen years has been to protect the public and the profession against irregular medical colleges and the hordes of illegal practitioners, midwives, and druggists, and other persons practising medicine illegally, and who would otherwise have swarmed in this city to the serious injury of all.

The burdens and expenses of these prosecutions have been borne solely by this Society, and though they have cost us nearly twice the aggregate amount received in fines, I am sure that we do not begrudge the cost when we think of the immense benefit that has resulted. Great credit especially is due the Society, since it was the pioneer, in 1807, and until very recently the only censor and worker in such field of prosecutions, and in which also we did not expect to, nor do we, derive any pecuniary benefit. Through the courtesy of Mr. Wm. A. Purrington, former counsel, and Mr. Robert C. Taylor, the present counsel of the Society, and our Treasurer, Dr. John S. Warren, I am enabled to give briefly a few figures as to the cost and results of the Society's work in this line, and the result will probably astonish the members of the Society, as well as others. The Society began this series of prosecutions early in 1880, shortly after it had secured the passage of a law for the suppression of illegal practitioners, etc.

From 1881 until October, 1884, the prosecutions were

under the charge of Mr. E. C. Ripley, the costs and fines being as follows; Costs, \$7254.45; fines imposed, \$1350.00; fines received, \$725.00. From November, 1884, until December, 1893, the prosecutions were conducted by Mr. Wm. A. Purrington, the result being as follows: Costs, \$20,041.23; fines imposed, \$14,650; fines received, \$10,275. From December, 1893, to October, 1897, the prosecutions were under the charge of Mr. Robert C. Taylor, with costs and fines as follows: Costs, \$9271.71; fines imposed, \$5385; fines received, \$3160.¹

It should be said in justice to the latter counsel that during his first year and a half of office, owing to an error in leaving out the penalty clause when the medical laws were codified just previously by the State Legislature's Committee, it was necessary to prosecute illegal practitioners under civil suits, and consequently the Society did little of that work at that time, and with little or no receipts from damages or fines. A change in the appointments of new magistrates in the new city courts also interfered with the work. Adding the foregoing figures we have the following as the total costs and receipts from prosecutions of illegal practitioners and others, from 1880 to 1897, inclusive: Counsel fees and disbursements, \$36,567.39; fines imposed by the courts, \$21,585.00; fines collected and paid to our treasurer, \$14,160.00,² the deficit between fines imposed and received being \$7425.00, this amount having been remitted by the courts, or served out by the convicted practitioners. The deficit between counsel's salaries and disbursements and the fines collected and paid to our treasurer was \$22,407.39, making the average yearly excess of costs for the whole period over receipts from fines, \$1318.08. During the past two years together, the counsel's costs has been \$5841.30, and the receipts from fines paid to the Treasurer, \$2610, or a total deficit for the two years of \$3231.40, or an average yearly deficit of \$1615.70.

The above figures do not include the extra legal expenses of the society during the past seventeen years for extra counsel fees, etc., in drafting, and passing, or watching bills in the legislature, or for legal opinions, and for subscriptions and expenses in the Purdy, Van Fleet, and other suits, which would probably increase the grand total of costs for legal work performed by the society during the period named to nearly \$45,000.

We must not stop this work, and from the opinion of our counsel we are led to believe that we cannot do so without having the city worse off than ever, for the city or its district attorneys will not take up the prosecutions. Why the medical profession should be made to prosecute and pay the expenses incurred in prosecuting criminals or others for infringing upon the medical laws, or for imposing upon the public, it is hard to understand. Certainly, no one would expect the legal profession, or any other, to fight infringements upon its and the public's rights. But doctors will submit to almost anything, and when they are not united the few workers cannot make up for

the drones, or the indifferent, and I presume this explains the reason for the imposition.

It is evident from past experience and the future's prospects, that for the counsel's fees and disbursements for the prosecutions alluded to, and which have generally been rendered at a minimum of costs for the work done, and for the other legal work of the society, that it will require an annual expenditure of at least \$3500, or fully three-fourths of our income from dues. It is true that we shall probably average, to be safe, a yearly return in fines of at least \$1200, although during the past two years the amount has exceeded this figure. But as a matter of fact we must have more money or allow this work to cease, for you will recall the fact that the last annual report of our treasurer shows the total annual expenses of the Society to have exceeded the receipts from all sources by nearly \$1000. To offset this, we must have five hundred more members, or else must increase our annual dues to \$4 or even \$5. Of the two propositions I prefer and would recommend the adoption of the former, for when we look over the list of medical men of standing in the city who are not members of this Society it will surprise us, and a canvass among these, I am sure, would soon fill our ranks to the required number to carry on the good work which every physician as a matter of fact ought to be interested in and support. While quality before quantity should be considered, there will be no difficulty in securing the additional well-qualified members if the history and labors of this Society are but half told.

Let us also hold out the olive branch to those physicians who left us fifty years ago owing to the quarrels over old dogmas, and who took upon themselves the name of certain sectarian practitioners. If they will but drop the sectarian title for that of physician, pure and simple, and let the "old" and "new" school questions die out, I am sure that we will welcome them with open arms, as we have received a great many of their practitioners during the past few years who have declared their abnegation of sectarian principles and practice. Let us also open the way for the return of those who left us nearly fifteen years ago, over a matter of the wording or phrasing of a series of ethical rules or by-laws, and whose return to the common mother would help us all, for after all, with a few exceptions, we are mostly at peace with each other, and are working on the same lines for the welfare and general good of the profession. With a united medical profession, working unselfishly for the common good of the public, as well as of the profession, there would be no need of "leagues" or other associations of medical men to spring forth to do that which formerly was and ought now to be our duty.

In closing, I ask for myself and associate officers your kind encouragement and support during the coming year; and you may rest assured that we each and all will endeavor to be honest and faithful servants of the good old Medical Society of the County of New York.

¹ This does not include \$400, which was due the Society, and which has since been paid to the Treasurer.

² Four hundred dollars more has since been paid to the Treasurer.

Illness from Eating Veal.—Sixty students of Vassar College are reported to be seriously ill from having eaten improperly cooked veal.

MEDICAL PROGRESS.

Pneumonia Following Anesthesia.—WHITNEY (*Boston Med. and Surg. Jour.*, September 23, 1897) says that attention has been called to the supposed increasing frequency of pneumonia after operations when ether has been employed as an anesthetic. There is no reason to suppose that this is a more common occurrence at present than formerly. It appears so, partly because other infectious processes have been eliminated to such an extent that this one stands out more prominently. Anesthesia-pneumonia does not differ from other types of pneumonia. There are plenty of microbes in the mouth of a healthy individual, but under ordinary circumstances they are rendered harmless. Under certain conditions this power fails, and a septic pneumonia results. Experiments upon animals have shown that prolonged etherization is one of these conditions.

The practical conclusion is that disinfection of the mouth before anesthesia should be carefully attended to, while the etherization should be as short and light as possible. The mouth should be cleansed, especially about the roots of the teeth, and the throat gargled several times with a warm solution of chlorinated soda. This should be done twelve hours before operation and again immediately preceding anesthesia. The following solution will be found of service:

℞	Liq. sodæ chlorinat.	. . .	3 iij
	Aq. menth. pip.	. . .	3 ij
	Glycerin	. . .	3 ij.

After which, the thorax and tonsils should be sprayed with a solution of peroxid of hydrogen, one part water to three parts of peroxid. Then the nose should be douched with a saturated solution of boracic acid, to which half a teaspoonful of salt has been added. As a last detail, the cone or sponge used for the anesthesia should be sterilized for each patient. Though this may seem like an excess of nicety in preparation, one never knows in which case these precautions may save the life of a patient.

A New Method of Treating Fracture of the Jaw.—HANSY (*Centralbl. für Chir.*, October 9, 1897) recommends the following as the best method of treatment for fracture of the jaw: After the complicating wounds of the gums and external skin have been properly cleansed the fragments of the jaw are replaced as carefully as possible by means of manipulations with the fingers and by pressure of the jaws together. Next, a piece of iron, copper, or zinc wire, flexible and strong, is bent so that in shape it approximates the inner margin of the teeth. It is bent around the back teeth, and brought together in the middle line, and the ends twisted lightly together. Then, a number of pieces of fine wire such as florists employ are passed between the teeth, and with them the anterior and posterior portions of the heavy wire are bound together. When the character of the teeth will permit it, the wire is wrapped around their necks. In this way the heavy wire is firmly fastened in position. If necessary the wires may be tightened on the following day. If the apparatus is efficiently applied the fragments will be held so firmly in position that neither accidentally nor by pressure of the

fingers can they be disturbed. With this method, Hansy has obtained excellent results in the treatment of three complicated fractures of the jaw, two of them being of the lower and one of the upper jaw. One advantage of this method is its great simplicity, nothing being required but wire, a pair of pincers, and cutting-forceps.

Proof of the Existence of Meconium.—SCHMIDT (*Centralbl. für Gynäkol.*, October 9, 1897), as a result of investigations has determined that meconium outlasts in the corpse by a considerable time all other tissues which are not free from water, such as bones, teeth, hair, etc., excepting such pathologic products as calcified tissues, concretions, etc. If meconium in considerable quantity is exposed to the air for six months or more, it dries only slightly, and in a thickened condition it is still easy to demonstrate both macroscopically and microscopically its anatomic characteristics. It is also easy to find microscopically, the characteristic points of meconium from spots or stains which are eight or nine years old. The particles of meconium are not bits of the coloring matter of bile, but are shrunken and partly degenerated cells, also cells of the vernix caseosa which has been swallowed, and cast off epithelial cells of the intestines which are stained with bile. The distinction sometimes referred to between yellow and green meconium is an artificial one. The evaporation of the water contained in yellowish-brown meconium, and the shrinking of the cells which results from it produces meconium of a greenish-black color.

THERAPEUTIC NOTES.

The Use of Senecio in Disorders of Menstruation.—FOTHERGILL (*Med. Chronicle*, September, 1897) reports his personal observations with senecio in disorders of menstruation. He used a tincture of *Senecio Jacobea*, 1-10; also, a 1-1 aqueous and alcoholic extract of the same plant; also, a dried extract. The doses used were 1 to 2 drams of the tincture, 20 to 30 minims of the fluid extract, and 1 grain of the dried product. Three or four doses were given daily. He found that senecio does not cause abortion, but will cure most cases of functional amenorrhea. In cases of anemia and other conditions of exhaustion due to disease, the drug was found to have little effect. It proved useful in certain cases of dysmenorrhea, but the relief was uncertain. In six healthy married women the administration of the drug caused the menstrual flow to appear from three to nine days before it was expected.

Ivy-Poisoning.—SCHONBERG (*Phila. Polyclinic*, October 16, 1897) says that none of the remedies used in the treatment of ivy-poisoning are specific. All of them are designed to relieve the itching and burning and subdue the inflammation. Of almost equal value are: (1) saturated solution of boric acid; (2) fluid extract of grindelia robusta, 1 dram to 4 ounces of water; (3) aqueous solution of sodium hyposulphite, 1 dram to the ounce, (4) Laborraque's solution, 25 to 50 per cent.; (5) black wash, diluted one-half with lime water; (6) bromin, 10-15 minims to 1 ounce of olive oil.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor: J. RIDDLE GOFFE, M.D.,

SATURDAY, NOVEMBER 27, 1897.

MEDICAL JOURNALS AND COLORED COVERS.

ON the title-page of the *Medical Record* for November 20th, we find in large type a notice to the effect that "The next issue will be a special number, with many attractive features, including a handsome colored cover." Think of it, you busy practitioners, struggling perhaps with a desperate case of pneumonia or a dangerous temperature in a puerperal woman, and hoping that your next week's medical journal will bring some helpful suggestion to aid you in the emergency! A colored cover! What comfort, what support, what help in your hour of need! And perhaps within that cover, instead of medical science, will appear many well-paying advertisements of winter-resorts and railroad transportation lines.

This cover in itself will doubtless stir the world of the provincial Medicus to its depths, and, incidentally, bring in bushels of subscriptions. We once heard the *Medical Record* spoken of as a scientific journal, but how greatly will its prestige be enhanced when it breaks upon an unoffending professional public in all the gorgeousness of the colored cover! With what breathless expectancy do we await this advance in medical journalism?

DOES INDIGENOUS PULMONARY TUBERCULOSIS EXIST IN COLORADO?

It can scarcely have escaped the notice of the careful observer of current literature, lay as well as medical, that during the past few years there has been an increasing number of patients with pulmonary tuberculosis in Colorado, without considering imported cases. The conclusion has been drawn that Colorado will eventually lose its reputation as a State free from indigenous disease of this character, and *pari passu* its high renown as a health-resort for consumptives. So serious has this prospect seemed to some of its inhabitants, that they have advocated the passage of stringent laws regulating the residents and habits of life of tuberculous patients, which, if enacted, would certainly have the effect of very greatly reducing the number of persons having tuberculosis who otherwise would seek health in Colorado.

According to Bonney (*Boston Med. and Surg. Jour.*, October 7, 1897), all this excitement is premature. "I am convinced," says this writer, "that as yet the data introduced upon this subject are entirely too meagre to warrant positive conclusions as to the supposed evidences of contagion in our community. I protest, therefore, against an undue agitation at this time, on the ground of insufficient testimony."

The reports of the Denver Health Department seem to show that the number of deaths from tuberculosis contracted in Colorado, is each year greater than during the preceding year. Thus in 1893, the native cases formed 13 per cent. of the total tuberculous death-rate; in 1894, 14 per cent.; in 1895, 15 per cent., and in 1896, 18 per cent. Bonney says that "these figures are not in every respect accurate, and that they are especially misleading, because the yearly increase in the relative percentage of deaths from native tuberculosis is due, not to an actual increase, but to a decrease in the number of deaths from tuberculosis elsewhere contracted, the practice of sending hopeless cases home to die, apparently being more faithfully carried out now than formerly."

Colorado suffers too, from the fact that an unusually high proportion of her children are of tuberculous parentage, and, therefore, are peculiarly prone to contract the disease. Hence, it is not surprising that, of 230 deaths from native tuberculosis which have occurred during the last four years, one-fourth were of

children under five years of age, and a considerable portion of these were from tuberculous meningitis, the development of which results as little perhaps from direct external contagion, as any variety of tuberculosis.

So far as clinical testimony is concerned, it is overwhelmingly against these conclusions which, strangely enough, have been advocated by the local health board. In the article referred to, Bonney quotes the views of a number of prominent physicians to this effect. As an illustration, the statement of Gardiner¹ may be taken, that in fifteen years preceding 1892, the physicians of Colorado Springs had observed only ten native cases of tuberculosis. "The well ones," says this writer, "are frequently confined with the sick, with the attendant anxiety, work, and worry, and there are many houses in which numbers of people have died from the disease." More recently, Solly,² also of Colorado Springs, is quoted as saying: "At least one-third of our population are consumptives; the town, which contains some 15,000 people, has been established twenty years. An inquiry made by interested physicians into the number of cases known to have originated in the town resulted in a report of twenty in all. Although it is probable that our brilliant sunshine and dry air more quickly destroys the vitality of the bacilli than an Eastern atmosphere, yet in the poorer lodgings of the town there are many ill-ventilated rooms, inside or on the north side of the buildings inhabited by consumptives and their families, where recklessness of expectoration and carelessness of ordinary cleanliness are marked features of domestic *ménage*. Yet cases of contagion do not average more than one a year."

Bonney also makes the point that there is, in many of the instances of death reported as due to tuberculosis contracted in the State, no sufficient demonstration that the disease was really so contracted. Aside from the fact that autopsies are a constant proof that tuberculosis may exist unsuspected, it is no uncommon experience with physicians in health-resorts for consumptives to find the disease in the supposedly healthy relatives who accompany the patients.

The practical bearing of the whole subject seems to be, that considering the vast tide of actually or potentially tuberculous individuals which has risen to the very mountain-tops of Colorado, there is a re-

markably small amount of indigenous tuberculosis. Whatever relative importance may be attributed to the predisposing and exciting causes of this disease, it is admitted by all that with reasonable precautions concerning sputa, the danger of infection is practically nil; and even without these precautions, the danger of infection in the open air is exceedingly slight. The situation is one which calls for the exercise of intelligence rather than the enactment of harsh restrictive laws.

WATER-BORNE TYPHOID.

EVER since the acknowledgment of the bacillus described by Eberth and Gaffky as the direct etiologic factor of typhoid fever, pathologists have believed, and clinicians have gradually come to accept the verdict, that the disease can only be produced by the ingestion of the bacillus with the food or drink. Clinical evidence of this mode of the propagation of enteric fever is not wanting, and almost every observer has been able to deduce convincing testimony by the direct tracing of an infection. Any evidence which tends to establish this view upon a surer basis is entitled to consideration. Dr. Ernest Hart, Chairman of the Parliamentary Bills Committee of the British Medical Association, has prepared the report of the committee, which has just been published (*Water-borne Typhoid; a Historic Summary of Local Outbreaks in Great Britain and Ireland, 1858-1893*).

The report is valuable not only because it leaves no further doubt in the mind of the reader as to the propagation of typhoid fever by the ingestion of infected water, but because it gains authority from a minute analysis of 205 epidemics, all of which had their origin, directly or indirectly, in the manner mentioned. Dr. Hart purposely omits from consideration eight epidemics of the disease because of their doubtful causation, relying upon those of certain origin to prove his position, although the eight epidemics are cited in detail, and leave little room to doubt the mode of infection.

The author first considers polluted wells as assisting in the spread of the disease, and selects several undoubted instances corroborated by bacteriologic examination. He condemns the employment of drinking-water from wells liable to pollution, and urges that "when the local conditions obtaining are such that they must needs cause excremental pollution of the ground around houses, then it is high

¹ *American Jour. Med. Sciences*, July, 1892.

² *Boston Med. and Surg. Jour.*, April 1, 1897.

time to close all wells sunk in the neighborhood of the pollutions." The New York State Board of Health promulgated a similar proposition many years ago, and its beneficent influence has been shown, in the course of time, among the rural population.

The report next considers the direct pollution of drinking-water by human excreta, as in the careless use of the banks of streams by workmen, and indirectly, as by contamination from leaky sewers. He has been able to trace outbreaks of typhoid fever from these causes not only, but, as well, from cesspools constructed in loose soil with no provisions for making them watertight. He shows that although it may seem safe to throw excreta into privies during a frost, the subsequent thaw may evoke a typhoid epidemic, since the germs of the disease remain actively potent. The author next discusses epidemics caused by drainage from manured fields, by polluted subsoil water, by diluted excreta used as water-supplies, and by river-borne infection. Canals as suppliers of drinking-water are absolutely condemned, and the proper filtration of public water-supplies is urged. Two epidemics are cited as having their origin from churchyard drainage, and the author writes: "Man, however, does not appear content to pollute his drinking-water by the voided filth of the living, but is too often careless in the matter of contaminating his water-supply by the drainage from the resting-places of the dead, and thus it comes about that danger arises from the proximity of burial-grounds to the areas of catchment for watering-pounding purposes."

The report mentions an epidemic during which 322 persons were attacked, and in which the infection was traced to the washing of milk-cans with polluted water. He discusses some minor points in the causation and course of the disease, and concludes by urging the abolition of cesspools where this is feasible, by insisting upon the maintenance of freedom of pollution of the watersheds and gathering-grounds of public water-supplies by condemning the close proximity of water-mains and sewer-pipes.

Although the results of these laborious investigations are not strikingly original, they prove beyond peradventure that typhoid fever is largely a preventable disease, and that the prophylaxis must lie in the hands of the sanitary authorities. This is especially true of large cities the water-supply of which

is apt to become contaminated if the most rigid watchfulness is not at all times exercised. The importance of careful scrutiny of the supply of drinking-water can not be too frequently impressed upon local and State Boards of Health, upon whose energy and wisdom the well-being of thousands of human beings constantly depends. In emphasizing this feature of sanitary work as it relates to typhoid fever, the committee has placed all communities under lasting obligations.

ECHOES AND NEWS.

Dr. George T. Kemp.—The appointment of Dr. George T. Kemp to the chair of physiology in the University of Illinois has been announced.

Elected Honorary Member.—Professor Von Röntgen of Würzburg has been elected an honorary member of the Swiss Scientific Society, Berne.

Russian Medical School for Women.—The newly established medical school for women at St. Petersburg recently opened with 165 students.

Retirement of Dr. W. E. Walters.—Lieutenant-Colonel William E. Walters, deputy surgeon-general, has been retired under the Thirty-Years' Service Act.

Typhoid at Clifton.—The recent outbreak of typhoid fever at Clifton, England, has been definitely traced to milk infection. Nearly 150 cases have been reported.

Druggist Fined.—A New York druggist has been fined \$150.00 for practising medicine without a license. This is the heaviest fine yet imposed for such an offense. The Medical Society of the County of New York was the complainant.

Yellow Fever in Florida.—A soldier died on the 18 inst. at the barracks hospital at Fort Barancas, Pensacola, Fla. After making an autopsy, State Health-officer Porter and the surgeon of the post, declared the cause of death to be yellow fever.

Röntgen Society.—At the inaugural meeting of the Röntgen Society, which took place recently in London, England, among other exhibits was a life-sized skiagram of the entire skeleton of a living woman, taken by Dr. W. J. Morton of New York.

Women Sue Druggists.—Two cases are now being heard in Brooklyn, N. Y., in each of which a woman is suing a druggist for \$5,000 and \$10,000 damages, respectively, for prescribing medicine which she alleges caused permanent injuries and impairment of health.

Death of Dr. Mark Olivet.—The death at Geneva, on the 24th ult., is announced of Dr. Mark Olivet, professor of psychiatry in the University of Geneva. Professor Olivet

was the author of numerous publications on medicine and hygiene. He was in his seventy-sixth year.

Typhoid Fever in Glasgow Harbor.—The Russian Volunteer steamer "Kieff," which at present is lying in dock at Glasgow, arrived at that port on the 23d ult. from Russia, *via* Leith, and reported one death from typhoid fever and six of the crew stricken with the disease.

Professor Forel Resigns.—Dr. Forel, professor of psychiatry in the University of Zurich and director of the State Asylum for the Insane, has resigned these offices, owing, it is said, to the attacks made upon him by the press for the part he has taken in opposing the use of alcohol.

Chicago Pathological Society.—The annual address before the Chicago Pathological Society will be delivered on the evening of Friday, December 3rd, by George M. Sternberg, M.D., Surgeon-General of the U. S. Army. The subject of the address will be "Yellow Fever; Its Etiology and Pathology."

Emergency Hospital in the Pension Office.—There are 1800 clerks employed in the Pension Office at Washington, and as some of them are veterans suffering with heart trouble, an emergency hospital has been fitted up in the building for the purpose of caring for any case of sudden illness which may occur.

Bubonic Plague in India.—The plague is still raging in the Poona district. There are now 634 cases in the hospital at Poona. Many new cases are reported daily, and the death-rate is nearly 100 a day. Several Europeans have been attacked with the disease. Business is practically suspended and the inhabitants are deserting the town.

Serum Treatment of Whooping-Cough.—Dr. Violi of Constantinople proposes to treat whooping-cough by means of injections of serum taken from calves which have been vaccinated against smallpox. He has treated a number of cases in this way in which the characteristic paroxysms disappeared within from eight to ten hours after the first injection.

New York Society for the Relief of Widows and Orphans of Medical Men.—The annual meeting of this society was held on the 17th inst. at the Academy of Medicine, Charles A. Leale, M.D., was re-elected president; Henry Tuck, M.D., treasurer, and Drs. G. M. Smith, S. T. Armstrong, W. F. Cushman, J. Cabot, C. H. Knight, A. Jacobi, and J. L. Kortwright, managers.

New Consumption Hospital for Vienna.—A large hospital for consumptives is to be erected, through the generosity of several citizens of Vienna, at Alland, a small hamlet near the city. It is expected that it will be ready for occupancy by the spring of 1898. It covers a large area, and is sheltered on all sides save the south by hills and forests. The building will accommodate about 300 patients, but will be enlarged in the future. It will contain all the latest hygienic appliances.

Department of Public Health.—At a meeting held recently, the New York Board of Trade and Transportation adopted a resolution declaring the health of the people of far more importance than the proposed enlargement of the navy or other preparations for war, and calling for the appointment of a committee to consider the desirability of the establishment of a national department of public health.

Intestinal Parasites in China.—It is said that 95 per cent. of Chinese children suffer from thread-worms. This is supposed to be due to the fact that in China unfiltered water is used, and vegetables are, as a rule, eaten raw. European residents there boil or filter their water and cook their vegetables, and are free from this trouble. The Chinese, however, who rarely eat any meat other than pork, do not suffer with tape-worm, whereas 20 per cent. of the Europeans, who eat a good deal of beef, are especially liable to these intestinal parasites.

CORRESPONDENCE.

THE TREATMENT OF ABORTION.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: I have read with interest Dr. Henry J. Garrigues' article on "The Treatment of Abortion" in THE MEDICAL NEWS of November 6th, and beg to be allowed to offer several criticisms:

1. The author very properly pronounces Thomas' small dull-wire curette as useless for the purpose of emptying the uterus during an abortion, and declares his (Thomas') "large dull-wire curette, with an opening admitting the tip of a forefinger, an admirable instrument for the purpose, formidable as it appears."

I think the author is in error in calling Thomas' large dull-wire curette a "formidable instrument." The only two dull-wire curettes which go by the name of Dr. Thomas, so far as I know, are the small one, which is used for removing intra-uterine vegetations and is useless in abortion, and a somewhat larger one, which I have employed for years in abortions *under two months*, where Dr. Garrigues says he uses Récamier's or Sims' curette or Simon's sharp spoon. I have never found it necessary, by the way, to employ a *sharp* curette in early abortions, or even later, unless there had been an acute endometritis with inflammatory adhesion of the placenta.

The curette which Dr. Garrigues must mean, and which he calls a "formidable instrument," can be no other than the *large dull* curette, attached to a long, stout shank and handle which I first introduced to the profession in 1883 (see *Am. Jour. Obst.*, Feb., 1883). "The Immediate Removal of the Secundines after Abortion" (and which is mentioned and pictured again in my "Report of the Gynecological Service of Mt. Sinai Hospital," *Am. Jour. Obst.*, Oct., Nov., Dec., 1895), and has been sold by instrument-makers under my name all these years. Strange to say, this fact seems to have escaped Dr. Garrigues' notice!

There are two shapes of my placental curette, one round and the other oval, the latter being especially designed for use when the cervical canal is long and not fully dilated. After the second month both can usually be inserted without difficulty through a fully dilated canal. A large flat forceps for the removal of the *detached* decidua accompanies the curettes. The curettes may be used whenever the canal is sufficiently dilated to admit the index-finger, and this brings me to criticism number

2. Dr. Garrigues omits to lay down as a condition indispensable and invariable, I think, for the efficient and thorough use of the curette after abortion, that the uterine canal should be sufficiently dilated to permit the index-finger to explore the uterine cavity to the fundus, in order not only to determine the quantity and location of the retained secundines, but also to enable the operator to be perfectly sure that the cavity has been entirely emptied when the operation is completed.

To trust to the information on this point imparted by the curette alone, even in the hands of the most expert operator, is notoriously unsafe.

3. Dr. Garrigues has omitted to mention that at times great assistance is afforded to the cervical dilators which he mentions by gently nicking the lips of both the external and internal os with a straight, blunt-pointed knife, especially when the edges of the external os are rigid and cicatricial as occasionally happens after a trachelorrhaphy.

I have found the index-finger, assisted by counter-pressure over the fundus with the other hand, as good a dilator as any of the cones or olives, provided it was possible to insert its tip ever so little into the internal os. In incomplete abortion, when any considerable portion of the secundines is retained this can usually be easily done.

4. I cannot agree with Dr. Garrigues' advice and practice to tampon either the uterus or vagina after emptying the former of the products of conception. An *empty* uterus after abortion *always* contracts, and all hemorrhage from its cavity ceases. A failure to contract at that time is an exception. To pack the uterus is therefore unnecessary, and rather tends to interfere with contraction and involution than to aid them. And why pack the vagina? I usually employ a hot sterilized or carbolyzed intra-uterine douche after emptying an aborting uterus, and I can scarcely recollect a case where prompt contraction and cessation of bleeding did not take place. Only in women very much exhausted from hemorrhage might it be advisable to pack the empty uterus after abortion with iodoform gauze, or better sterilized gauze, in order to save her even the few drops of blood which would ooze away during the first day or two, until she has rallied. At least that is my opinion, and has been my practice for many years, and I have no reason to regret or change it. Of course, if the object of packing the uterus is to influence a septic condition of the endometrium, the case is different. But then it would seem to me that gauze soaked in peroxid of hydrogen or kept moist with the forty-per-cent dilution of alcohol recently recommended by Dr. Ill must be preferable to iodoform gauze as a uterine packing.

With the above exceptions I agree substantially with all Dr. Garrigues has said in his instructive and practical article.

PAUL F. MUNDÉ,

20 West 45th Street.

NEW YORK, November 20, 1897.

OUR BERLIN LETTER.

[From our Special Correspondent.]

ACCIDENT INSURANCE AND CARCINOMA DEVELOPING AFTER TRAUMA—THE PATHOGENEITY OF BLASTOMYCETES AND THEIR CONNECTION WITH CANCER—CLINICAL EXPERIENCES WITH LUMBAR PUNCTURE—THE SPREAD OF ANCHYLOSTOMIASIS THROUGH EUROPE.

BERLIN, November 16, 1897.

AS the result of a discussion which occurred some time ago in the Berlin Medical Society, Dr. I. Boas published in the last number of the *Deutsche Medicinische Wochenschrift* an article on "The Connection between Trauma and Intestinal Cancer, and the Question of the Liability of Accident-Insurance Companies in Such Cases." In a series of sixty-two cases of intestinal cancer in which the previous history and antecedents were carefully studied, he found in nine a clear history of trauma which seemed to have some etiologic connection with the development of the neoplasm. Curiously enough, he found in only two direct heredity (in general, he considers the influence of heredity in cancer much overestimated), though in seven a brother or sister had suffered from cancer. None of these patients with hereditary cancer, however, presented a history of trauma, so that the disturbing factor of a possible hereditary predisposition is excluded in the cases in which an injury is considered to have been the cause of the disease. Dr. Boas does not consider that the injuries were the immediate cause of the development of cancer, but is of the opinion that small cancerous nodules of the intestines, in an absolutely latent and quiescent stage, are irritated into developmental activity by the trauma.

In the discussion, Professor Führbringer and others went further than this, and advanced the opinion that the injury to intestinal tissues had either lessened vital resistance and so given an opportunity for cancerous infection, if cancer is an infection, or had disturbed the equilibrium of cellular elements in the tissues and so occasioned an overgrowth of the epithelial elements, which constitutes a cancer. Any of these opinions, even the most conservative, would give the patient the benefit of the accident.

In insurance, according to German law, it seems it is not necessary to prove that the accident in question was the only cause, or that it was the immediate cause, of the inability to continue one's occupation, of the mutilation, or death which followed. If it stands in a clear causal relation to these consequences, and if this can be demonstrated to the court, then the verdict will be that the insurance must be paid.

As Dr. Boas says, "it is not clear whether these quiescent cancerous nodules would ever have taken on

activity but for the irritation resulting from the trauma, though malignity might have developed about the time of the apparent arousal of the disease by the injury." He considers, however, that the statistics of cancer after trauma are too rich in examples for it to be a mere question of coincidence. He considers that in this connection the only thing still remaining open to discussion is how long after an injury has been received may the development of a cancer be fairly thought to have resulted from a trauma. In his own cases the disease developed at varying periods of from two months to four years subsequent to the injury. He does not seem to consider the shorter interval too short or the longer one too long for the relation of cause and effect to be held as existent. As to shorter intervals than two months, he would hesitate to attribute the cancerous development to the injury, though he seems to think that a longer period than four years might intervene and yet the injury be a causal element in the neoplastic activity.

The question has more important bearings when cancerous disease other than of the intestine is taken into consideration. Many patients with cancer of the breast present a history of injury, even if it be no more than the traditional blow of the nursing. If accident-insurance companies are liable for cancers which develop after injuries, it will only be a question of time when the courts will recognize that railroad companies and other corporations should be held liable on the same grounds. This involves a vision of long-continued legal proceedings and the consequent precious opportunities for legal and medical experts to discuss a question which ought to prove as profitable in the future as traumatic neuroses, railway spine, etc., have in the past.

Of special interest, in connection with the etiology of cancer, was the discussion on "The Pathogeneity of Blastomycetes and Their Causal Relation to Cancer," which occurred at the last meeting of the Berlin Medical Society. Dr. Buschke read a paper on the subject, the subsequent discussion of which evidenced the consensus of the opinion in the matter. The general sentiment was in accord with Dr. Buschke's idea, who considered that notwithstanding the claims made for it (San Felice of Palermo, and Roncali of Rome) there is absolutely no possibility of blastomycetes being the cause of cancer. Dr. Buschke himself has experimented with cultures of blastomycetes, which had, under the influence of electricity and artificial brooding temperatures, been rendered especially virulent, but he has never been able to cause the appearance of a tumor in any way resembling cancer in a series of some twenty cases with which he experimented.

On the other hand, now that special attention has been called to the subject, the pathogeneity of blastomycetes for various animals and for man is becoming better known with further clinical and experimental experience. Here the doctor made his acknowledgments to American experimenters—Curtis, Gilchrist, and Rabinovitch. He considers that the subject of the pathogenic yeasts which is just opening up will yet prove an extremely interesting branch of microbiology.

While the neurologists decry the frequent use which is

made of lumbar puncture for diagnostic and therapeutic purposes, and oppose, on theoretic grounds, its employment except under the most urgent circumstances, the practitioner, and especially the specialists in diseases of children, are coming to consider it more and more as a simple and extremely useful diagnostic method with scarcely any attendant risks. As the neurologists oppose it on theory while the practitioners can point to a large number of cases in which the procedure has not done any harm, it is clear what impression the profession in general is going to have of this difference of opinion.

At the last meeting of the Society for Internal Medicine Dr. Stadelman reported a series of cases in which lumbar puncture had been made without accident or even inconvenience, and he considers that now the purpose of the procedure, at least as regards diagnosis, may be widened in its application. It is useful not only in distinguishing the forms of meningitis, and the existence of intrameningeal pressure from hydrocephalus, and brain and spinal tumors, but also for the differential diagnosis of other conditions simulating central nervous affections.

When, for instance, a state of stupor has intervened during one of the infectious fevers and the absolute prognosis will depend upon whether or not the serous membranes of the cord and brain have been infected by the specific virus, lumbar puncture will often decide the otherwise extremely difficult question. When an obscure unconsciousness is present the condition of the cerebrospinal fluid will often furnish valuable diagnostic evidence. In these cases the risk of any serious result is extremely slight, while in some instances the relief of cerebral pressure has an immediate beneficial effect. It is only in cases of acute increased intracranial pressure, however, that Stadelman has ever seen any good effect resulting from this procedure. He considers that the diagnosis of hemorrhage into the brain or cord is possible when the cerebrospinal fluid is found uniformly tinged with blood. As to the bacteriologic examination of the fluid, he considers that negative results either microscopically or even by culture methods cannot be relied upon for diagnostic purposes, and it is only when the results are positive that reliable conclusions may be reached.

One of the striking things in all clinics at which patients suffering from anemia are presented is the care taken from the first to exclude the *anchylostomum duodenale* as the cause of the condition, though why, since it is oftenest found in the jejunum or upper part of the ileum, while the duodenum is often entirely free, is not quite so clear as it might be.

Twenty years ago the parasite was practically unknown here. When the St. Gotthard cases occurred the explanation of their etiology came as a distinct surprise; for the parasite was considered endemic only in Egypt, and perhaps in parts of Italy. Since Grawitz found four cases in the neighborhood of Berlin some three years ago a number of cases from all over Germany have been described, and this parasite is no longer considered a rarity. At the present time the stools of every patient suffering with severe anemia are examined for the *anchylostomum*. The spread of this parasite has been traced to the introduction

of Italian workmen for trench- and tunnel-work, and for brickmaking. One case is known to have infected a large number of workmen. As it is just this class of men that we, in America, are receiving from Italy, it would seem to be only a question of time, unless special precautions are taken, until our clinicians will also have to think of this parasite in their cases of anemia.

Paris.

CONTUSIONS OF THE ABDOMEN—TREATMENT OF IN-OPERABLE MALIGNANT TUMORS BY LIGATURE—THE LAST WORD ON FORCIBLE REDUCTION IN POTT'S DISEASE—SIMILAR TREATMENT OF SCOLIOSIS—RELATIVE VALUE OF NEPHRECTOMY AND NEPHROTOMY—RADICAL CURE OF HERNIA IN YOUNG CHILDREN—INDICATIONS FOR OPERATIVE TREATMENT OF CANCER OF THE RECTUM.

THE Eleventh Annual French Congress of Surgery was held at Paris October 18 to 23, 1897. A paper by DEMONS on *Contusions of the Abdomen* brought out widely different views upon the indications for operations in these cases. The conditions under which the various abdominal organs may be injured, and the most reliable points in diagnosis were given at length. In regard to prognosis, the writer said that medical treatment, directed toward the relief of shock and pain, the arrest of hemorrhage and the maintenance of immobility of the affected organs, has given such good results that surgeons are unanimous in employing it. It is in the cases which are between the extremes that opinions differ as to the course to be pursued. Recognizing the failure of medical measures in many cases, surgeons often take a position which may be called one of "armed expectancy," and defer operation until signs, which cannot be met by medical treatment, are manifested. Experience has shown that these signs rest, not upon the lesions themselves, but upon complications already present at the time the signs become obvious; such as peritonitis or intestinal perforation. Hence, while not entirely rejecting this "armed expectation," it is a dangerous doctrine to advocate.

Theoretically celiotomy is a satisfactory procedure in these cases, offering as it does, an opportunity to prevent or to relieve complications including hemorrhage, infection, abscess, etc., but practically it has not fulfilled our expectations. Future results will probably be better than those so far obtained. The operation should be performed as early as possible, and the best time seems to be between the symptoms caused by the accident, and those which develop later, that is to say, within the first twenty hours. The sole contraindication to an immediate operation is the existence of shock so profound that the patient will not withstand a surgical operation. A young man who was kicked by a horse was operated upon twelve hours after the accident. Although three liters (quarts) of blood were found in the peritoneal cavity, from a contused wound in the liver, the patient recovered. The writer said that he did not believe this patient would have recovered had operation been delayed,

and had it been sooner performed, the patient would certainly have died upon the operating-table.

DENTU said that lesions of the kidney and bladder are easy to diagnose, which is not true of other abdominal injuries. Lesions of the abdominal wall are not of great assistance in diagnosis; but a hyperesthesia of the abdomen is an indication for operation. An increase in the respirations to twenty-eight or thirty per minute he considered an absolute indication for operating. Cold extremities are also significant. Suppression of the secretions, not to be confounded with retention of urine, points to the necessity for immediate interference. In the consideration of shock, it is important to determine whether it be of nervous origin or due to the loss of blood. In the latter case, if the symptoms are becoming constantly more accentuated, there is no reason for a moment's delay in operating. In other cases, it is better to wait for an hour or two after the accident before operating. Undoubtedly cases of grave contusion of the abdomen may exist without giving rise to symptoms, but their number is far less than it was before the symptoms were as carefully noted as they are at present.

According to MICHAUX celiotomy is the only treatment to apply in contusions of the abdomen. It has been sufficiently demonstrated that the symptoms are not an adequate index of the gravity of the lesion or lesions; and if we cannot tell what the injuries are, the only thing to do is to investigate. True, Mendy found that in 289 cases of contusion from the kick of a horse, thirty per cent. of the non-operated patients died; and also seventy-one per cent. of those operated upon. These figures have no value; for in many instances no details were given, and in 18 out of 25 fatal operative cases, peritonitis was already established. Of the speaker's own cases, 20 in all, 14 of the patients were operated upon, with 2 deaths, while of the 6 not operated upon 2 died. He denounced the doctrine of "armed expectancy" as absolutely unreliable.

MOTY is an advocate of opium if operation is not performed. He regards the use of ice in such cases as productive of grave complications—notably of phlebitis.

DOYEN spoke of the use of a jet of vapor to control hemorrhage from the contused liver or omentum, as advised by Sneguirev. The remedy has antiseptic as well as hemostatic virtues. If a tampon is employed, it is well to shut off the surrounding peritoneal cavity by a few sutures. Large blunt glass drains are inserted, the outer end being connected with a rubber tube which falls into an antiseptic solution. In this way the abdominal cavity is kept sterile, and if necessary may be pumped out.

TUFFIER has revived the *treatment of inoperable malignant tumors by ligature*. In the pre-antiseptic days this method of treatment was productive of very bad results. Under aseptic precautions he has obtained results in some instances which were most satisfactory. Thus, by tying the four arteries supplying the uterus in a woman afflicted with an epithelioma, the growth diminished to such an extent that after sixteen months the patient had very little trouble from it. In cancer of the tongue, lig-

ature of the external carotid gave him only a temporary improvement in seven cases. Infection may be limited in a similar manner. Thus, he tied the pedicle of a suppurating kidney in a patient who was too septic for a nephrectomy, and in whom nephrotomy was contraindicated by the multiplicity of the abscesses. The toxic symptoms disappeared at once, though the patient died two months later of suppuration of the other kidney.

BOSQUET succeeded with this treatment in several cases of neoplasms of the face. HARTMANN found it to be of value in fibromata of the uterus, though it had not been successful in epithelioma of the uterus.

CALOT gave further *details and results of the treatment of Pott's disease by forcible reduction*. A traction of 60 to 160 pounds is made for some seconds; the deformity obliterated by a direct pressure of from 30 to 80 pounds; finally, a bandage is firmly applied. Very large or very old projections are reduced in several *stances*, separated by an interval of three or four months. Of 204 children treated by this method, 2 died in a couple of days, 3 in some months of brochopneumonia and meningitis; in 1 patient partial paralysis occurred within a few days, while in 2 others intervention was followed by the formation of an abscess.

From observation of thirty-five cases, REDARD regards this treatment of Pott's disease as most valuable and calculated to give relief in a great number of cases. Ankylosis and large abscesses are contraindications to its employment.

CALOT also *applies this form of treatment to scoliotic patients*, reducing the deformity as much as possible by an apparatus especially constructed for the purpose, or by means of a plaster cast. The jacket should be changed every three months, and, if necessary, the correction of the remaining deformity is attempted each time. From a year to eighteen months are required for completion of the treatment.

ALBARRAN has *removed a kidney for a tuberculous process* eight times with one death. Five of the survivors are apparently definitely cured, having gone from fifteen to thirty months without evidence of further trouble.

Of 11 patients upon whom he performed nephrotomy for tuberculosis, 1 died from the operation, and 7 others died in from three to seven months; hence, in cases of miliary or caseous tuberculosis of the kidney, uncomplicated by pyonephrosis, removal of the kidney is far better than its incision; but in any case one should assure himself of the presence, and as far as possible of the functional activity of the other kidney before performing a nephrectomy. Genital and vesical lesions are rarely contraindications to operation.

FROELICH advocated a *radical cure for hernia in all children over ten years of age*. To save time and avoid hemorrhage, the sac is neither extirpated nor even isolated, but its neck is closed by passing through it one of the sutures used to draw together the pillars of the ring. If the sac is too large for the accomplishment of this procedure, enough of it is isolated to permit of the application of a ligature.

BROCA said that there were undoubted instances of

cure by a bandage when the hernia had existed two years; but that he preferred the radical operation, because the treatment with a truss is so tedious. To suture or ligate the neck of the sac under pretence of hastening the operation, is not a good practice. The radical cure of a hernia depends upon the high dissection of the sac, and when this is well done, it is possible to make a successful operation either with or without buried sutures. Even with a complete dissection, the operation need not exceed ten minutes in length.

Frölich recommended in cases in which pelvic drainage is necessary in the male, that it should be secured through the posterior wall of the pelvis. This is accomplished by following the right border of the cecum, until the finger comes upon the level of the lesser sacrosacral ligament. Then with a Wollfer's clamp, a drain may be pushed through the pelvic wall at this point. The clamp will protrude at about the middle of a line drawn from the posterior superior iliac spine to the most prominent part of the ischium. No one who has not attempted this procedure will appreciate how easily it may be accomplished.

QUENU and HARTMANN presented the *indications for and the operative treatment of cancer of the rectum*, and the different methods thereof. The radical operation in the hands of the best surgeons has a mortality of about twenty per cent., fully thirty per cent. of the deaths being due to sepsis in some form. A high situation of the cancer is no contraindication for operation; secondary deposits in organs within the abdomen of course exist. An iliac fistula should be established at least ten days before the rectal resection, as it is not possible to disinfect the rectum in less time. Then, in spite of the most thorough washing of the bowel with permanganate of potash, nitrate of silver, etc., the task is still imperfect, and immediately before operation the sphincter should be dilated, and the rectum, as well as the lower limb of bowel at the artificial anus, should be swabbed dry with sterile gauze, and finally tamponed.

If the growth involves only the lower bowel, the perineal operation will suffice, even when it has extended to a height of six inches, if the coccyx be removed. If a more extended involvement is present, or if glands, etc., are to be removed, the sacral route is preferable. If the disease is "total," *i.e.*, commencing at the anus and ascending to the third sacral vertebra, the perineal route is again preferable. The anus should be closed, and after the upper cut end of the bowel is sutured, the artificial anus should be made permanent.

In these opinions BOECKEL, GALLET, HEYDENREICH, and others concurred. GALLET called attention to the superiority of the vaginal route for low rectal cancer in the female.

DOYEN and JUILLARD spoke of the relief and prolongation of life to be obtained by an artificial anus. From two three years of comfort is often gained by it. POLLOSSON said that after operation the anus should not be closed. DOYEN does not ordinarily precede the radical operation by an artificial anus; but at the time of the major operation he brings a loop of the sigmoid to the

surface in the groin, and opens it three days later if the patient's condition warrants the additional procedure.

Vienna.

THE ETIOLOGY OF TRACHOMA—TREATMENT OF HAY-FEVER AT CARLSBAD.

At the Imperial Royal Society of Physicians MULLER discussed the *etiology of trachoma*. In the conjunctival secretion of trachoma patients he has found a bacillus morphologically identical with the influenza bacillus. It is 0.2–0.4 μ in length, stains with carbofic fuchsin and alkaline solutions of methyl blue, and does not react to Gram's test. It grows only in media which contain blood. Thus far, as already said, no difference has been found between this bacillus and that of influenza, either in appearance or method of growth, but the investigator refrains from stating that the two are identical. He found this bacillus in eleven out of fifteen trachoma cases, and was unable to find it in the healthy eyes of several patients suffering from influenza. In three instances, the bacillus was demonstrated to exist in the tissues of the conjunctiva almost as a pure culture. In twenty-five cases of non-trachomatous conjunctivitis with abundant discharge it was not found in a single instance. However, out of sixteen cases in a light epidemic of trachoma occurring in a regiment of soldiers the bacillus was only found four times. Under these circumstances it seems probable that the bacillus which was isolated is really the cause of trachoma, although further experiments are desirable, particularly inoculation experiments. It will be very difficult to succeed in the latter because a favorable disposition toward a growth of the bacillus is probably necessary. This would explain, for instance, how trachoma can exist for years in one eye, while the other eye remains unaffected.

At the session of the Vienna Medical Club, held October 20th, MULLER of Carlsbad, described his *experience with a number of American patients suffering with hay-fever*. All of the patients except two were men. All of them were individuals who appeared to be overworked and all of them suffered from gastric and intestinal disturbances in addition to the usual local symptoms of this disease. Treatment was, therefore, directed to the alimentary canal and the upper respiratory tract. Carlsbad water was given in abundance, and the mucous membrane of the nose was touched with a twenty-to-thirty-per-cent. solution of silver nitrate, and immediately thereafter sprayed with Carlsbad water. The effect of the nitrate was to produce an immediate increase of the secretion which was again diminished under the influence of the spray. After about ten applications the irritability was diminished, and the nose touched with a solution of menthol and resorcin, equal parts, in spiritus vini dilutus (3, 3, and 14 parts). By this treatment the patients were not absolutely cured, but they had no further attacks, and were so much improved that they were able to return with comfort to America and without fear of a fresh attack, when in previous years it had been necessary to await the coming of winter before it was possible to go home.

SOCIETY PROCEEDINGS.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Tenth Annual Meeting, Held at St. Louis, Mo., November 9, 10, and 11, 1897.

FIRST DAY—MORNING SESSION.

THE meeting, the sessions of which were held at the Southern Hotel, was called to order by the President, DR. GEORGE BEN JOHNSTON of Richmond, Va.

DR. C. A. L. REED of Cincinnati read the first paper, entitled

GALL-STONES IN THEIR RELATION TO CANCER OF THE GALL-TRACT.

The paper was based upon a report of four cases in which a distinct gall-stone history had preceded that of malignant disease. The diagnosis had been confirmed in all of them by exploratory incision, and in two by autopsy.

CASE I.—Woman, aged fifty-two years. She had hepatic colic during the five preceding years, associated with all of the usual gall-stone symptoms. During the previous thirteen months pain in the right hypochondriac region had been constant. Within the preceding six weeks persistent jaundice had developed. Globular tumefaction was detected below the right costal margin. Exploratory incision revealed primary carcinoma of gall-bladder and gall-tract with secondary development in the liver. Diagnosis confirmed by autopsy.

CASE II.—Male, aged sixty years, who had gall-stones twenty years, confirmed by their frequent passage *per via naturales*. Patient had undergone rapid emaciation, and during the preceding month pain had become constant. More latterly he became profoundly jaundiced. No physical symptoms could be detected. Exploratory incision revealed carcinoma of the gall-bladder and gall-ducts with secondary nodules in the liver. A calculus was found in the common-duct, and disintegrated by needle puncture. Primary recovery with amelioration of all symptoms, followed by death four months later; no autopsy.

CASE III.—Woman, aged forty-five years, who had had hepatic colic for several years. During the preceding six months she had been profoundly jaundiced; lost flesh rapidly. Examination of the blood revealed marked cholemia. There were no physical symptoms in the right hypogastrium. Exploratory incision revealed induration about the head of the gall-bladder and common-duct, to both of which the duodenum was firmly attached for a distance of several inches. A calculus could be felt within the common-duct just within its orifice. This could not be dislodged by prudent pressure or disintegrated by needle. It was delivered by incision through the duodenum. Patient never rallied, but died within thirty-six hours after the operation; no autopsy.

CASE IV.—Man, aged fifty-two years; confirmed alcoholic. Had severe attacks of hepatic pain during preceding fifteen years. Last attack was persistent and continued over six weeks. In addition to the usual symptoms

he complained of sweating and had a vacillating temperature. Operation revealed empyema of the gall-bladder with induration at its duct end. The gall-bladder was stitched to the abdominal incision and drained. Death occurred one week later; autopsy revealed carcinoma of the ducts at their juncture. Numerous small calculi were found in the hepatic duct well up in its main trunk, and in a number of the smaller branches. Multiple abscesses were found in the liver substance.

These cases have a suggestive significance, and point to an etiologic relationship. This is explained by the result of persistent irritation of the foreign bodies upon the mucous surfaces, inducing hypertrophy, cell proliferation, and in the event of the existence of original tendencies to cancer of prenatal origin, induces rapid development of the malignant neoplasm.

DR. EDWIN RICKETTS of Cincinnati reported two interesting cases of cancer which he believes were due to gall-stones. He said Courvoisier had found malignancy in seventy of eighty-four cases of gall-stone.

DR. JOSEPH EASTMAN of Indianapolis reported a case which had come under his observation within the last two weeks and which confirmed the remarks of the essayist. He believes that cancer of the gall-bladder and gall-ducts, as in the uterine cervix, is often the outgrowth of prolonged local irritation.

DR. JAMES T. JELKS of Hot Springs, Ark., has seen cancer of the liver unmistakably produced by gall-stones; hence, the deductions of the author in urging operative interference in all cases to prevent carcinoma of the liver were prudent.

DR. RUFUS B. HALL of Cincinnati expressed himself as being firmly convinced that the deductions drawn from the paper would be sustained by future work in this direction. Nine cases tabulated by him confirmed the conclusions of the essayist.

DR. A. M. CARTLEDGE of Louisville, Ky., said that in many cases presenting a history of the passage of gall-stones, the patient may have had beginning carcinoma of the ducts two or three years previously. He endorsed the views of the essayist relative to operative interference in cases of gall-stones.

DR. L. McLANE TIFFANY of Baltimore thought the causative relation between gall-stones and cancer was not yet well established; but that cancer is frequently accompanied by gall-stones is well known.

DR. THADDEUS A. REAMY of Cincinnati took a more conservative ground, and thought the Association ought not to go on record to the effect, that because gall-stones are associated with cancer of the abdomen, that every man or woman having gall-stones, must necessarily be operated upon lest he or she, as the case may be, may possibly have cancer.

DR. REED, in closing, again emphasized the significance of the persistent coincidence of cancer in long-standing gall-stone disease. His own brief experience embraced cases in which there had been a long-standing gall-stone history.

DISPOSAL OF THE STUMP AFTER REMOVAL OF THE APPENDIX

was the title of a paper read by DR. W. D. HAGGARD, JR. of Nashville, Tenn. The author considered appendicitis preeminently a surgical affection. Isolation of the infected appendix is as essential as the hygienic isolation of any of the infectious diseases. The various methods of disposing of the stump by invagination were discussed, and the modifications and technics employed by Van Hook, Dawbarn, McBurney, Murphy, and Morris were described. The ideal of all surgery is completeness which, when applied to the surgery of the appendix, means total extirpation of the organ. He then described the following method practised by Deaver in suitable cases: After freeing the appendix from adhesions and meso-appendix, the cecum is stripped of its contents and grasped between the fingers and thumb of the left hand, the appendix being held by forceps and cut off flush with the colon, and is then united by continuous Lembert sutures, during which the cecum is still securely held with the left hand just as in a gun-shot or stab wound of the intestine. Sutures may be inserted in two layers: (1) uniting the edges of the wound, and (2) approximating the peritoneal covering to the cecum over it. This method is not applicable to cases where the cecum is bound down by adhesions which prevent its delivery in the abdominal incision. This procedure does away (1) with subsequent perforation of the stump under the ligature from infection in its own cavity, (2) abscess of the wall of the cecum from invagination of the infected stump, (3) continuance of an infective process from stricture of the stump between the distal ligature and the proximal opening of appendix into the cecum, (4) imperfect invagination with incomplete drainage of the stump on account of the cecal wall being thickened and stiffened with inflammatory exudate. The author has employed this method in five cases with entire satisfaction.

REPORT OF FOUR CASES OF ABSCESS OF THE UTERUS,

was the title of a paper read by DR. GEORGE H. NOBLE of Atlanta, Ga. The first case was one of puerperal origin, the operation being done at the end of the second week. There was a pus-tube and abscess of the left ovary. The appendages on the right side were normal. After separating extensive adhesions for unilateral disease, an abscess of the fundus uteri about the size of an ordinary lemon was discovered which was excised, curetted, and cauterized with carbolic acid. The cavity extended from the median line to the stump of the appendages on the left side, which latter was turned into it, and fastened with sutures to prevent the formation of a dead space. A glass drain was placed in Douglas' pouch after flushing the abdominal cavity. The woman made an uneventful recovery, and has continued to be without pelvic disturbance. The histories of three other cases were detailed by the author. The four cases show what a surgeon will sometimes do for a septic uterus when given a chance. They also support the view that it is not always necessary to extirpate the uterus in suppurative inflammation of its parenchyma, and that such operations should be confined to cases in which the uterus is thoroughly septic or riddled with abscesses.

DR. A. M. CARTLEDGE said that the results following

the method pursued by the essayist were better than those of hysterectomy for infected uteri complicating the puerperia.

DR. J. WESLEY BOVEE was pleased with the advanced position taken by the author of the paper. Gynecologists had to fear, however, that, following this method, the future usefulness of the uterus might be impaired; it might tend to the production of rupture of the organ during subsequent labors.

DR. T. J. CROFFORD said that in cases of abscess of the uterine wall originating from the mucous membrane, if the cervix is dilated, the uterine cavity emptied with a curette, thoroughly cleansed and packed with iodoform gauze, these abscesses will open through the endometrium, which event will be followed by relief in the majority of cases.

DR. RICHARD DOUGLAS treats cases of infection following abortion or full-term labor by the Carossa method with decided benefit.

DR. W. E. B. DAVIS said that uterine abscesses complicating the puerperia can be successfully treated by incision and drainage in a large proportion of cases, even though they extend beyond the uterus. Illustrative cases in which this treatment was employed were cited.

DR. R. M. CUNNINGHAM said it was extremely difficult in general surgery to get primary union after curing and disinfecting abscesses, in that it was almost impossible to destroy the staphylococci, and more particularly the streptococci, which perhaps have already extended beyond the abscess wall.

DR. NOBLE, in closing, emphasized the point that the uterus is the seat of infection, and not the appendages. Only in cases where there are one or two, or possibly three abscesses, is this method of treatment applicable.

A paper, entitled

A STUDY OF RETROPERITONEAL NEOPLASMS AND SUPPURATIONS WITH SPECIAL REFERENCE TO DIAGNOSIS,

was read by DR. RICHARD DOUGLAS of Nashville, Tenn. The author accepted the definition of Mr. Lockwood of a retroperitoneal neoplasm; *viz.*, a solid or cystic tumor growing behind the peritoneum into the fold and not connected with any of the great retroperitoneal organs. He then dwelt at length upon the pathology of these growths and their causation. While not an advocate of the use of the aspirator in intra-abdominal diagnosis, yet, under proper conditions, the author thought that this instrument will reveal valuable evidence, not only as to whether a growth is solid or cystic, but as to its character. In retroperitoneal sarcoma aspiration reveals only a little blood or blood-serum in the needle. This sign enabled Weir and Bull to correctly diagnose a case reported by Devlin.

TUBAL AND OVARIAN HEMORRHAGE RESEMBLING RUPTURED ECTOPIC PREGNANCY,

was the title of a paper by DR. J. WESLEY BOVEE of Washington, D. C. The author said that a few years back pelvic hematocele was a condition which every practitioner appeared to meet occasionally, and many were the

supposed causes of it. When the subject of ruptured tubal pregnancy was so universally studied some of the most aggressive investigators told us to search in every case of pelvic hematocele and a ruptured ectopic pregnancy would be found. This dictum, though not endorsed by all observers, found a ready following, and up to the present time the majority of students of diseases of the female pelvic organs have accepted it. Many cases have been reported in which a presumptive diagnosis of ruptured tubal pregnancy has been made—cases in which such symptoms as shock, sharp pain, irregularity of menstruation, even amenorrhea, the presence of a small tumor in the pelvis, and possibly a fatal termination, and yet autopsy failed to reveal pregnancy; but, instead, hemorrhage from a Fallopian tube, ovary, or both. The speaker offered conclusive evidence against the positive statements which have been made. There are many instances in which women are deeply wronged by these diagnoses. These hemorrhages result from ectopic pregnancy, from malignant disease of the uterus, appendages, or rectum; from varicose veins of the broad ligaments, from disease of the appendix, from inflammatory disease of the tubes and ovaries, and from many other causes.

FIRST DAY—AFTERNOON SESSION.

DR. J. G. EARNEST of Atlanta, Ga., reported an interesting case of

EXTRA-UTERINE PREGNANCY OPERATED UPON AT THE SEVENTH MONTH.

The patient was thirty-six years of age, and the mother of seven children. She came under his care September 19, 1897. Five months before he had been called to see her on account of a profound collapse which threatened life. A history of irregular uterine hemorrhages was elicited, and he made a diagnosis of ruptured tubal pregnancy on the left side. Operation was deferred at this time, for the reason that it was feared the patient would die under the anesthetic. Nothing further was heard from the patient until the date mentioned, when the abdomen was found distended by a tumor on the left side and in the center as high as the umbilicus. On the right side was another apparently distinct cyst filling that side of the pelvis, and extending well up into the abdominal cavity. On opening the latter a large tumor, occupying the center and left side, presented. Its surface was somewhat irregular, very dark in color, and traversed in every direction by large blood-vessels. The enlarged uterus was enclosed in this mass. The tumor of the right side was about the size of an adult head, and seemed to be distinct from the larger one, the dividing line dipping down between them about half the diameter of the mass. To the larger growth was attached several coils of intestine, which were dark and changed in texture at the points of contact. The cyst on the right side peeled out without much hemorrhage. But an appalling flow of blood began with the work of peeling the placenta off from the pelvic and abdominal walls. Peeling it as rapidly as possible, the mass was loosened and iodoform gauze quickly packed behind it. The cyst was still unbroken, and had the appearance when lifted up of being a fibrocystic tumor of the

uterus. The author concluded to remove the uterus and drain through the vagina. As the uterine arteries could not be reached a wire attached to a *serra naud* was thrown around the uterus, tightened, and the mass cut away. The patient was now in such a critical condition that the author abandoned the idea of draining through the vagina. He tied the uterine and ovarian arteries, and packed the cavity with iodoform gauze, which was brought out at the lower angle of the wound, and closed the abdomen with silkworm gut. The gauze was removed on the sixth day. On the eighth day fecal matter passed from the drainage tract. From this time until she left the hospital, October 30th, most of the feces passed by the fistula. Five days later she was having free rectal evacuations with a corresponding falling off of the fecal discharge from the fistula.

The large tumor was entirely covered by an enormously expanded placenta beginning in the bottom of the pelvis, and firmly attached to the pelvic and a portion of the abdominal wall, its villi reaching well down into the tissues. From the top it was deflected from the abdominal parietes over and beyond the center, everting the body of the uterus. In the cyst thus formed a fetus of about seven months was found.

DR. L. McLANE TIFFANY of Baltimore read a paper, entitled

CYSTIC DISEASE OF THE MAMMA.

He said that the occurrence of cysts as a confusing element in the course of solid tumors of the breast is not so uncommon and might greatly resemble the subject dealt with in his paper, yet the clinical history and anatomy of cystic adenomata is sufficiently clear and the prognosis sufficiently important to justify careful study. In most cases an accurate diagnosis could be determined before operation. Dr. Tiffany reported eleven cases which showed many symptoms in common.

DR. A. V. L. BROKAW of St. Louis, Mo., made some remarks upon

THE X-RAY AND ITS APPLICATION TO SURGERY, and exhibited 200 radiographs. He showed excellent radiographs of the heart, thorax, fractures of the dorsolumbar vertebrae, pelvis, and fractures and lesions of the long bones. Of the many hundred exposures he has made, he has yet to see harmful effects following the use of the X-ray.

SECOND DAY—MORNING SESSION.

DR. D. F. TALLEY of Birmingham, Ala., read a paper on

CHRONIC PROCTITIS.

He dealt with two varieties of non-specific chronic proctitis: (1) Those cases in which a diffuse, persistent inflammation, superficial ulceration, and papillomatous vegetation are the prominent features; (2) those in which the submucous tissues are principally involved in the hypertrophic process, causing a proliferative stenosing proctitis. The main symptoms of these two forms of proctitis were described. Rest in the recumbent position was recommended as being of paramount importance in the treatment of the first form of the disease. The diet

should be of a liquid character, bland, and nutritious. In the absence of ulceration, where there is a diffuse chronic inflammation, the mucous membrane should be mopped with a strong silver or copper solution. The after-treatment consists in putting the patient to bed, washing the rectum daily with warm boric-acid solution, and the use of suppositories of iodoform and boric acid. In chronic cases in which the ulcers are extremely indolent, the solid stick of silver nitrate or a crystal of copper may be used. In these cases it is necessary to make repeated applications before the ulcers become healthy and begin to heal.

DR. WM. H. MYERS of Fort Wayne, Ind., read a paper on

THE EARLY DIAGNOSIS AND TREATMENT OF CANCER OF THE UTERUS,

in which he first dwelt upon the various theories respecting the nature of cancer, the last theory being that the disease is purely local in origin. The author dealt with the elements of diagnosis, and gave the statistics of the results following operations by different authors for this disease. He considered that the value of the microscope as an aid in the clinical diagnosis of cancer has been overestimated, and quoted several high authorities in support of this opinion. He closed by saying that the knife had become the emblem of gynecologic treatment. It had supplanted the curette, intra-uterine injections, caustic applications, the quaint conceits of the monkish craft, and the brutal records of the cancer cure. The knife had become, in a surgical sense, the specific therapy of this particular disease.

SECOND DAY—AFTERNOON SESSION.

DR. F. D. THOMPSON of Fort Worth, Tex., reported

A CASE OF TETANUS FOLLOWING A SURGICAL OPERATION.

The patient, a male, was twenty-one years of age, with a good family history, for whom a radical operation had been performed for extensive varicocele. Thorough asepsis was carried out. The result of the operation was excellent; yet on the morning of the ninth day after operative interference the patient could not open his mouth very well, and there was more or less stiffness about the muscles of the neck. A diagnosis of incipient tetanus was made, and the patient died less than three days after the first appearance of the tetanic symptoms. The speaker could not account for the infection with the bacillus of tetanus.

At this juncture the President, DR. GEORGE BEN JOHNSTON, delivered an address. He selected for his subject

THE PREVALENCE OF SPECIALISM AND WHO SHALL BE SPECIALISTS.

The tendency of the times was toward specialism in medicine. Specialism is desirable because it gives to the profession and the people the most intelligent consultants and the most skilled attendants the art of medicine can supply. He divided specialists into two kinds: the *true* and the *false*. The former he defined as one distinguished

for learning and skill in a given pursuit; the latter as one having merely a special occupation. He made the difference between these varieties very clear; for one reached the distinction of a specialist by reason of his training, experience, skill, and wisdom; whereas, the other was made a specialist by the possession of a diploma, a door-plate, and a "kit" of special instruments. The professional qualities of the true specialist he likened to a massive pyramid, the finished capstone of which constitutes the specialty. This pyramid of experience, learning, and skill is a stable edifice, a pillar of strength which cannot topple or reel. In the case of the pseudospecialist this pyramid of learning is inverted. There is no base of a knowledge of detail, of general information, of professional attainments. The structure has no foundation in fact. It began with the specialty, and its growth spreads as it ascends, overshadowing what is below, thus rendering it an unstable, top-heavy structure. The public has been improperly educated in the idea of specialism. In its eye all specialists stand upon the same footing, all possessing the needful requirements to give the best service. The profession has misled the public and is responsible for this lack of discrimination. Medical colleges should vigorously discourage the practice of recent graduates becoming specialists. Teachers should point out to them the error they are about to commit. Colleges should recognize only the real specialists. Reform in the present system of specialism must be accomplished through the instrumentality of medical colleges and societies, and when they take the matter properly in hand, the general profession and public will lend cordial support and the evil will vanish.

A paper, entitled

OVARIOTOMY IN THE AGED,

was read by DR. A. M. CARTLEDGE of Louisville, Ky. The patient upon whom the operation had been performed was born October 29, 1816. Eighteen months before the speaker saw her an abdominal enlargement was noticed, followed shortly after by pressure symptoms. Latterly the gastric and digestive disturbances from pressure had been very troublesome; emaciation and ovarian expression appreciable, but not marked. Examination revealed that the abdomen was well filled with a cystic growth, which was diagnosed as ovarian. Naturally the great age of the patient—past eighty years—made the decision as to operation a debatable one. However, an operation was deemed justifiable, urged, and consented to, and was performed May 12, 1897. The ovarian cyst originated from the right ovary, was multilocular, and, with fluid and omentum, weighed about forty pounds. The operation consumed fourteen minutes. The patient sat up fourteen days after the operation, and left the infirmary on the seventeenth day.

DR. H. H. GRANT of Louisville contributed a paper on OPERATIVE TREATMENT FOR ENLARGED PROSTATE, in which he drew the following conclusions: (1) That in malignant disease any operative step except palliative suprapubic drainage, even if based upon an error in diagnosis, is a serious mistake. (2) That in myomas, fibromas, and adenomas it is yet uncertain that good results will follow

castration, and, furthermore, that such conditions render enucleation by the Alexander method very difficult, and perhaps impracticable. Hence, when the interference resists catheterization and is not remedied by the permanent catheter, as suggested by Kern, suprapubic section and removal of the projecting portion, if possible, or the permanent fistula of McGuire, is the wisest course. (3) In conditions including stone in the bladder, suppuration in the gland, and the suspicion of intravesical growths, exploration by the suprapubic method offers the best insight into the nature of the lesion, as well as the most hopeful prospect of relief. (4) Inasmuch as castration is unsatisfactory, and is less acceptable to men under sixty-five years of age than later, it appears that the commonest form of enlargement, the chronic parenchymatous, to which the operation of Alexander is especially appropriate, will be best treated by this method, provided it appears practicable or necessary after section, which, if it bears out the promise of the present, will surely take a high place in the future, as it has almost no disadvantages aside from the seeming gravity of the step.

THIRD DAY—MORNING SESSION.

DR. RUFUS B. HALL of Cincinnati read a paper, entitled

IMPROVED TECHNIC IN OPERATION FOR INTRA-LIGAMENTOUS CYSTS.

After reviewing the literature of the subject, the Doctor said he believes the mortality from operation for intra-ligamentous cyst is much higher than the statistics would lead one to think. A large percentage of the deaths are due to hemorrhage, either on the operating-table or within a few hours after the patients are put to bed. He thought the operation proposed by him will save many lives, as it is practically bloodless. It is applicable to those cases in which the adhesions are very firm and the cyst cannot be easily stripped from the pelvic floor. The operation he proposes is as follows: First tap the cyst and empty it. Ligate the ovarian artery on the tumor side at the pelvic border; ligate the ovarian artery on the opposite side, outside the healthy ovary; divide the broad ligament. Divide the peritoneum above the top of the bladder and push the bladder down. Ligate the uterine artery on the healthy side. Cut across the cervix and clamp or ligate the uterine artery on the tumor side. The blood-supply is then cut off, and the patient has not lost a dram of blood. The capsule of the tumor may now be divided above the top of the bladder at a suitable point behind, and the tumor enucleated from below upward with a very much greater ease than from above downward and with corresponding safety to the ureters, rectum, and iliac vessels. Close the peritoneum over the pelvic floor with a running suture of catgut. This method brings every part of the field of operation into view. The ureter may be seen, recognized and pushed aside. The adhesions are separated along the line of cleavage instead of against it as in the old method.

SYMPHYSEOTOMY AS COMPARED WITH OTHER OBSTETRIC OPERATIONS.

This paper was read by DR. GEORGE J. ENGLEMAN of Boston. The author illustrated his remarks by diagrammatic

sketches. Symphyseotomy is not as attractive an operation as is Cæsarean section or the Porro operation, yet it is very successful as compared with the results of the former procedure. It is a successful all-round operation for the city and country. The mortality statistics of the different operative procedures were given and compared. There has been no trouble in getting union of the pubic bone after symphyseotomy. Quite a number of women have been delivered by a second symphyseotomy. There is no trouble in the locomotion of women so operated upon. A number of cases are on record of normal labors which have followed symphyseotomy. The first symphyseotomy in this country was performed by Dr. Williams of Dennison, Texas. Dr. Englemann showed what had been accomplished by the operation, and said that surgeons must be guided in a measure by the quoted results.

PLASTER OF PARIS AS A UNIVERSAL FRACTURE DRESSING,

was the title of a paper by DR. JOHN B. S. DAVIS of Birmingham, Ala. The author finds that less than 3 per cent. of the physicians who use plaster of Paris as a primary dressing cut the plaster at the time of applying it. The object of incising the plaster of Paris is to allow it to yield and at the same time fit the contour of the limb. For fractures of the shaft of the humerus, as elsewhere, he believes plaster of Paris is the best dressing.

The following officers were elected for the ensuing year: President, Dr. Richard Douglas of Nashville, Tenn.; vice-presidents, Drs. H. H. Mudd of St. Louis, and James A. Goggans of Alexander City, Ala.; secretary, Dr. W. E. B. Davis, Birmingham, Ala.; treasurer, Dr. A. M. Cartledge, Louisville, Ky.

The next meeting of the Association will be held at Memphis, Tenn., the second Tuesday of November, 1898.

REVIEWS.

INTERNATIONAL CLINICS. A quarterly of clinical lectures. Edited by JUDSON DALAND, M.D., J. MITCHELL BRUCE, M.D., F.R.C.P., and DAVID W. FINDLAY, M.D., F.R.C.P. Volume II., seventh series. Philadelphia: J. B. Lippincott Co., 1897.

THE present volume contains contributions on treatment, medicine, neurology, surgery, gynecology and obstetrics, ophthalmology, laryngology, and dermatology. The selection of topics is good, and the lecturers by well-known clinicians. There is a great temptation in publishing a series of lectures to insert inferior productions. Such has not been the case with the editors of "International Clinics," who, in each succeeding volume, prove the value of carefully chosen and instructive lectures. These lectures must be particularly valuable to those to whom attendance at clinics is impossible. This volume is splendidly made and handsomely illustrated.

URINALYSIS: A GUIDE FOR THE BUSY PRACTITIONER. By HEINRICH STERN, Ph.S., M.D. New York: E. R. Pelton, 1897.

THIS little volume will prove very useful to the physicians in general practice, as it covers the ground of uri-

nalysis in a clear, concise, and practical manner, and avoids all unnecessary details and refinements of methods. Exception must be taken to the following statement, however: "Pathogenic bacteria, so-called, are said to occur in the urine in two varieties—as micrococci and bacilli. A number of micrococci and bacilli do certainly occur in the urine. In the estimation of the writer, however, they are not pathogenic, nor does their presence aid and establish a trustworthy or rational urinary diagnosis." With this exception the book is well up to date. Every alternate page is left blank for notes, and several wood-cuts of the various crystals and casts illustrate the text.

THERAPEUTIC HINTS.

A Local Application for Tuberculous Laryngitis.—First, anesthetize the larynx by means of a 10-per-cent. solution of cocaine, and then, beginning with the weaker solution, apply the following:

R	Ac. carbolic	. . .	m.xv — lxxx
	Ac. lactic	. . .	3 ss — iv.
	Glycerini pur.	. . .	3 v.

For Chilblain.—

R	Calcii chlorid.	. . .	gr. i
	Ungt. paraffin	. . .	3 i.

M. Sig. Apply with gentle friction for five minutes at bedtime, and then cover with a bandage.

Diuretin in Acute Nephritis.—This drug is valued by STEINER for its efficiency in causing diaphoresis and lessening the dropsical symptoms. It may be prescribed as follows:

R	Diuretin	. . .	gr. lxxx
	Syr. simp.	. . .	3 v
	Aq.	. . .	3 v.

M. Sig. One tablespoonful every two hours.

For the Relief of Painful Affections of the Bladder, Prostate, or Urethra the following have proven efficacious:

R	Morphin hydrochlor.	. . .	gr. ii
	Atropin sulph.	. . .	gr. 1/4
	Aq. dest.	. . .	3 iii.

M. Sig. From 30 to 80 drops should be injected into the rectum. In addition, should fever be present, the following is advised:

R	Cocain	. . .	gr. xiv
	Antipyrin	. . .	3 iiss
	Sod. salicyl. } aa.	. . .	3 iiss
	Aq. dest.	. . .	3 iii.

M. Sig. Inject 80 drops per rectum three times daily.

For Pelvic Peritonitis and Peri-uterine Exudate.—

R	Iodol.	. . .	3 iss
	Ext. glycyrrhizæ	. . .	q. s.

M. Ft. pil. No. LX. Sig. One pill four times daily during four days, and then gradually increase until 10 pills daily are taken.

Within five days there will be a decrease of pain, fever, and abdominal tension, and the exudate will be quickly resorbed.

No. 23.

ORIGINAL ARTICLES.

MAJOR LESIONS OF THE GENITAL TRACT IN THE PUERPERY.¹

By S. MARX, M.D.,
OF NEW YORK;

ASSISTANT SURGEON TO THE NEW YORK MATERNITY HOSPITAL.

SOME years ago I observed two cases of uterine rupture occurring during labor, both of which terminated fatally. In the first the rupture took place at the site of a large diphtheritic ulcer; the other was subsequent to a very difficult forceps extraction. During the past two years I have seen a remarkable number of complicated obstetric or puerperal conditions from which some instructive lessons may be drawn.

Grave lesions of the genital tract are not common. When they do occur, it seems impossible in most instances not to associate them with errors in technic on the part of the physician in charge. Spontaneous ruptures of the uterus are very rare, but in them, as a rule, there has been so marked a degeneration of the uterine tissues preceding the accident, from either a fatty or cancerous process, as to stamp them as eminently pathologic. In this paper normal uteri and normal pre-existing states are exclusively considered. The most difficult problem in midwifery, and one requiring the most discriminating judgment is to determine clearly and positively the indications for interference or non-interference. The former is too frequently postponed to such a time as to place elective and successful operations out of the question. When well-defined indications are present all hesitancy and fear should be banished and the necessary procedure instituted promptly and "with brains."

It is seldom that active interference is demanded on behalf of the child; it is the mother who requires our constant attention. When a dangerous condition is imminent, the signals are always present, and display themselves in aberrations of pulse and temperature. In extreme cases there is an acute, constant pain in the abdomen, not the alternating relaxing and contracting phenomena of labor, but a tetanic contraction which is so characteristic of one form of uterine exhaustion or irritability. It is a constant, dull, aching, boring pain. In still more severe cases the presence of the contraction ring may be noted, with a corresponding thinning of the en-

tire lower uterine segment, extending at times as high as the umbilicus. Again, by abdominal palpation the outlines of the child may be mapped out with alarming distinctness. These, in short, are the real urgent premonitory signs of true uterine exhaustion which, when exaggerated, become pathognomonic of uterine rupture. When a rise in temperature with a corresponding pulse-rate is present, or where the pulse becomes progressively more rapid, especially between the pains, the indications are to terminate the labor at once, always remembering not to endanger the integrity of the maternal parts by the interference.

If the os is not sufficiently dilated to permit of the application of forceps, manual dilation or the Dührssen operation should be performed. The field for the latter procedure is extremely limited, but when called for in urgent cases it can be rapidly and safely done. When rupture is threatened or has already occurred, there is certainly a distinct indication for its use. But it must be remembered, to make the operation a safe one, that the incisions should be complete from the cervicovaginal junction downward, neither more nor less, in order to fully dilate the os by artificial means.

While I am radically opposed in most cases to the use of the forceps when the head is above the pelvic brim (the so-called high-forceps operation), I see an indication in such threatened or already present uterine rupture for instrumental termination of the labor in preference to version. Under all other conditions and circumstances I prefer, in these cases, the latter operation. The fear of causing a rupture or increasing the extent of the tear is my only excuse for making these the exception. In the large number of the more exaggerated cases we can and do expect that the child has already been suffocated, and for this reason the perforator is the instrument of choice. When an impacted shoulder is a complication, it would seem preferable to at once detruncate the head regardless of whether the child is dead or alive; since here, by performing a forced version, the mother is subjected to the most awful risk of either rupture or increasing the lesion already present. Under these conditions the chances are most decidedly against the birth of a living child. Here again, in weighing the chances between a forced version of an impacted, living baby and a Cæsarean section, it would appear that the chances for mother and

¹ Read before the Harlem Medical Association.

child will be best conserved by the latter operation. Where the child has wholly or in great part escaped into the peritoneal cavity, I think we are fully justified in at once subjecting the woman to a celiotomy, so as to not only remove the fetus, but to treat the uterine wound by suture, or in extensive lesions to extirpate the organ *lege artis*.

The first case presented is a typical example of uterine rupture in a woman pregnant for the second time and in labor forty-eight hours:

CASE I.—Stout, healthy woman, whose first labor had been short and normal. The labor began with good, hard pains, which continued twenty-four hours. In spite of an os fully dilated, the head rested quietly at the brim, apparently in a normal position. This patient was first seen by a physician who, while recognizing the fact that the woman could not deliver herself, advised delay, and this in the face of a rapid pulse and extreme suffering. Within another twenty-four hours she finally worried a dead baby into the world. At this time her temperature was 103° F.; pulse, 124; abdomen enormously distended. The placenta came away spontaneously. Shock was profound, and the condition went from bad to worse. She developed the symptoms of rapid and general sepsis, and within thirty-six hours all the evidences of an acute general peritonitis were present, with severe, continuous, and uncontrollable vomiting. When I saw the patient a few hours later she was completely collapsed; pulse, 150; temperature, 104° F.; intensely distended peritonitic abdomen. The fundus of the uterus could not be felt, and there was a foul-smelling discharge from the vagina. The history of the case made me at once suspect uterine rupture, and upon vaginal examination two fingers could be readily passed posteriorly through the inferior uterine segment and into the peritoneal cavity. The condition was apparently due to prolonged pressure by the head, subsequent sloughing, and final rupture. Active stimulation was the only treatment advised, and, as might be expected, the patient died within twelve hours.

The patient, the history of whose case has just been told, evidently possessed a normal pelvis; for she had previously given birth to a living child. The tardy labors were probably due to a malposition of the head, very likely an occipitoposterior position. There is very little doubt, had the physicians acted when premonitory symptoms presented themselves and delivered her at once, the case would probably have terminated differently; and yet, in spite of classic symptoms (temperature, rapid pulse, and agonizing pain) of grave exhaustion, this woman was left unaided, the physicians thinking that the physical disturbances were but momentary, and that as she had delivered herself once normally, she could do so again.

The next case is another example of uterine rupture, due to the application of the forceps when the

head was above the brim, the head being in a vicious position.

CASE II.—Mrs. M., whose previous labors had all been normal and of average duration. This, her fifth labor, continued longer than the other four together. The waters were early discharged, and the os slowly dilated under the influence of slow nagging pains. After many hours of fruitless effort, seeing that the labor would have to be terminated by artificial means, the physician in charge, while fully recognizing that the head was deflected and above the brim (really an ear presentation since this was the only part of the head to be readily made out), applied the forceps under deep chloroform narcosis. No sooner had the necessarily powerful traction been instituted, than the anesthetizer reported a rapid and flickering pulse. This was followed by instant collapse of the patient, associated with a very marked and rapidly increasing tympany of the abdomen. The child was born alive; placenta and membranes expressed. The collapse continued forty-eight hours, and the treatment, which consisted of saline injections and the administration of heart-tonics, was instituted under the impression that the case was one of heart failure from chloroform. About this time I was asked to see the patient and found the condition a desperate one. Shock profound; pulse rapid and hardly perceptible; temperature, 103° F.; foul lochia, and a very intense tympany of the abdomen. Here again the history was so suggestive that a presumptive diagnosis was made before examination. Exploration with the hand revealed a complete uterine rupture, a clean tear of the lower, right, uterine segment, extending into the corresponding broad ligament. The entire vagina and vulva were emphysematous. The uterus was washed with a physiologic salt-solution, preceded by the guarded use of a large blunt curette, avoiding as much as possible the neighborhood of the lesion. The entire rupture was tamponed with iodoform gauze, and active hypodermic stimulation advised. The patient died three hours after my visit.

This case is of great interest, and the lesson to be learned thereby of the greatest value. Was the physician in attendance justified in the use of the forceps in this case? It has been my contention that the application of forceps above the brim is very, very seldom justifiable. When the head fails to engage, there is always reason to suspect either a relative or absolute pelvic contraction, or what is more frequent, a malposition of the vertex, if this presents. For this reason it would seem advisable to perform version at once, since a malposition of the vertex can rarely be permanently rectified, and further it is easier to deliver the after-coming head following version, through a contracted pelvis than to complete delivery by the use of forceps when the opposite presentation obtains. Manual rectification of the head has been tried by many, especially in occipitoposterior positions of the vertex, and found wanting.

I have tried it on many occasions, and have almost always failed; because the causes originally producing the faulty position will, in the greater number of cases, reproduce it even after rectification has been complete. Again, it is my contention that when once the hand is in the uterus, attempting to correct a malposition, it is but one step further to do a version and at once terminate the labor, thereby performing what is a certain and positive procedure instead of one that is at best purely experimental and likely to fail.

In the case in question a pelvic contraction did not exist; as has been stated the pains were slow and nagging; there was early discharge of the waters, and a disinclination of the head to engage. I have always associated this symptom complex with, and very characteristic of, malpositions of the vertex, especially occipitoposterior positions, in the absence of a pelvic deformity, and in not a few cases a diagnosis of a posterior occiput has been made, even before examining the patient. In the face of these symptoms, the hand was introduced and the position of the head determined under chloroform narcosis. Since these symptoms were present, it was the duty of the attending physician by exploration to find out why the head failed to engage. He should have reached a positive conclusion as to the conditions present before applying the forceps. This is a "never to be forgotten rule." This woman would have stood a fair chance of recovery had a manual rectification of the head been accomplished, or what would have been still better, an internal version.

CASE III.—Multipara, whose previous labor had been normal. The pains began at 5 A.M., with a typical transverse presentation, one arm appearing in the vagina. Repeated, ineffectual attempts at version were made until about 3 P.M. the same day, without anesthetic and without result. Another attempt was made under chloroform by a different physician, who, upon realizing the gravity of the case, refused to persist, and I was asked to see the patient and found that two hands had already been delivered, and that the child was bent on itself, with the head and both feet on a level near the fundus. The child, of course, was dead. The uterus was moderately tetanic and a faint contraction ring evident; profuse hemorrhage; pulse, 80; temperature, apparently normal. Decapitation, on account of the position of fetus, was utterly out of the question, and as the fetus was not impacted, it was thought advisable to attempt version under deep chloroform narcosis. This was easily accomplished and the child delivered. At this time the family physician volunteered the statement that he had early that morning discovered a strange cavity with whose anatomy he was not familiar. This information came after I had completed the labor and found the entire vagina pulled away from the uterus through the cul-de-sac, and a corresponding hole in

the uterus at the cervicovaginal junction. This large hole allowed the entire hand to pass readily into the peritoneal cavity. After delivery the pulse was normal, and there were no symptoms of collapse. The uterus and peritoneal cavity were washed out with a physiologic salt-solution; the lower peritoneal cavity was tamponed with sterilized gauze. The patient was put to bed with good pulse, no hemorrhage, and in very good condition. On the sixth day, symptoms of general peritonitis appeared. The gauze was removed under chloroform, and the whole peritoneal cavity was found to be shut off by a broad area of fresh adhesions. A simple drain was introduced. The patient developed a well-marked general peritonitis, and succumbed within twenty-four hours.

This case requires no comment. But a word as to the method employed in delivering the patient: Because of the presence of a dead child, the treatment would seem to have been paradoxical. Decapitation was out of the question. Total embryotomy would have been such a prolonged operation that it seems to me that I was justified in performing a version. In the event of failure, on account of impaction of the fetus, Cesarean section would undoubtedly have been the operation indicated. Another fact worthy of mention is the normal pulse and temperature, and the absence of shock in the presence of so grave a lesion, which continued up to the time of the occurrence of the general peritonitis.

CASE IV.—Multipara; previous labors normal; two weeks before full term. She had not felt life during the five previous days, and she informed her physicians that her baby was probably dead. Os was rapidly and fully dilated; membranes were ruptured; waters badly colored and offensive escaped; head presented, but did not engage. Forceps were applied, traction made, and the physician found himself, head grasped by the forceps, on the floor. The head had parted from the trunk. The arms were pulled down, traction made, and they in turn were torn off. The sharp hook was then introduced deeply into the neck and chest, but as soon as traction was made it pulled through the fetal tissues and failed to deliver. When I saw the patient, at this time, she had been under chloroform about two and one-half hours. She looked very bad, and presented a rapid respiration and a rapid, flickering pulse. Having no instruments with me, version was readily accomplished, and traction on both legs combined with firm external pressure, delivered what remained of the fetus, but only after pulling off one of the legs. The placenta and membranes were removed. Examination revealed a tear of the vagina on the right side, extending from the cervix to the right pelvic wall through the broad ligament and into the peritoneal cavity. This evidently occurred when the sharp hook slipped, tearing not alone the fetal structures but the maternal tissues as well. The cavity was drained by means of gauze, and in spite of stimulation, the patient died within two hours.

CASE V.—Multipara; previous labors all very difficult; present labor very tedious, lasting nearly forty-eight hours; child macerated, pieces of skin being discharged. Head above the brim in the L. O. A. position. The physicians in charge did a version to terminate the labor. Traction was made by grasping both legs, which promptly parted from the trunk. At this stage I was asked to see the case. The pelvis was very small; the estimated true conjugate diameter could hardly have been more than two and one-half inches. An irregular mass presented at the pelvic inlet which evidently was the lower part of the abdomen, the pelvis and lower extremities having been torn away. On examination a piece of bony structure was found to be deeply imbedded in the uterine wall. The patient collapsed from the prolonged interference and chloroform narcosis. Evisceration and embryotomy were undertaken, the last of the fetal parts being removed only after one and one-half hours of very trying work. During one of the numerous attempts to dismember the child, a hole was torn in the posterior vaginal wall. The uterus and vagina were tamponed with sterilized towels. Regardless of stimulation the patient died from exhaustion within forty hours.

In the two cases, whose histories have just been related, forceps were applied in one, and in the other a version was performed, both measures being instituted in the presence of a dead and macerated fetus. Would not better results have been obtained had the heads been perforated at once? In the first case the head was torn from the body during an attempt to deliver; but had the skull been opened, thus diminishing its circumferences, less resistance would have been offered and the chances are that, with the cranioclast, delivery would not have been so complicated. In the second case, version should not have been done, since nothing could be gained by this operation; for there was present a dead baby and a very much contracted pelvis, a pelvis offering almost an absolute indication for Cæsarean section. Perforation is a very simple operation, and should, in my opinion, always be the operation of election in the presence of a dead child. It will certainly prove safer than a difficult forceps delivery or a forced version, with their attendant dangers to the mother. The plea may be offered by many that it is sometimes impossible, by auscultation, to certify as to the life or death of the child, and as embryotomy on the living child is considered by many to be unnecessary and reprehensible, it might hold good. But, to be certain, it should be remembered that the introduction of the hand into the uterus and direct palpation the cord will furnish the necessary evidence. Again, in the second case, when it was found that both legs were torn off, the physicians should not have persisted in their efforts; for a method occasionally used by the writer might have proved of material assistance

in delivering the rest of the baby. In cases of impacted breech with a dead baby, where, as it sometimes occurs, it is impossible to grasp a member to further delivery, I have employed the cranioclast, introduced into the rectum, taking a good bite of the sacrum and lower spinal column, and preceding the introduction of the instrument by enlarging the anal orifice by means of liberal incisions with scissors. In this way a good hold on the fetal body is obtained, which rarely fails to be efficacious.

CASE VI.—Primipara, with a normal pelvis, in labor twenty-four hours. When the first stage was completed, the forceps was applied, followed by delivery of a living child. I was requested (four hours *post-partum*) to sew up an ordinary perineal laceration. In trying to obtain a history of the case, the attending physician gave rather meager and confusing data. To my dismay, on examination, although the condition of the patient was excellent, there was a complete tear of the vagina and rectum extending as far as the eye could see and the finger reach. Having nothing better with me, I employed both hands as a speculum in order to separate the walls of this great cavity. There appeared to be gut at the bottom of Douglas' cul-de-sac, prolapsing slightly into the vagina. The parts were thoroughly washed with a 1-10,000 bichlorid solution, and being unable to apply sutures at this depth, the upper part of the vagina was snugly tamponed with gauze to protect the gut. The vagina and rectum were sutured with catgut, and the anus and perineum with silk-worm gut. The gauze was removed on the fourth day, and the stitches on the tenth. At this time union was almost perfect, and the patient recovered after a practically normal convalescence.

What caused this terrible lesion I am not in a position to state positively. I could glean nothing from the family physician, who evidently knew more than he wished to tell. It is safe to assume that, the patient being a primipara with a normal pelvis, the presenting head would engage; and, again, that the head was in a normal anterior position was positively proven by the presence of a well-marked *caput* situated well back over the parietal bone. Both these statements fairly show that forceps was not applied to the head above the brim. By carefully weighing all the factors in the case, it can at least be safely assumed that the lacerations were either due to a forcible and unwarranted effort in the introduction of one of the blades, or else to a slipping of the instrument from misdirected traction. As to the first presumptive cause, direct perforation by one or the other blade, the lesion would appear to have been too extensive to be thus explained; for under such circumstances patients have presented a simple, almost clean-cut wound, situated, in the majority, high up in the cul-de-sac, and showing exactly where the perforation from the blade occurred. It is safe to

state that when much force is required to introduce one or the other blades of the forceps, something is radically wrong, providing the attempt to apply this instrument is correctly made. But occasionally a case is seen in which it is impossible to introduce the first blade except by means of brutal efforts. Such force should not be persisted in, and in the several cases coming under the observation of the writer he considers it in order and perfectly legitimate to reverse the introduction of the blades, applying the right blade first and then the left. These inversed manipulations (the application of the left blade after the right one) give no further trouble, and the forceps not only hold, but delivery is readily accomplished. The locking of the blades is easily performed by either applying the left blade underneath the right or else by applying it above and gently crossing the handles after both blades are in place. The probable cause of the laceration in the instance under consideration most likely was the slipping of the instrument from faulty axis traction. It is a very common experience, when the family physician undertakes to deliver such a case, to note that in the majority of such operations, no matter where the head is located, traction is almost invariably made too far forward. This is a very common error. In teaching post-graduates the use and application of the forceps, the writer has seldom met the man who does not make direct forward traction, even though the head be above the brim. This faulty manipulation always predisposes to slipping of the blades, and the operator may consider himself lucky if serious lesions do not result. I hold that traction can never be made too far backward, for if the head does not follow such traction, the direction of the blades may always be gradually modified so as to bring the traction a little further forward each time. If the attending physician is at a loss to know exactly in what direction to institute the traction, apply the blades, without chloroform, and let the woman have several pains, then note the direction which Nature causes the handles of the instrument to assume. This proves the proper axis of traction, and can be at once and safely followed. The ideal forceps operation to-day is performed with the typical axis traction instrument. The direction of correct traction is indicated by the handles of this almost intelligent instrument. But the objections to its use are cost, and, what is more important, in inexpert hands it is as dangerous as it is safe and strength-saving in those of the expert. Another frequent cause of slipping of the instrument is the presence of a large head or the grasping of an average-sized one by its longest diameter. When one pair of forceps slips it is folly to repeatedly attempt the application of different varieties of the

instrument, for when one forceps holds it is safe to assume that all will. It is only necessary to apply the blades to another diameter of the fetal skull, and when the forceps still continues to slip something is radically wrong, and other measures are certainly indicated.

THE THYROID-GLAND TREATMENT OF CRETINISM, WITH REPORT OF A CASE.¹

By SAMUEL H. FRIEND, M.D.,
OF MILWAUKEE, WIS.

CRETINISM, myxedema, and other diseases allied to abnormalities of the thyroid gland have received such carefully detailed attention since the results of the work of Gull, Schiff, Ord, Reverdin, Kocher, Bircher, and Horsley were made known, that the time seems fitting to draw absolute conclusions as to the physiologic function of the gland and to interpret the far-reaching physical effects caused by its disease or absence, and, at the same time, to indicate the range of the specific therapeutic application of thyroid treatment. The following report of a case of cretinism I trust may lend assistance in the interpretation of this curious disease:

H. G., female, aged fourteen years, was admitted to the Milwaukee County Hospital and came under my care during November, 1893.² She was the second youngest of ten children. The moral as well as the physical family history was extremely bad. One sister of the patient had died at the age of twenty-five years from pulmonary tuberculosis.

The child presented the usual picture of an extreme type of cretinism, there being almost entire absence of special functional development. The anterior fontanel was widely open, and there was curvature of the spine. The bones of the upper and lower extremities were enlarged and thickened at their epiphyseal ends. Knee-jerk, though much diminished, was present. The prick of a pin failed to elicit sensation of pain. Internal strabismus was pronounced, but the pupils reacted equally and normally to light. Attraction for color was the only indication that sight was present. The voice was harsh and guttural, though at times high-pitched. The presence of the sense of hearing could not be absolutely defined, and the same was true of that of smell. Taste was present, as indicated by the refusal to partake of certain foods. The power of speech was absent, and the patient was unable to sit or stand erect. Arm and leg movements were very limited in extent.

The bridge of the nose was flattened, the soft parts being broad and spreading. The palpebral fissures were slit-like, the chin receded, and the upper lip protruded. Measurements taken at this time were as follows: Glabella to occipital protuberance, 29 cm.; from center of one external auditory meatus, over the vortex, to the opposite one, 31.5 cm.;

¹ Read at a meeting of the Wisconsin State Medical Society.

² I am indebted to Miss Louise R. King, Superintendent of the Children's Hospital, for many important details of the clinical history.

greatest circumference of head, 50.7 cm.; circumference of neck, 27.5 cm.; of thorax at nipple line, 54 cm.; of abdomen through umbilicus, 52 cm.

The hair of the head was very thin, coarse in quality, and of a dirty yellow color. There was no hair on the pubes. The skin over the entire body was of a chalky-white color, very dry, and that covering the hands and feet was puffed and shining. The tongue appeared to be too large for the mouth, and was almost constantly visible. There was an uninterrupted dribbling of saliva. The roof of the mouth was deeply arched, and the twelve teeth present were discolored and worn down to the level of the gums. The patient's bowels moved once daily, the feces being formed and of a normal color. The kidneys acted freely, but the urine was passed involuntarily, and none could be obtained for examination.

During April, 1894, the administration of thyroid-gland extract was begun, and immediately a marked change in the condition of the patient was noticeable. Her intelligence improved, she became more observant, the anterior fontanel gradually began to close, the voice changed, and there was a decrease of the puffiness about the eyes and of the forehead. One day, six weeks later, I was summoned to the hospital by the resident physician, who reported that the child was dying. I found her temperature to be 104° F., pulse 160, and respirations from 40 to 50 per minute. As no symptoms indicative of any special complication were present, and as the thyroid extract had been given in 5-grain doses three times a day, I concluded she was suffering from thyroidism, and at once ordered the administration of the drug to be discontinued. A few days later she was removed from the hospital by her mother and taken home—two rooms in an indescribably filthy condition, which the woman occupied in common with an adult son and daughter and three negroes.

The child's temperature, pulse, and respiration continued abnormally high during about three weeks, and on July 13th I had her removed to the Children's Hospital. During the ten days subsequent to her admission her condition remained about the same, and then her temperature gradually subsided. The only treatment prescribed until August 14th was a warm bath every morning before breakfast, the administration of cod-liver oil thrice daily, and a full diet. Under this regimen she gained three pounds in weight, registering thirty pounds on the last-named date. At times her mental condition appeared to have improved. On August 14th, her temperature then being 98.2° F., and pulse 108, the former treatment was resumed, 2 grains of the thyroid extract divided into three doses being given daily. The dose was gradually increased, with remissions of the treatment during seven days every fourth week, until on October 22d she was taking 2½ grains of the extract three times a day. Her weight at this time varied between thirty and thirty-two pounds. From August 14th to October 15th her temperature varied between 98.2° and 100.4° F., and her pulse between 102 and 114. During this period she was very restless and cried a great deal, but her general

improvement was marked. Her voice was less shrill, memory and sense of association appeared to improve, her hair became of a finer quality, the puffiness of the skin disappeared, and the anterior fontanel almost closed. One of the most striking changes observed was in the shape of the forehead, for, whereas formerly it had terminated at a slightly obtuse angle at the junction of the skin and scalp, it now assumed a perfectly rounded form. This, of course, was due to the closure of the fontanel.

On October 4th the first signs of menstruation were noticed, good-sized clots being passed, and this continued during four days. As the patient still cried almost incessantly, I had her teeth extracted. They apparently belonged to the first dentition, although on account of their length (from 1 to 1.5 cm.) they resembled the second growth. Two weeks later, seven new teeth made their appearance almost simultaneously in the upper jaw and nine in the lower. During this time the patient was very nervous and fretful. From October 28th until November 19th the thyroid treatment was discontinued and cod-liver oil substituted. Her weight during this period increased each week, and on the last-mentioned date she weighed 31½ pounds. She menstruated again on November 8th, the flow continuing until the 14th. On the 19th she began taking 1 grain of the thyroid extract three times a day, and on the 22d the dose was increased to 1½ grains; but as the bowels moved too freely on the 24th its administration was stopped.

From August 14th to November 30th the patient had taken, in all, 431 grains of the drug. From October 22d to November 30th the improved physical condition was marked by entire closure of the anterior fontanel, an increased quantity and finer grade of hair, an absence of all puffiness of the skin, absence of salivary dribbling and protrusion of the tongue, the appearance of sixteen teeth, and of menstrual flow, development of stronger imitative faculties, and by attempts at forming distinct sounds. Mental association and accommodation remained in an infantile stage of development. Urine continued to be passed involuntarily, but after considerable difficulty an ounce of the fluid was secured and analyzed. It was neutral in reaction and indicated nothing worthy of note. A count of the blood-corpuscles at this time revealed 3,500,000 of the red cells and a large number of leucocytes to the millimeter.

On November 25th accurate measurements were again made, and resulted as follows: Glabella to occiput, 35.5 cm.; from the center of one auditory meatus to the other, 32 cm.; greatest circumference of head, 52.5 cm.; circumference of neck, 25 cm.; of thorax at nipple line, 53 cm.; of abdomen at level of umbilicus, 54 cm.; length of body, 84 cm. A comparative study of these figures and those obtained before treatment was begun indicates an increase in the measurements of the head, abdomen, and body-length, and a decrease in those of the neck and thorax.

During December, 1894, and up to August 1, 1895,

the following observations were made: Eight hundred and ninety-four grains of thyroid extract was taken, an average of less than four grains daily, and every fourth week its administration was interrupted for a period of seven days. A teaspoonful of cod-liver oil was given twice daily during all this time, and a plunge-bath, lasting ten seconds, in water at 70° F., each morning before breakfast. I had observed that the patient had made a distinct mental gain whenever the administration of the thyroid extract was pushed to its physiologic limit, and, therefore, during the months of May and July I increased the doses gradually until she was taking from 3½ to 4 grains three times a day. Six ounces of milk was given every two hours. This increase was maintained during twelve days in May and ten days in July. During these two months, and also during June, sys-

marked progressive improvement, the bones appearing firmer and the teeth large and fully developed.

The mental change during the first of these months was hardly perceptible, although the patient was placed in the same room with other children in order to stimulate her imitative faculties. During the latter part of the period, however, the improvement was marked, probably as a result of the medication and gymnastic treatment. She became more observant and at times indicated that hearing and association and projection were more acute, although this improvement was not progressive. More marked was the development of associated action, as, through observation of the other children she learned to grasp a chair and stand by it, and to sit up in bed. The arms and hands became more useful members, and while lying in bed she developed the habit of lifting

FIG. 1.

Cretinism. Child aged fourteen years. Before treatment was begun.

tematic extension of the entire body was made, lasting five minutes at first, and, finally, increasing the time to one hour, combined with manipulation of the joints. Her weight remained practically at thirty pounds, although it occasionally varied from half a pound to a pound each way. Her highest temperature at any time was 100° F., her pulse ranged between 74 and 112, and her respirations between 20 and 30. The blood count was the same as before. Her physical condition improved in every way. During December she had an attack of diarrhea, which lasted two days, but the appetite and digestive processes were good throughout the entire period. She menstruated in December, February, April, and May, the flow being scanty but continuing three days during the first two months named and two days during the latter. The osseous system showed a

one leg. The only abnormal nervous manifestation observed during the latter months was the sudden occurrence of paroxysms of hysteria during the day or night, in the latter case the child awakening from a sound sleep and laughing, crying, and thrashing about the bed. These attacks lasted from fifteen minutes to an hour, and occurred at irregular intervals, at times every third or fourth day, and again every day during three or four days. They continued during May, June, and July, and then all at once ceased. The administration or withholding of the thyroid extract had no effect upon them. On July 19, 1895, the patient had gained 4.5 cm. in height since the preceding November.

The third period of treatment dated from August 1, 1895, to January 22, 1896. During this time she was given 879 grains of thyroid extract, an average

of 5 grains per day. The administration of cod-liver oil morning and afternoon was continued, as was the daily bath. Massage and gymnastic exercises were not persisted in as she became too restless under the treatment. She was placed on the floor of the ward so that she might play with the other children, this being the only change in her environment. Her weight continued to vary, on August 5th being 29 pounds, and on December 30th 37½ pounds. Her pulse ranged between 80 and 120, and temperature between 97° and 104.2° F. The blood count was the same as before.

Nothing worthy of note was observed during this period except a very slow improvement mentally and a much more marked one physically. During the evening of January 20th, her temperature suddenly rose to 104° F., her pulse to 160, and respiration

pubic symphysis demonstrated the presence of underlying adipose tissue of the thickness of 1 cm. Upon removing the sternum the thymus gland was found. It was attached to the subclavian artery on the right side, to the tissues surrounding the aorta on the left side, and in the median line to the deep fascia covering the trachea. It measured 10.5 cm. in length and 9.5 cm. in width, the left lobe being 1.8 cm. thick, the right lobe 2.3 cm., and the superior and inferior lobe each .5 cm. It weighed 64 grains. Small glands studded the entire pleura. The organ covered the anterior pleura from the suprasternal notch almost to the ensiform cartilage, the smaller glands being of the average size of a dime.

Nothing abnormal was found in the pericardial sac or heart. There were a few hard nodules, varying in size from a millet-seed to a kernel of wheat, in the

FIG. 2.

Cretinism. After eight-months' treatment.

became so short and quick that it was only with difficulty they could be counted. At this time she was taking 6 grains of thyroid extract daily. Medication was immediately stopped, but her condition remained the same, with one remission of temperature and pulse-rate, during two days, when, on January 22d, at one o'clock in the afternoon, she died.

A *post-mortem* examination was made four hours later, of which the following is a summary: Body fairly well nourished, presenting nothing of special interest externally. Weight, 35 pounds. Height, 105 cm. Cadaveric discoloration of the neck and back. A careful dissection around the trachea failed to reveal the thyroid gland. On the left side of the cricoid cartilage was found a pear-shaped gland, 2.5 cm. in length, 1.2 cm. thick, and 2 cm. wide, which, on section, presented the appearance of an enlarged lymph-gland. An incision from the chin to the

apices and bases of the lungs; otherwise these organs were normal. The spleen measured 8 cm. in length, 4.5 cm. in width, and 2 cm. in thickness, and was perfectly normal in color and structure. The pancreas, stomach, intestines, and liver were normal, the latter organ measuring 18 cm. transversely, 13 cm. anteroposteriorly, and 5 cm. from above downward. The suprarenal capsules showed no abnormalities. The left kidney was normal. It measured 9 cm. in length, 5 cm. in width, and 4 cm. in thickness. It was soft, and the capsule was non-adherent. The right kidney was found lying in the space made by the curvature of the spine, which began at the seventh dorsal vertebra and carried the entire structure to the right (see Fig. 3) so that the distance between the twelfth dorsal vertebra and tenth rib on the right side was 2.5 cm., that between the end of the eleventh rib and middle of the crest of the ilium

being 7 cm. on the right side and 3 cm. on the left. The kidney was in contact with the crest of the ilium, and conformed to the shape of the cavity, being 10 cm. long, 5 cm. wide, and 4.5 cm. thick.

The bladder presented an interesting pathologic condition. Its walls were much thickened, the anterior wall being 1 cm. in thickness and the posterior .5 cm. The capacity of the cavity was one-half ounce. Embedded in the wall above the ureteral openings was a calculus about the size of a dime. The uterus was of infantile size. The ovaries were small, but contained normal ovarian tissue, and in one of them was found an ovum.

Upon opening the calvarium the dura was found to be thickened and firmly adherent throughout its entire extent to the bone. Extending from 1 to 1.5 cm. on each side of the longitudinal sinus was a deep-

sules, as well as of other tissues throughout the body, merely showed an excess of fibroid growth in all.

A study of this case strikingly illustrates the place occupied by the thyroid gland in the physiology of man, as well as the therapeutic application and limitation of its extract. Structurally, there was present in this patient, an increased thickness of the skin, softening and inhibited growth of the bones, with a compensatory enlargement after coordination was produced, and dwarfism.

As a result of the knowledge obtained by the study of the cases reported, it is evident that structural changes and their cause may be classified under the following headings:

FIG. 3.

Showing curvature of spine in cretin aged fourteen years (soft tissues eaten away by mice).

red discoloration of the membrane from which bloody fluid exuded. Nothing of interest was observed in connection with the pia mater. The gray and white matter of the brain was of normal consistence. About two ounces of bloody fluid was found in the lateral and fourth ventricles. The convolutions were flat and the sulci very shallow. The weight of the brain was 1456 grains. As I desired to preserve it for future microscopic examination, sections were not made. The pituitary body was .8 cm. wide, .7 cm. long, and .3 cm. thick, and weighed 2 grains.

An examination of the marrow of all the bones revealed nothing but the red variety. A microscopic examination of the pear-shaped gland found in the thyroid location revealed nothing but hypertrophied and hyperplastic lymph-cells. A like study of the pituitary body, thymus gland, and suprarenal cap-

1. Congenital absence, diminution in size, or acquired atrophy of the thyroid gland results in myxematous thickening of the skin, persistence and enlargement of the thymus gland, hypertrophy and hyperplasia of the lymph-glands, changed structure and retarded development of the entire osseous system, and dwarfism. Functionally, there is mental apathy and lack of development, retarded and deficient motor- and sensory-nerve mechanism, and manifold incoordinations and muscular retrogression.

2. Acute disease of the thyroid gland results in softening and retarded development of the osseous system, and anemia, producing a condition which retards absorption and excretion in the stomach and intestines, bronchitis, and abnormal nervous manifestations.

3. Chronic disease of the thyroid predisposes to malignant, adenoid, and cystic growths, and microbic diseases.

4. Hypertrophy and hyperplastic excess of thyroid structure, as shown by Mobius and Greenfield, and by Horsley, results in exophthalmic goiter or Graves' disease.

To recapitulate: Anatomic, physiologic, therapeutic, and pathologic evidence predominates in indicating that the thyroid gland directly controls the coordinate growth and development of the entire organism; that this evidence suggests that the diseases of the gland are limited by the absence, diminution, or excess of special gland structure, and by changes in the gland secretions and excretions, resulting in the production of cretinism, rickets, and exophthalmic goiter; that the skin and thymus gland attempt above all others to compensate for the absence of the thyroid function, and that structural and functional diseases of the bones are directly caused by disease of the gland; and that therapeutic application of the extract of the gland should be confined to conditions in which there is absence, diminution in size, or disease of the thyroid structure, as indicated by functional changes in the skin, sensory or motor nervous systems, structural changes in bones, and dwarfism.

WHAT CONDITIONS INFLUENCE THE COURSE OF INFANTILE SYPHILIS?

By JAMES NEVINS HYDE, M.D.,

OF CHICAGO;

PROFESSOR OF VENEREAL AND SKIN DISEASES IN THE RUSH MEDICAL COLLEGE.

In order to take a comprehensive survey of the field covered by the above inquiry it is necessary to determine definitely what is to be understood by "Infantile Syphilis." The words, strictly interpreted, relate only to syphilis in infants. Restricting the discussion, however, to such a narrow division of the subject would mean an exclusion of some of the most important and interesting of the ascertained facts. It is desirable instead, to include under this general term (1) the phenomena of syphilis as displayed in intra-uterine life, syphilis of the products of conception, of the ovum, and of the fetus, (2) extra-uterine or hereditary syphilis in the infant, and, (3) acquired infantile syphilis, the disease as it affects otherwise healthy infants who suffer from what has been termed contact-syphilis.

The course of the *lues venerea* in the unborn products of conception is one which is often wholly uninfluenced not only by treatment but by external interrupting circumstances. In the acquired forms of the disease this is the exception rather than the rule; for in syphilis of the second generation the social condition of the infected progenitors is a factor of importance. Infantile syphilis is decidedly more common in hospital and dispensary patients, among the poor, the degraded, and the filthy than among the better classes who suffer equally with the others from the acquired disease. The educated, the wealthy, and the comfortably housed contract syphilis, it is true, but *after infection* secure appropriate treatment, and then, for the most part, refuse to marry or to procreate until there is a reasonable prospect of the birth of healthy children. If infection of the wife does occur and pregnancy follows, treatment is promptly instituted. In the case of the poor, the destitute, the uncleanly, and the ignorant, the mother, without conspicuous stigmata of the disease, concludes her pregnancy prematurely or at term, often without any interference with the complete evolution of the disease both in herself and in her offspring. It is well to bear in mind the errors most commonly committed in the effort to properly interpret the signs of this intra-uterine syphilis of uninterrupted course. Not every abortion, not every miscarriage of a pallid-faced mother whose husband gives a history of premarital infection, is necessarily syphilitic. Not every still-born child, and even, not every macerated fetus is dead in consequence of *lues venerea*.

There is no question to-day among the informed as to the fatal termination, as regards the fetus, in a large percentage or all pregnancies when the product of conception has been infected. This may be set down as one of the few irrefutable facts of syphilis. Waiving, for the moment, consideration of the question whether this mortality is conditioned upon an infection of either paternal or maternal origin, whether the placenta be or be not involved, whether the maternal infection, if such there has been, was ante- or post-conceptional, with a view to the determination of the present question, it should be asked, what percentage of pregnancies is concluded at term with the birth of a living child, and what percentage is prematurely terminated by abortion or miscarriage? The obstacles to a precise collation of the required data are simply insuperable. The best that may be made is an approximate estimate based upon the statistics of a group of careful observers such as Kassowitz, Lancereaux, Neumann, Coutts, Jullien, and Warner. These authors, it must be admitted for the most part, give figures which it is

difficult to compare by reason of the fact that they draw no hard and fast line at the date of the completion of pregnancy, but class together in the fatal issues of each, all instances of abortion, miscarriage, still-birth, and of children dead at or soon after birth, the limit last named being by one of these authors extended to six months. In 1700 syphilitic pregnancies, however, which it is possible to employ in studying the course of syphilis as it affects the fetus, the total number of abortions, miscarriages, and still-births amounts to 579. It follows that about one-third of all pregnancies of syphilitic women terminate by the death of the fetus before or at the completion of pregnancy. These are about the figures reached by a study of the statistics of Kassowitz. When they are added to those representing the mortality of the children born at term and surviving for variable periods, a clearer view may be obtained of the evolution of the disease in the second generation.

It has been the destiny of syphilis to be confounded with more maladies than any other single disease. Instances of the acquired form of *lues venerea* are daily assumed to belong to another category. Daily, also, are non-syphilitic affections diagnosed and treated on the assumption that they are of specific origin. It is as common to discover these errors in the inherited as in the acquired forms of the disease, and yet the possibility is often overlooked in accepting reports of cases and in the study of the literature of the subject. In view of these facts one is almost tempted to advance toward the extreme position lately taken by Parker who, certainly with proper appreciation of the dangerous errors committed in this connection, distinguishes between "inherited syphilis" and diseases "inherited from syphilis," demanding, in order to establish the fact of the former, that proof be given of the contagious character of the disease exhibited by the suspected infant. Not every child with Hutchinsonian teeth, with cranial bosses, with a natiiform skull, or suffering from a rebellious affection, is the victim of inherited syphilis. Even the painstaking labors of a Parrot have not sufficed to obliterate the distinction between syphilis and rickets. The puny infant with coryza and eruptive symptoms about the mouth and anus may not be a source of infection for others. It would seem trivial to refer to such commonplace occurrences were there not a constant recurrence in the medical press of the blunders originating in the misinterpretation of these facts. Within the last six months, for example, one of our most extensively circulated medical journals of a high rank published a communication from an officer of an important State institution for the care of the insane, in which

it was held that four patients affected with general paralysis (*délire des grandeurs*) suffered from the disease as a consequence of the inheritance of syphilis; because in each instance there was no history of the acquired disease, and yet Hutchinsonian teeth were exhibited, the article being accompanied by illustrations of the teeth in question. Avoiding the possibilities of errors of this and a similar kind, a study of the facts of extra-uterine syphilis of the second generation, when collated from trustworthy sources, throws further light upon the natural evolution of the malady.

As the result of the 1700 pregnancies to which reference has been made, there were born 1121 living children of whom 956 died within the first twelve months. Of the remaining 165 children who chanced to survive a year nothing is known. It is, however, certain that they had not yet reached a stage of development when they could be regarded as exempt from the dangers which had destroyed so many of the others. The proportion of those succumbing later is unknown. The ascertained figures, then, representing the mortality affecting these 1700 products of conception both during and after pregnancy, are 1535, or nearly 95 per cent. of the total number. The estimates made by other competent observers vary between sixty and ninety per cent. of fatal issues when the data of intra-uterine life and those of infancy are combined. For the purpose of comparison I have collated the figures embodied in the histories of twenty-five syphilitic mothers resident in Chicago, consecutively recorded, as a result of whose forty-one pregnancies there were thirty-one abortions, miscarriages, and children dead at birth or within one year. One of these children unquestionably escaped infection. Of the fate of the nine survivors at the end of the year nothing is known. This points to a mortality of about eighty per cent. of all the products of conception. If these figures be accepted as trustworthy, it follows that the issue of syphilis as it is developed in the products of conception of diseased parents is comparable only with the gravest of the plagues and pestilences to which the human family is subject. Smallpox in infants is estimated to be followed by a mortality as high as ninety per cent. but great allowance should be made for the varying severity of different epidemics. Many of the formidable incursions of yellow fever and cholera spare a larger proportion of victims than survive the scourge which is the subject of this discussion. In point of fact one is at a loss to discover mortality statistics with which these may be justly compared, if recourse be not had to the progress of the plague in Europe during the Middle Ages.

Most of the text-books on syphilis are written for

the benefit of the practitioner and of the student who purposes one day to be a practical physician. As a consequence the chapters on hereditary syphilis contain many pages which are properly enough devoted to a description of the clinical and other symptoms of the disease as they occur in the meagre number of survivors of the malady, while but a few paragraphs are devoted to the enormous mass of pathologic facts which are to be gathered from a study of abortions and miscarriages in the syphilitic. Of the blighted germs and the macerated fetuses only a few are preserved among the morbid specimens of the medical museum, the great mass of which are swept with the sewage into the limbo of the unseen, to descend by retrogressive metamorphosis to the primary elements from which they were evolved. Having in view the number of clinical facts to which the figures cited above significantly point, one is in position to formulate an approximate answer to the question propounded, *viz.*, "What Conditions Influence the Course of Infantile Syphilis?"

The Virus.—Twenty years ago the word "virus" would probably have been defined as a secretion containing an animal poison; to-day the word is set down as equivalent to a pathogenic micro-organism; to-morrow it will be necessary to add the words "or its toxin." In the case of syphilis the germ and the toxin, if such there be, are as yet undemonstrated as efficient factors in the production of the disease. But no better working hypothesis is at hand than the general assumption that syphilis, with regard to its ultimate cause, is to be aligned with the other infectious granulomata, and is dependent upon an undiscovered bacterium, which, either by virtue of its presence or by the potency of its toxin, is capable of transmitting the disease. Does this virus of syphilis, recognized as effective in the second generation of its victims, differ in its energy according as it acknowledges a paternal or maternal origin in the first generation? Looking to the facts of inheritance in general, we can discover no preponderance of one sex over the other in the power to transmit disease. Inherited tuberculosis descends with equal destructiveness from father or mother. Syphilis offers no facts controverting such a position. That the energy of the virus is to a degree related to the activity of the disease in the progenitors is generally accepted. It is conceded that with both parents recently infected the chances of grave syphilis in the offspring are increased, that with one parent exhibiting the disease in marked activity, the dangers are greater than when the malady in the parent has waned, that the virus furnished after the production of a series of abortions and miscarriages is likely to be attenuated to the point of lessening

its activity and its capability of transmission, and lastly, that in almost every syphilis of the parents there are to be recognized periods, often alternating, of aggravation and of amelioration, transmissibility in these pauses of the disease being either greatly weakened or wholly lost. Even after due consideration of the appalling mortality which furnishes one of the chief symptoms in syphilis of the second generation, it is not to be forgotten that cases of mild inherited syphilis do occur, and that recovery, complete and satisfactory, follows in a small percentage of the patients.

The Individual.—Turning now from consideration of the virus, it is apparent at a glance that the individual product of conception in syphilis is practically deprived of the resources provided, in the great majority of all other patients, for resistance to the onset of the disease. The individual attacked with acquired syphilis is often assured of a sound ancestry, and of uninterrupted opportunity for nutrition and development prior to the date of his or her infection. In hereditary syphilis, on the contrary, the individual is poisoned *ab ovo* by the introduction of a pathogenic germ, either into the sperm-cell or ovule, or both, and at every point of subsequent evolution suffers from impaired nutrition and from a retardation of growth through the influence of a morbid process which is likely to invade every organ. Shall we then hasten to infer that in syphilis of the second generation the virus is wholly efficient and the individual absolutely helpless in influencing the course of the disease? It is, indeed, rare in the purview of nature that man is abandoned as an utterly unaided creature in the face of the encroachments of disease. Even an aortic aneurism may undergo calcification! In the case of infantile syphilis, when the odds are heavily against the survival of the remnant, an individual is provided with resistance by the force of whose interference the course of the disease is influenced to a remarkable degree. This is a fact the significance of which is apt to be overlooked, and the instructiveness of the result is of the highest importance in throwing light upon the two factors named in the subject of this discussion. The individual in this case is the mother who can offer to her child a breast filled with milk, a being at one time undivided from her child, a being really taking position as a separate individual only after the child is weaned. It is a well known fact that in some of the vertebrata the suckling at the mammary gland is often enclosed in a protective pouch where it exists in a fetal state for some time after extra-uterine existence has begun. The influence upon the mortality statistics of infantile syphilis of the nursing mother operating under the disad-

vantages of a cachexia which is shared by both parent and offspring, cannot be challenged. Several writers, such as Henoch,¹ claim that all infants affected with hereditary syphilis die if they are not suckled at the breast. Widerhofer² puts the percentage of such deaths in children artificially reared as high as ninety-nine per cent. Other observers conclude that between ten and twenty per cent. of infants affected with hereditary syphilis are either completely snatched from peril or enjoy prolongation of life in consequence of being nourished at the breast of the mother. On a field then, more thickly covered with a proportion of the dead and dying than any battle-ground of modern times, we find women stricken with the same dart which has destroyed the multitude, who succeed in snatching from destruction a calculable number of infected infants by simply providing them with breast-milk. This notable result is attained solely by virtue of improving the nutrition of the infant. We are therefore justified in somewhat qualifying the response to the categorical question which forms the subject of this debate. The virus is *not* solely efficient in influencing the course of infantile syphilis. The individual, in this case represented by the mother who is the food-supply of the helpless being, is capable of diminishing the mortality of the disease to the extent of saving between ten and twenty out of every hundred of infected children. If the mere fact of an improved nutrition can work this effect in the victim of hereditary syphilis, I will leave it to my distinguished colleague to estimate the value of the same factor in acquired disease. To ignore it would be as short sighted as it would be fatal to safe conclusions. The subject of late inherited syphilis, as it relates largely to the adult, is relegated to the gentleman to whom has been assigned the duty of reporting on that branch of the subject.*

With respect to acquired infantile syphilis, it is gratifying to note that the disorder is far less common than is usually believed. Fournier has a record of but forty-two patients of this class coming under his observation, though he adds that he believes as many more have been seen by him in regard to which no notes were taken. I have a record of less than a score of cases in which there was no doubt respecting diagnosis. Five resulted from arm-to-arm vaccination; two from soiled instruments; two others were produced by the kisses of women whose lips were the seat of mucous patches; one infant was infected from the chancre of a male parent when the two occupied a bed in common; the other

eight occurred in families in which there were infected adults, but in which the mode of transmission is unknown. With two exceptions (one of the vaccination cases, another described more fully in this paper), all these were dispensary patients coming from the very lowest grade of society.

The most remarkable contrast is afforded by the statistics of recovery in this class of young subjects as compared with those suffering from inherited syphilis. Fournier states that all his cases resulted in recovery save in one instance, that of a child dying of cachectic pneumonia. With reference to the issue in the parents who have come under my personal observation, it can merely be set down that no one of the children is recorded to have died of the disease, though, as is well-known, American dispensary patients are remarkable for the ease with which they escape from observation and elude the compiler of statistics.

It is so rare that an infant acquires syphilis at the moment of birth, or almost immediately thereafter, that a study of even one such carefully observed case, when compared with that of a child affected with hereditary syphilis, possesses some interest:

A well-nourished infant, aged two and one-half months, of parents who were both wealthy and of good social position, was brought to me by the physician who had delivered the mother, himself a professor of obstetrics in one of our large medical schools. The child had a well-developed but lapsing initial sclerosis over the tip of the right ear (at the site of a wound inflicted by the obstetric forceps with which it had been brought into the world). It exhibited, also, accompanying adenopathy, and a brilliant macular exanthem. Mucous patches existed in the mouth, and the child had promptly infected its mother who exhibited a chancre of the nipple, with axillary adenopathy. The eruptive symptoms in the mother made their appearance in due time, in fact, after those of the child had quite disappeared. The father, who was absent from home months before and after the birth of the child, was carefully examined on his return, and was found to be even in unusually sound health, and denied prior venereal disease of every kind. The medical attendant was one of those brilliant and busy men to be found in all large cities, doing a great deal of work under an enormous pressure, and eventually dying under the strain of it. When privately taxed with the possibility of having used unclean instruments in this case, he could only say that he was in the habit of taking proper precautions. The nurse who had dressed the child after birth was examined and found free from evidences of disease.

The mother of this infant had been a delicate woman before marriage, and could give her child only deficient alimentation by the breast. It was necessary to resort in part to artificial feeding. A photograph of this child stripped naked, after it had

¹ *Vorlesung über Kinderhautkrankheiten*, S. 105, 1889.

² *Klin. Vorlesg. Wien. Allg. Med. Zeitung*, 1886.

* "What Conditions Influence the Course of Syphilis?" THE MEDICAL NEWS, October 30, 1897.

attained two years of age, indicated that the result of its prolonged treatment had been wholly satisfactory. It was plump and well nourished. The mother had a long and serious convalescence after repeated attacks of iritis, with at one time the formation of a gumma in the breast.

With a view, then, to answering the question, what conditions influence the course of acquired infantile syphilis, the virus or the individual, experience would point to the conclusion that in infants the individual, as against the virus, exerts that degree of higher influence which may be recognized in the case of acquired syphilis of adults. Many writers who touch upon this theme have introduced, in the presentation of these cases, the influence of treatment as a modifying cause. With a view to gaining some insight into the truth of the matter, we may be permitted to compliment the Council in the elimination of the element of treatment from the terms of the present discussion. Here it is a question simply of virus *versus* individual, with the weight of evidence now on one side and now on the other, according to the conditions presented in different cases. These conditions are wholly different in the case of chemic intoxication, and in the instance of poisoning by living micro-organisms. In the former the pathologic results are proportioned with approximate exactness to the dosage of the chemic poison. In the latter, the multiplication of fission-fungi within the animal organism may proceed with the greatest activity after a minimum quantity of the virus has once been introduced into the economy; and the soil, together with favorable or inhospitable environment, has much to do with the question of multiplication and toxin production of the implanted germs.

If we turn to the facts of general pathology we find the answer which awaits us there the same as in syphilis—a malady which Andrel once declared would furnish a key to the study of all morbid phenomena in the human body. The smallest dosage of the variolous poison, even in the attenuated form of mild varioloid, is capable of transmitting to the unprotected the severest confluent form of the disease. In certain epidemics of hemorrhagic variola even the protected at times may suffer. By the attenuation of a virus many of the brilliant advances of modern therapeutics have been attained. Diphtheria, hydrophobia, and tetanus bear ample witness of this fact. But he is indeed blind who cannot see in the subject of tuberculosis, of septicemia, of yellow fever, and of cholera the wall which is ever and again built as a bulwark to the encroachments of disease, by the sound constitution, the satisfactory habits, and the hygienic environment of the selected individual.

CLINICAL LECTURE.

A CASE OF SUSPECTED CARDIAC ANEURISM; FOUR CASES OF CHRONIC PAREN- CHYMATOUS NEPHRITIS; THE USE OF INTRAVENOUS SALINE INJECTIONS IN UREMIA.¹

By H. A. HARE, M.D.,
OF PHILADELPHIA;

PROFESSOR OF THERAPEUTICS IN THE JEFFERSON MEDICAL COL-
LEGE; ATTENDING PHYSICIAN TO THE JEFFERSON
MEDICAL COLLEGE HOSPITAL.

THE first patient shown to-day is of more than usual interest, because, if the diagnosis is correct, he is suffering from a very rare cardiac affection, a condition which is still more rarely correctly diagnosticated during life. He is about thirty-five years of age, and while a very young child suffered from an attack of acute infantile palsy, which, as you see, has seriously interfered with the proper use of his right leg. At the age of nine years he had a severe attack of acute articular rheumatism, which confined him to bed for a number of weeks, and at fourteen he was again incapacitated by an "attack of dropsy," as he expresses it, which his physician told him was due to the condition of his heart. He remained fairly well until 1892, when he began to suffer somewhat from dyspnea, and from 1894 to the present time he has suffered from a constantly increasing dyspnea, which has been so severe as to prevent him from doing any form of labor or taking any but the gentlest exercise. The dyspnea is more or less constant, is greatly aggravated by exercise, and he tells me that the disturbance of his heart following slight exertion has within the last week twice resulted in a sudden attack of syncope. His face, as you notice, is unusually pale but not at all cyanotic; indeed, he presents rather the appearance of a patient with chronic parenchymatous nephritis. When we examine his urine, we find that it is heavily loaded with albumin, that it contains a few epithelial casts and some uric-acid crystals. An examination of his heart shows a very extraordinary condition: There is considerable bulging over the whole precordial region, and palpation reveals a heaving impulse, which is most marked two inches below the nipple and half way between the anterior axillary and the mammillary line. The impulse in this area is not only forcible, but it is distinctly expansile, giving one the peculiar distensile sensation so frequently felt in cases of aneurism of large blood-vessels—for instance, aneurism of the thoracic aorta, of the abdominal aorta, or of the popliteal artery. This peculiar expansile pulsation is one of the most important points in the diagnosis of this case. An examination of the heart by auscultation reveals the fact that in the particular spot where this expansile pulsation is felt there is a soft bruit or murmur, a bruit which cannot be heard over other portions of the heart. The ordinary heart-sounds are so muffled as to be practically indistinguishable, and we simply have a sensation both on pal-

¹ A clinical lecture delivered at the Jefferson Medical College Hospital.

pation and auscultation of a moving body in the place in which the heart ordinarily produces its characteristic valvular sounds.

On inspection you can actually see the powerful apex beat and its somewhat expansile character. A careful study of this case leads me, for the following reasons, to believe that it is one of cardiac aneurism: (1) The markedly expansile character of the apex beat. (2) The fact that this apex beat is far below the normal point and much further to the left than it ought to be; in other words, it is in a position where an aneurismal dilatation of the ventricular wall at the apex would naturally project itself. The attacks of dyspnea from which the patient suffers on exertion, while they often occur in cases of valvular disease of the heart, are usually associated with considerable dilatation of the organ, a condition which does not exist in this case. We find that the area of cardiac dulness is not materially increased to the right nor to the left, except in the direction named. Finally, the murmur probably does not depend upon a valvular lesion, as it is not constant; it varies in intensity before and after exercise, and in all probability disappears when the patient rests and takes stimulants. This latter fact is made clear when it is understood that he recently had his life insured for \$5000, successfully passing the medical examination by taking full doses of strychnia beforehand and thereby rendering the action of his heart not only regular, but devoid of murmur. I have carefully gone over the other lesions which might possibly produce symptoms similar to those from which he suffers, and am unable to discover any signs pointing to a condition other than that which I have named.

The treatment should be almost identical with that which we usually give a patient with aneurism. He should, if possible, be placed upon his back, should receive moderately full doses of iodid of potassium, and a sufficient quantity of aconite to act as a marked sedative upon his heart without at the same time depressing it too greatly. His diet should be regulated, and, should he for any reason refuse to stay in the house, we will earnestly urge him to avoid anything like a sudden strain, as running, or the ingestion of powerful stimulants such as alcohol, a drug which he is accustomed to use in excess.

I neglected to say that one reason for believing that the patient is suffering from cardiac aneurism is the character of the impulse which is present, the force of the heart, as it were, seeming to be expended upon itself; as a result the peripheral circulation is poorly maintained. On first seeing this patient you might be tempted, because of the feeble circulation in the peripheral arteries, to give him digitalis, but in my belief this would be improper therapeutics; since it would raise arterial pressure, thereby increasing the pressure of the blood inside the ventricle, and further, digitalis, would stimulate the remaining healthy fibers of the left ventricle to such an extent that the aneurismal swelling would be markedly increased in size. (At this point the patient interrupted the lecturer by stating that digitalis had often been given to him and was "poison" to him; that its use always gave him precordial distress and marked dyspnea, and that alcohol taken in full doses

had a somewhat similar effect.) For these reasons, then, if any cardiac stimulant is to be administered, strophanthus would be the best, because it would not raise the arterial pressure. Indeed, he tells me that nitroglycerin has also done him great good at times, particularly when he has had a severe attack of cardiac disturbance. The relief afforded by this drug under these circumstances is probably due to the fact that the nitroglycerin, by relaxing arterial tension, diminishes the dilatation of the aneurismal sac. I shall carefully watch his case and report to you any interesting details which may develop.

I now bring before you four patients, all of them in different stages of chronic parenchymatous nephritis. Two of the patients, as you see, are afoot, one of them is fairly stout but exceedingly pale and waxy-looking. As you notice, he has considerable dyspnea, but this is much less marked than it was when first he walked into the hospital, as he now has had several minutes' rest. An examination of his heart reveals a prolonged systolic murmur which is probably due to mitral regurgitation, although the action of the heart is so irregular and its sounds so indistinct that an exact diagnosis of the character of the murmur is difficult.

The second patient you will notice is evidently a man who has been much exposed to weather and to the excessive use of alcohol. He presented himself at the dispensary two days ago with urgent dyspnea, and with slight twitching of the muscles in various portions of his body. An examination of the heart failed to reveal any lesion sufficiently severe to explain his respiratory symptoms, but an examination of the urine showed a large amount of albumin and it was also found to contain epithelial and granular casts. An examination of the first patient's urine also shows the presence of an enormous amount of albumin.

Now these two patients are brought before you to emphasize one important clinical point, namely, that in the presence of a history of dyspnea of recent onset you should always examine the urine in order to discover whether or not the respiratory difficulty depends upon uremic poisoning. I wish to emphasize this fact because such an examination is often neglected and the careless and frequently incorrect diagnosis of primary cardiac or pulmonary dyspnea is made. Then, again, if you are not cautious, you may be misled into believing that frequent attacks of shortness of breath, particularly when nocturnal, are due to asthma, when in reality they are uremic; and the safest rule for you to follow is to examine the urine in every case of dyspnea, even though there seems to be sufficient cardiac and pulmonary difficulty to account for the symptoms. Thus, an examination of this man's chest, posteriorly at the bases of the lungs, may show impaired resonance and numerous râles, and you will be inclined to think that the patient is suffering from ordinary pulmonary congestion or catarrhal pneumonia when in reality there is present an edema of the lung due to a renal lesion. The marked dyspnea in both of these patients is evidently uremic in origin. The fact that one of them has already had diffuse muscular twitching indicates the onset of a uremic storm. The scanty amount of urine

which they have been passing and the feeble condition of the circulation in each case make it necessary that we should at once do something for their relief. They are too feeble to receive pilocarpin, too feeble to be bled, too feeble to be purged, and, on the other hand, their circulations are not so feeble as to require stimulation. What then shall we do? By far the best thing would be to place them in a hot pack, preceding which they should be given a bath and be washed with Johnson's ethereal antiseptic soap. This will remove from the skin all dirt and dead epithelium, and will open the pores so that the use of a hot pack immediately after the bath will result in the free outpouring of the impurities in the blood through the sweat-glands. During the time the patients are in the hot pack, if there is any delay in the appearance of the sweat, each should receive a glass of ice-water, as this frequently causes the sweat to appear at once, probably by contracting the central blood-vessels and driving the blood to the periphery. Should there be any tendency to cardiac feebleness we will administer a dram of gin every two or three hours; for this alcoholic preparation will at once stimulate the circulation and the diseased kidneys to increased activity, and because, in one of the patients, a deprivation of all alcoholic stimulation might precipitate an attack of delirium tremens.

The other two patients which are shown have been exhibited before. One of these men, when he entered the hospital a week ago, was so uremic as to drop off into unconsciousness whenever he was left to himself a minute or two. He was dyspneic, his pulse was exceedingly feeble, he was suffering from anasarca, and his lips and facial muscles were twitching from the uremic poisoning. At that time the anterior abdominal wall could be easily pitted on pressure. In his case, too, it was evident that bleeding and purging or a pilocarpin-sweat were all contraindicated by an exceedingly feeble condition, and I therefore decided to at once resort to the intravenous injection of a normal saline solution. I opened a vein on the anterior aspect of his forearm, inserted a small glass cannula which had a shoulder at its tip so that I could readily tie it in a blood-vessel, filled the cannula with salt solution in order to exclude air, connected it with the tube from the irrigating apparatus containing normal saline solution, and allowed a quart of the latter to flow very slowly into the vein.

As a result of this treatment the patient, who, in the previous sixteen hours had not passed any urine, passed within the next few hours no less than thirteen ounces, and perspired quite freely. As now, six days later, he sits before you in a rolling-chair, you will notice that he is pale to excess, and has the characteristic appearance of a patient with chronic parenchymatous nephritis, but he will tell you, as he has told me, that he is now free from headache for the first time in several months, that he feels very much better in every way, and that his dyspnea has disappeared. He has developed an inordinate hunger, indeed, so great that we have been forced to allow him a larger quantity of food than is ordinarily advisable in these cases. He is also receiving a dram of gin every two hours, and you may see from the chart that, since the gin has

been administered and the intravenous injection used, he has passed from twenty-eight to thirty-two ounces of urine in each twenty-four hours, although, as I have said, previous to his admission to the hospital, he was not passing more than five or six ounces in that period.

The other patient has been before you on three previous occasions. Twice he has been tapped before the class for ascites occurring in connection with a general anasarca; for the reason that the pressure upon his diaphragm was such as to seriously interfere with comfort. The fluid is once more returning, but you will notice that his face and hands are not at all edematous, and that his feet are far less so than when he came before you on previous occasions. — Further, he has been able, during the past week, to sit up a number of hours each day instead of being constantly confined to his bed. His appetite is fairly good and he passes urine freely. His treatment has consisted of the administration of 5 drops of the tincture of strophanthus three times daily, with 2 drops of the tincture of cantharides every eight hours. He has now received this treatment a month, and in addition small doses of Basham's mixture have been occasionally administered. He is very much better, although it goes without saying that the grave renal lesion precludes a favorable prognosis. Four or five days ago he was seized with a severe cough, and his temperature rose to 103° F. I feared during the next twenty-four hours that he was being attacked by pneumonia, but the lungs cleared, the cough has largely ceased, and I am in hopes, inasmuch as he is so much better, that the pulmonary condition was a mild attack of influenza or else one of those cases of transitory pulmonary congestion sometimes observed in patients with nephritis.

CLINICAL MEMORANDA.

CHANCRE OF THE LIP PROBABLY ACQUIRED THROUGH THE USE OF A "ROUGE STICK".¹

BY DOUGLASS W. MONTGOMERY, M.D.,
OF SAN FRANCISCO;

PROFESSOR OF DISEASES OF THE SKIN IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF CALIFORNIA.

ON December 18, 1896, I was called to see an unmarried girl, twenty years of age, who was suffering from a sore on the left side of the vermilion border of the lower lip, which she had first noticed about one week before. The lesion was covered by a brown, flat, depressed scab; but a raw surface extended down a short distance on the inner side of the lip, and there abruptly ended. The right submaxillary lymphatic nodule was very much swollen, hard, and somewhat painful. This was the only subcutaneous node which was demonstrable, and, except the lesion on the lip, there were no eruptions of the skin, or in the mouth, and the hair did not show a tendency to fall out.

The appearance of the sore, as well as the marked enlargement of a neighboring lymphatic nodule instantly raised the suspicion that it was a chancre. The closest questioning could only elicit that she had had a "cold-

¹ Read at a meeting of the California Academy of Medicine, September 18, 1897.

sore," which a druggist had touched with a stick of silver-nitrate. This cauterization had, however, taken place only about a week before I saw her, so that it was clearly not at that time that the infection had occurred.

The gravity of the question involved was explained to the patient, as was also the necessity of making an accurate diagnosis even at the expense of great personal discomfort. A positive diagnosis was not made until January 30, 1897, forty-three days after she first came under observation. At that time the sore was very large and painful, and projected out from the lower lip in the characteristic dish-form, with rolled edges and with a great deal of firm induration in the surrounding tissues. The enlarged lymphatic node under the right side of the lower jaw had decreased in size, but the anterior and posterior cervical lymphatic nodules on both sides were now demonstrable, and there was a well-marked roseolar eruption upon the chest and abdomen. There were also mucous patches upon both tonsils. There was pain and tenderness over the inner aspect of the upper third of both shin bones.

She was given mercury and chalk tablets internally, and unguentum hydrargyri was applied to the chancre. The patient was again seen on February 16th, by which time the ulcer on the lip had perfectly healed, leaving its site only slightly indurated. There was no rash whatever, and she appeared to be in perfect health.

On one of her visits to my office, the patient, as a possible solution of the riddle of how she became infected, told me of a custom of which, up to that time, I had known nothing. She said "that in some of the hair-dressing establishments, the hair-dresser, as a final touch, drew a moistened "rouge stick across the lips of her customers." This "rouge stick" is a cylinder composed of a firm, red ointment. The firmness necessitates a slight moistening before being applied, and, disgusting to relate, this is frequently accomplished by the hair-dresser first putting it in her own mouth and then deftly drawing it across the lips of her customers. Then, again, all customers are treated with the same "stick," and my patient told me that "in the shop where she usually went to have her hair dressed she had noticed many 'chemical blondes' and otherwise strikingly dressed women." As far as the character of the young woman under consideration is concerned, however, it may here be remarked that during the entire terrible ordeal of doubt and anxiety which she went through before the diagnosis was absolutely confirmed, she conducted herself in an entirely modest and straightforward manner, so that it was not held likely that she acquired the affection otherwise than by accident. The fact that she went to a shop patronized by those females with whom Isaiah was so out of patience, "they who walk with outstretched necks and wanton eyes, mincing as they go," must not place her by inference among the unrighteous. Neither must her passive submission to an obviously filthy practice stamp her as being uncleanly, for people otherwise dainty in their ways, will passively submit through embarrassment or a desire not to offend to many things at the hands of barbers and hair-dressers.

It of course can never be known whether this patient

was actually inoculated with this public "rouge stick," but there was no doubt that she had a chancre of the lip, and there is also no doubt that this would be a perfectly reasonable way of conveying the disease. It would be analogous to the conveyance of syphilis by means of the stick of nitrate of silver of which there are so many cases on record, and the danger of which was so well recognized that Fournier advised that it be entirely banished from all hospitals and clinics.¹

It is not at all likely that this filthy use of the "rouge stick" is a custom peculiar to San Francisco, and with such a favorable means of conveying syphilis it is wonderful that cases so acquired have not been reported before. One would even think it would give rise to some of those fearful epidemics of the disease such as have been reported in glass-blowing establishments, where a whole row of workmen have contracted syphilis from the blowpipe passed from one to another.

A CASE OF FATAL INFANTILE ANEMIA, WITH GREATLY ENLARGED SPLEEN.

By HERMAN F. VICKERY, M.D.,

OF BOSTON;

INSTRUCTOR IN CLINICAL MEDICINE AT THE HARVARD MEDICAL SCHOOL; PHYSICIAN TO THE OUT-PATIENT DEPARTMENT, MASSACHUSETTS GENERAL HOSPITAL.

H. M., aged eighteen months, born of Portuguese parents, was brought to the out-patient department of the Massachusetts General Hospital, and came under

Anemia, with greatly enlarged spleen, in a child aged eighteen months.

my care December 4, 1895. The family history was good, except that the father, a sailor, had suffered severely

¹ Quoted by F. Muenchheimer. "Ueber extragenitale Syphilis-infection." *Archiv f. Dermatologie u. Syphilis*. Bd. xl, S. 200.

from malaria. No history of venereal disease was obtained from either parent. The patient had been fed partly upon breast-milk and partly upon raw, undiluted cow's milk. He seemed well until eight months old, when he began to grow pale and weak, and the abdomen became swollen and hard. These symptoms persisted and increased. Relief was sought especially for a persistent diarrhea. There were three or four greenish, liquid movements daily.

On physical examination, the child was found to be feeble, ill-nourished, extremely pale, and appeared to be suffering. The anterior fontanelle was still open. There was a slight rosary where the ribs joined their cartilages. The epiphyses were somewhat enlarged. In the neck, axillæ, and groins hard glands about the size of a pea could be felt. The rectal temperature was 99° F. The chest was normal, except that the left base was encroached upon from below. The liver was slightly increased in size. The spleen was uniformly enlarged and hard. It reached slightly beyond the navel toward the right, and extended downward to within two fingers-breadth of the anterior superior spine of the left ilium. The blood contained an excess of white corpuscles.

On December 13th, the hematocrit demonstrated the number of red globules as 2,500,000, and the white as 25,000 per cubic millimeter. The percentage of hemoglobin was thirty-two. A differential count of the white corpuscles was made at this time by Dr. W. H. Smith, and on January 23d two counts were made by Drs. Richard C. Cabot and Henry F. Hewes, respectively. The accompanying table gives the results of these counts.

BLOOD EXAMINATION.

Smith, Dec 13th.		Cabot, Jan. 23d.	Hewes, Jan. 23d.
Red cells.....	2,500,000	2,500,000	
White cells.....	25,000	22,000	
Hemoglobin.....	32 per cent.		
No. of white cells counted	250	1000	1000
Small lymphocytes.....	16 per cent.	48 per cent.	30 per cent.
Large lymphocytes and transitional cells.....	16.7 per cent.	8.9 per cent.	10 per cent.
Polymorphonuclear neu- trophils.....	42.5 per cent.	29.4 per cent.	38.6 per cent.
Eosinophiles.....	10.4 per cent.	4.8 per cent.	9.2 per cent.
Myelocytes.....	12.8 per cent.	8.2 per cent.	6.6 per cent.

It will be seen that the number of red corpuscles was larger than in pernicious anemia, that the case certainly was not one of lymphatic leukemia, and that the number of white cells was too small for splenic-myelogenous leukemia. Myelocytes and nucleated red blood-corpuscles are seen in both pernicious anemia and splenic-myelogen-

ous leukemia. "The presence of myelocytes in numbers," remarks Dr. Hewes in his report, "with the pernicious anemia-type of blood, always suggests to me that the two diseases, pernicious anemia and myelogenous leukemia, are but different types of the same pathologic condition." Cabot,¹ after discussing this very case, said, "We meet with cases in infancy which are apparently intermediate between leukemia and pernicious anemia."

It seems to the writer that there has not yet been gathered a sufficient number of reports of cases, since the new methods of studying the blood have been developed, to furnish a basis for exact classification. It is, therefore, wiser to report all such observations and to leave the interpretation of them until a later day. Many would call this an instance of the disease described by Von Jaksch, under the name of "Anemia Infantum Pseudoleukemia." Rachitis, which was present in a moderate degree in this patient, may cause great enlargement of the spleen, as has been shown by Dr. J. Lewis Smith,² who stated that "in a recent very anemic and fatal case of rachitis, in the New York Foundling Asylum, the spleen extended below the level of the umbilicus."

The case was regarded as hopeless. Advice was given about feeding, and $\frac{1}{2}$ minim of Fowler's solution of arsenic, afterward increased to 1 minim, thrice daily, was prescribed. The digestion improved, but the patient grew weaker and died about two months after he was first seen. There was no autopsy.

AN ADDRESS.

BELLEVUE AND ITS RELATION TO MEDICAL PROGRESS.³

By LANDON CARTER GRAY, M.D.,

OF NEW YORK;

PROFESSOR OF NERVOUS AND MENTAL DISEASES IN THE
NEW YORK POLYCLINIC.

THE alumni of this college who graduated a quarter of a century ago look back with very tender memories to the remarkable men then composing its faculty, probably the most brilliant group of medical teachers ever gathered together in this country. By an easy effort of the memory, so striking were their characteristics, we can recall them all: Austin Flint, with his massive head and benign face, which was once compared to that of Fénelon, the French prelate and author; James R. Wood, the incomparable operator, eagle-eyed, rubicund of visage, spotlessly attired in his dress suit, even during the morning, and invariably adorned with a buttonhole nosegay; Van Buren, grand of manner, with an easy flow of simple words, and his high head knocking the stars; Hamilton, erect in his military bearing and precise in language; Barker, husky of voice, but of strikingly commanding presence; Isaac E. Taylor, a tremendous man, as I recently heard him called; Sayre, now living at a ripe age, with the satisfaction that is rarely vouchsafed a man of genius, of seeing his own original

¹ "Clinical Examination of the Blood," p. 345.

² Starr's "American Text-Book of Diseases of Children," p. 342.

³ Delivered on the occasion of the laying of the cornerstone of the new building of the Bellevue Hospital Medical College, New York, November 13, 1897.

ideas universally accepted; and Austin Flint the younger, whose lectures are to-day as lucid and charming as of yore, when we sat on the benches nervously apprehensive lest a mistake of one-hundredth of an inch in the diameter of a Malpighian corpuscle or blood-globule should make us miss our sheepskin.

We medical men have no saints, or else this school would be our shrine. But it is doubtful after all, whether laying the cornerstone of a medical school is not as important as the same ceremony in relation to a church, or whether any power short of omniscience itself can determine which is the most far-reaching in effects; for the minister and the physician certainly have an identical purpose, the relief of human suffering, although each attains his purpose in his own way, the former by the inculcation of ethical principles and the belief that happiness will come after death, the latter by easing pain during life by material means. It should be no reproach to either Religion or Medicine that their agents must be of necessity fallible human beings, who are often cruel and short-sighted, but it should be remembered that the persecutions of the one and the cruel methods of the other are more frequently the outcome of organic limitation of the human brain than of unworthy motives. In the dawn of civilizations, as Herbert Spencer has shown, the priest and the medical man were one, but with the differentiation of pursuits incidental to the evolution of society they have gone apart, notwithstanding their real unity of purpose. Nevertheless, even to-day most of the charitable work of the church would be impossible without the aid of the physician. Go down the street into Bellevue's great city of the sick, into its great wards, teeming with patients, and you will be impressed at every turn with the evidences of man's humanity to man, but at the same time you will be very apt to forget that back of it all is the medical school—even the precise cleanliness is due to a physician, because cleanliness is nothing more than popular antisepsis, while antisepsis is only scientific cleanliness; aye, and back of every hospital, dispensary, and sick-room in the land is the medical school. The bubonic plague, now limited to the East, extended throughout Europe during the Middle Ages, causing hundreds of thousands of deaths. Typhus fever, which was familiar to practitioners thirty years ago, has never been seen by many middle-aged men in this room. The control of smallpox is so efficient that numerous insurance companies do not require vaccination on the part of applicants. We all remember how the Asiatic cholera knocked at our doors a few years ago, and failed to get in. The death-rate of diphtheria has been lowered fifty to seventy-five per cent. The number of people in the community wearing eye-glasses is a striking object lesson of what the oculists have done, and every medical man is familiar with the revolution of recent years in the treatment of women's ailments, nervous and mental diseases, and surgery. What has rendered all these improvements possible is the medical school. In it has been taught the natural course of disease and the results of the employment of medicinal agents, and through it has come the training school and the vast improvements in hygiene and dietetics.

The prize of the French Salon in 1892 was given to a picture by Fritel, entitled "The Conquerors." It represents a serried phalanx of magnificent warriors, whose spears glisten across a vast plain as far as the eye can see. In the van is Julius Cæsar, "the foremost man of all this world," as Shakespeare calls him, the Egyptian Rameses the II., Attila, the "Scourge of God," Hannibal, the Carthaginian, Tamerlane the Tartar, Napoleon, Alexander the Great, Nebuchadnezzar of Babylon, Charlemagne, and many others who have made history. On either side are the stark and naked bodies of the dead in ghastly array. But these were not the true conquerors of the world. Fritel should paint another picture representing a long white-robed procession, not bedecked with martial trappings, of those who have tried to lessen the sorrows of the world, no passing between aisles of the dead, but through tumultuous throngs of the glad living, singing pæans of praise and joy; and among these stately aristocrats would be found Jenner, who gave us vaccination; Morton and Simpson, from whom came ether and chloroform; Pasteur and Lister, who made modern surgery possible with antisepsis; Koch, to whom we owe tuberculin and antitoxin; and Koeller, who bestowed upon us cocaine, which has revolutionized minor surgery.

In a curious book lately published in Paris, I happened upon an astonishing illustration of the progress of medicine. It appears that in 1686, Louis the XIV., the greatest monarch of his day, was found to have a fistula. At first it was treated with a plaster composed by a lady of the court, but this proved unavailing, and twenty days afterward the abscess was opened with a cautery, which was applied one hour and a half. Then the waters of Barèges were recommended to his majesty, and four persons suffering from fistula were sent thither while the court surgeon experimented upon them with the waters. The waters of Bourbon were next exploited, and many individuals were put into the hospital and treated with various vaunted remedies. Finally, at the end of a year, the knife was used, but before this was done all fistulous patients were operated upon by the surgeon, Fèlix, so that he might acquire the necessary skill. In spite of all these precautions, it was fifty-four days after the operation before the King could walk out. For this bungling surgical procedure the first surgeon, Fèlix, received 300,000 livres (equivalent to about \$120,000 of our money), a large property, and two titles of nobility. The next surgeon obtained 100,000 livres, another 80,000, a fourth 40,000, and the assisting apothecaries each 12,000. At the present day any fistulous Weary Waggles of the comic papers picked up intoxicated from the gutter and sent to the Island would be cured within the two-weeks' sentence which the magistrate would probably impose. This is the difference in 200 years of progress!

In view of this identity of purpose of the minister and the physician, it is rather singular that the former should have received such generous aid in the way of endowments in this country, while the latter has been given very meagre support. Abroad, in France, Austria, and Germany, the medical schools are endowed by the State, and it is a significant fact that from this portion of Europe,

especially from Germany, in which there are over fourteen endowed universities, have come all the great advances of modern medical science. In this modern world with its far-driven specializations, the specialist in money-making must necessarily accumulate wealth with more facility than the professional man, to whom pecuniary gains are only incidental, and whose chief energies are given to his profession; and medicine is the least lucrative of all professions, as so much teaching is required of its best men. No medical professor in the United States receives the salary frequently paid by a first-class insurance company to its medical director, and the compensation for one-to three-hours' daily teaching or the duties incident thereto, is usually less than the salary of the medical director of the smallest insurance company, while there is often no remuneration at all, for such services. This lack of endowment is not only extremely unfortunate in that it limits the facilities of the medical schools, but also because it absolutely debars many men from entering upon much magnificent scientific work which in itself is non-lucrative. Talent, after all, seeks the best market, just as do potatoes, cabbages, meat, or cattle. Some cloudy-minded transcendentalists may scout at this idea, yet it is an obstinate fact. What difference does it make, after all, even if it is so? The world should be thankful that every once in a while it has the great benefit of men who can think clearer and farther than the average, and it ought to encourage them in every way. Carlyle once said that England could very much better afford to lose its Indian Empire than to go without Shakespeare. A few years ago I was rather startled by the statement of a celebrated French surgeon who was visiting this country, that he believed New York would be the medical center of the world within twenty-five years, "because," he said, "you have the enormous population around you here, you have the wonderful transportation facilities which bring patients to you from all over your vast continent, you have the hospitals, you have the medical schools, and all that you now need are the endowments, which must come by that time out of the superabundance of the wealth of this richest of all lands."

MEDICAL PROGRESS.

Orthoform.—EINHORN and HEINZ (*Ther. Monatshefte*, October, 1897) have discovered a local anesthetic to which they have given the name of orthoform. It is a white, light, crystalline powder, without taste or smell. It is only slightly soluble in water, and therein lies its chief value. It dissolves just fast enough to cause a lasting anesthetic influence. Its action is observed upon mucous membrane, granulation tissue, or the surface of a wound. Either as a powder or mixed in a salve it is especially adapted for use upon burns of the third degree, upon painful ulcers, carcinomatous or otherwise. The remedy is absolutely non-poisonous. It limits the amount of secretion, absolutely prevents putrefaction and fermentation, and as a stimulating, healing dressing for a wound it has much to recommend it. In painful ulcers of the larynx, a single treatment with this drug will reduce the

smarting during a period of twenty-four hours. It may be used internally for the relief of stomach or intestinal pain. Its action is especially noticeable in ulceration and carcinoma of the stomach, but in cases of chronic gastric-catarrh or dilation little benefit is to be expected from its use. The muriate of orthoform is freely soluble and may be used internally, but is not adapted to subcutaneous injections on account of the intense pain which the acid solution occasions. On account of the lack of poisonous qualities it may be dusted upon surfaces *ad libitum*. In salves a strength of 10 per cent. is recommended. Internally, from 5 to 15 grains may be daily administered.

Eka-iodoform.—A preparation produced by SCHERING (*Münch. Med. Wochenschr.*, October 12, 1897) in which a small quantity of paraform is mixed with iodoform, is called eka-iodoform. According to Gottstein's investigations the remedy is sterile and has antiseptic action, properties which are lacking in iodoform. Thomalla has employed it in 100 cases with good results.

Detection of Spermatic Fluid.—According to LECCO (*Therapeut. Monatshefte*, October, 1897) it is easy to recognize spots of spermatic fluid, even after the lapse of some years. The following microchemic test is peculiarly sensitive. The spot should be soaked in water, and a drop of the solution introduced between the microscopic slide and the cover-glass; next, a drop of a saturated solution of iodine in potassium iodide is allowed to flow under the cover-glass—a number of remarkably beautiful crystals which are characteristic of spermatic fluid will then be formed. They are stained brown, and are rhomboidal in form, often occurring in the form of crosses. After the discovery of this reaction Lecco learned that Florence had independently made a similar discovery.

THERAPEUTIC NOTES.

Eunatrol as a Cholagogue.—Eunatrol is a name given to the oleate of soda. It occurs as a white powder, with a slight, not disagreeable, odor, and does not become rancid. It may be given in capsules or tablets, the daily dose being from 30 to 40 grains. BLUM (*Bull. Gen. de Therapeutique*, July 23, 1897) has found that eunatrol has a marked influence on the flow of bile, due presumably to a direct stimulation of the hepatic cells, since the drug acts in this way, both when given by the mouth and when injected subcutaneously in aqueous solution.

The Treatment of Contusions by Menthol Collodion.—NAME (*Jour. de Méd.*, September 12, 1897) gives the following directions for the treatment of contusions:

(1) Rigorous antiseptics; careful cleansing of the parts with ether. (2) The application once or twice daily of collodion, containing ten to twenty-five per cent. of menthol. Under this treatment pain quickly subsides and the constrictive influence of the collodion causes the disappearance of the effusion in from two to four days. Extensive contusions about the joints are not so favorably influenced.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be type-written.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

SATURDAY, DECEMBER 4, 1897.

DR. JACOBUS' ADDRESS.

THE inaugural address of the new president of the Medical Society of the County of New York, Dr. A. M. Jacobus, which was published in the last number of THE MEDICAL NEWS, contains much which merits careful consideration. The sharp criticism of the methods employed by the New York City Board of Health will meet with approval or indifference, according to the point of view of the individual physician who may or may not have come in personal contact with that body, but the fact remains that a sharp line should be drawn between its proper functions and the rights of the family practitioner, if for no other reason than to lessen the possibility of controversial encounters.

Dr. Jacobus dwelt at length upon one subject of such paramount importance that his words should sink deep into the inner consciousness of all and result in the abrogation of a system which, in the light of present knowledge and practice, is nothing less than a disgrace to intelligence. "The name of midwife in this city to-day is synonymous with feticide, infanticide, and homicide. Midwives have no legal status; it seems only requisite, in order that they may qualify for such a calling, that they shall have

attended one or more cases of confinement, perhaps their own, obtain a certificate from two physicians and file the same at the Health Department, when they are graduated to go on their errand of mercy and, not unfrequently, death."

It is unnecessary to lay stress upon the importance not only of again agitating this subject to the greatest possible degree, but of hastening the motion of legislative machinery whereby a law shall be enacted for the suppression of the evil entirely, or, at least, providing for the proper education and preparation of midwives as a class. The Society of Medical Jurisprudence has already appointed a committee of its members looking to this end, and it is sincerely to be hoped that the County Medical Society will join hands with it in its laudable endeavors.

Even to those who are supposedly familiar with the work of the Society it is a matter of surprise to learn of what has been accomplished during the past seventeen years in the way of protecting the public and the profession from irregular medical colleges, and physicians, midwives, and druggists illegally practising medicine. Until very recently, it has been the only organization in this city to prosecute offenders of this class, and the expense attendant upon the work during these years has amounted to nearly \$45,000. This admirable work must not be allowed to cease, but to carry it on more money is needed by the Society. The annual dues are but \$3, a sum within the reach of all. Five hundred new members are necessary, and this number, added to the eighteen hundred now on the active list, will make the County Society a greater power for good in State and municipal affairs than it has ever been. It is the duty of every reputable physician in this city to show his appreciation of what is being done for his benefit, individually, and for that of the profession collectively, by adding his name to the Society's list.

THE "TRADE" OF MEDICINE.

THAT the profession of medicine is the noblest of all vocations we personally are not inclined to doubt. By the world at large, it has been held as second only to that of the clergyman, the apostle on earth of the Great Healer. That this honored calling should in recent years have become so largely a mercantile pursuit, that it is affected by our practical ideas in a country where all is business is per-

haps not at all surprising. This spirit has largely contributed to degrade the physician from his former high estate; but a more immediate cause is the excessive development of specialism.

Far be it from our purpose to speak slightly of special work! The extraordinary development which has marked the progress of medicine and surgery during recent years has compelled men to devote themselves to some one branch, and no one knows better than physicians themselves how much mankind owes to broad and comprehensive specialism practised by so many distinguished men at the present day. But while mankind has profited, our own profession has suffered. Specialism has altered the personal relation between the physician and patient; it has made it a transient and generally a purely business connection. It has developed a large number of men of little special, and less general, knowledge of a great science, whose interest in the patient is limited to the amount of cash which he may pay. It has developed men to whom a profession is purely a matter of business, to whom the practice of medicine is as a department-store in which they have a counter.

Specialism, we believe, has greatly lessened that scholarship in medicine which was once characteristic. Indeed, there is a well-grounded fear that it will eventually banish the "scholar in medicine," whom Dr. DaCosta describes as "an attractive figure, indeed": "We see him pursuing what noble ends; ambitious for what lofty recompense; passing from life's beginning to its end, through what scenes of sustained satisfaction—not grasping and scrambling for petty prizes or fleeting reputation and wealth, but aiming only at lofty objects."

And with the scholar has passed also the old practitioner whose heart was generous and whose ways were gentle, who to a sound knowledge added a wide range of sympathies, liberality of thought and feeling, and who, above all, was deeply impressed with the ennobling responsibility of his profession.

We remember entering the office of such a physician, now dead, just as he arrived, deeply affected, from the death-bed of a patient and friend of fifty-years' duration. While we were talking the telephone bell rang, and he asked the writer to answer it. The message was from the wife of his former patient, who begged that, as their clergyman was away, would the

old doctor come and be with them to the end. What would the specialist of to-day, with his departmental view of man, his narrow sympathies, and his cash consultations, think of such a relation as this between the physician and his patient?

It goes without saying that there is nothing in specialism as such, which militates against a high purpose in medicine; the fault lies with some of the men who practise it. It is the modern, up-to-date, mercantile specialist who has done so much to change the science of medicine from a profession to a business; it is a business to them and as a business must be advertised, and hence the constant appearance of even reputable physicians in the public press; hence the "advance notices," as our theatric friends would say, which are given to the daily papers; descriptions of supposed discoveries of cures for this and that disease, as has become quite customary in many of our large cities.

What would our professional fathers, we wonder, think of the physician who covered the walls of his waiting-room with pictures of his patients, duly signed with such dedications as: "To the great Dr. —;," "To the only Healer;" "To the distinguished, the only surgeon;" "To my savior Doctor —." What would they think of a physician who pins notes from distinguished patients on his waiting-room door that they may be read by and duly impress those seeking his *distinguished* services? What would the old physician say of a doctor who gave his patients charts (with the doctor's name inscribed thereon in large letters) upon which the outline of the patient's heart was mapped out "before the treatment," "during the treatment," and "when discharged—cured." As a matter of fact the patient's condition (the charts to the contrary notwithstanding) had grown worse and worse and he sought another physician to find out what the *new* ailment was!

What would the older men think of physicians who, like railroads, announce special rates to professionals, preferring a hundred patients at \$3 a piece, with a picture, autograph, and inscription, which would serve to advertise when hung up in a proper place, to twenty-five at \$5 and no lithograph.

These examples are all of a kind, and could be indefinitely multiplied. Medicine to these men is a business, and the secret of business success being, as the late Mr. Barnum remarked, "to advertise,"

they follow the distinguished circus man to the best of their ability.

The man of whom we are speaking never allows the "Doctor" to be forgotten; his shop is ever with him. We are reminded in this connection of what Mr. Hayward says of Sir Henry Holland, that scholar, physician, and gentleman, "That, except when humanity required, he discreetly suppressed 'the doctor,' " and in speaking of his reticence about his patients, adds: "He rightly deemed that the physician's lips should be sealed like the confessor's." How strange this must read to some of our professional friends who so love to tell of those they are and have been treating!

That the trade idea in medicine is abroad in the land, or that advertising and unprofessional methods are resorted to by many men—even members of reputable medical societies—or, finally, that the old spirit which gave the older physicians and their profession so high a place in the community is dying, if not already dead, we suppose will hardly be denied.

And the remedy! He who runs may read. The advertising doctors are not likely to mend their ways—there is too much money in it; but it seems to us that a little, or rather a good deal of, discipline administered by medical societies might have a salutary effect on the particular kind of quack to which we have alluded.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION AND THE MARINE HOSPITAL SERVICE.

THE latest plea for a Department of Public Health in the *Journal of the American Medical Association* of November 20th, is so acrimonious and biased in many of its statements that we must protest against it as unbecoming the journalism of a liberal profession. Personal abuse is no argument, nor is misstatement of facts a help to the establishment of truth and right.

The necessity for a more authoritative, Federal supervision of general matters of public health is admitted by all. The question at issue is, shall a new department be created, with new officers and indefinite expenditures, or shall these public health functions be assigned to an already existing branch of the Treasury Department—the Marine Hospital

Service, a body of sanitarians already organized, disciplined, tried, efficient, and only needing more authority and the frank and manly cooperation of local boards of health to fulfil all the requirements of a national guardian of public health.

The organization of a National Board of Health with a departmental officer at its head, is an untried experiment. The plan proposed in the *Journal of the American Medical Association* establishes a deliberative body which in number and diversity of character would be equivalent to a third house of Congress. On the other hand, the Marine Hospital Service is an organization whose work is on record and whose future in the larger capacity of national guardian of public health can therefore be foreseen. In the face of an epidemic *action* is what is needed, not deliberation. In what way can this be better accomplished than by an organized body of men under military discipline and military orders?

Accusing the Marine Hospital Service of inefficiency and decadence proves nothing, and the characterization of its Supervising Surgeon-General as "indolent, arrogant, tyrannical, and playing for social prominence to the disregard of the best interests of his service" is likely to stamp the writer as more jealous than truthful. Neglecting the personal accusation because of its absurdity, let us take up the more serious charge that the Marine Hospital Service, as a conservator of public health, is inefficient. Its work in a recent epidemic is referred to as "the miserable fiasco at Brunswick." We shall here briefly outline the history of the yellow-fever epidemic of 1893 at Brunswick, and leave it for our readers to conclude for themselves, first, whether the Marine Hospital Service can be held responsible for the admission of the disease and, secondly, whether its management of the epidemic was a "fiasco."

In the first place it is now known that yellow fever occurred, but was not reported, in Brunswick in October, 1890. The epidemic of 1893 has been traced to gross violations of Treasury regulations by the local quarantine authorities. Several vessels from Cuban ports, instead of stopping at the Marine Hospital Station at Sapelo Island, as they should have done, went directly to Brunswick where they were dealt with by the local health authorities. It was the duty of the local quarantine officers to send these vessels back to Sapelo Island at once. This

was not done. The first death occurred June 25th, and the victim was the master of a probably infected vessel from Havana, which was disinfected by the local health officers and released in two days. Here again quarantine regulations were disregarded. The vessel should have been returned to Sapelo where it would have been disinfected and detained for at least five days instead of two. Had these precautions been taken, the master's disease would have been diagnosed and he would not have been allowed to go to Brunswick and stay at a hotel, which the local authorities permitted him to do.

Before July 17th, two other probably infected vessels arrived from Cuban ports with sand and earth ballast. The crews after discharging this ballast returned in each case to Brunswick and scattered about the city.

When it was found that the local authorities could not or would not enforce strict quarantine regulations, Marine Hospital Surgeons were ordered to the scene. Assistant Surgeon Branham, M. H. S., took charge of the local quarantine station July 31st, and died of yellow fever August 20th. He acquired the disease there and the probability is that the epidemic was due to the filth brought as ballast in vessels from Cuba. As soon as the first case was reported in Brunswick, the infected areas were depopulated, cordoned, and disinfected. When the disease became epidemic a comfortable detention camp was established twenty-five miles out of town to which refugees might go; revenue cutters and small boats patrolled the water-ways about the city; a cordon of land-guard posts surrounded the city at a distance of four miles, and a system of train-inspection was established.

The result of the vigorous enforcement of these precautions by the Marine Hospital Service was, that besides Brunswick and its environs, only the town of Jesup became infected, and this infection occurred before the Marine Hospital Service assumed control. The number of cases of yellow fever occurring during the epidemic was 1070, of which 46 were fatal; certainly a most creditable showing when one considers that the disease appeared early in the season and found the city in a most unsanitary condition.

Indeed, the successful manner in which this epidemic was confined and suppressed by the Marine Hospital Service is in striking contrast to the dilatory methods of the local quarantine officers.

ECHOES AND NEWS.

Quinin and the Klondike.—A physician of Louisville, Ky., is reported as making a fortune in the Klondike gold fields by selling quinin capsules at \$3 apiece.

Scarcity of Dissection Material at Cambridge.—It is said that the study of anatomy at Cambridge (Eng.) is seriously hampered by the difficulty experienced in providing subjects for dissection.

The Faculty of Medicine of Paris.—According to the *British Medical Journal*, the decree excluding foreign students from the medical classes of the Faculty of Paris will shortly be withdrawn.

Kangaroo Ailments.—It is said that kangaroos in captivity suffer greatly from enormous corns, several ounces in weight, and difficult to remove. In damp weather they also develop gouty symptoms.

Woman's Hospital Society of New York.—The following officers have been elected for the ensuing year: President, Paul F. Mundé, M.D.; vice-president, Leroy Broun, M.D.; secretary and treasurer, James N. West, M.D.

Spain Quarantines against Pensacola.—Owing to the death of a man from yellow fever at Pensacola, Fla., a royal decree has been issued in Spain ordering that all vessels arriving at Spanish ports from Pensacola be quarantined.

Music and Measles.—An orchestra composed of women was to give a concert at Stroudsburg, Pa., last week, but when the time came not one of them appeared. Inquiry revealed the fact that every member had been stricken with measles.

Gloves in Surgery.—Wolfer advises the use of gloves in all septic and aseptic operations, and also for making examinations of the mouth, rectum, and vagina. He employs the ordinary military glove of leather, which he keeps in three per cent. carbolyzed glycerin.

New Sources of Malarial Infection.—Dr. S. Pulverenti of Naples claims that he has established the fact that malaria can be transmitted in the dust of cereals and textile plants, flax, hemp, etc. It is, therefore, possible for malaria to be contracted without the presence of heat, moisture, or soil.

Death-Rate for Week Ending November 27.—The Bureau of Vital Statistics of the New York Health Board reports 611 deaths, including 11 from measles, 6 from scarlet fever, 18 from diphtheria, 5 from typhoid, 37 from heart disease, 88 from pneumonia, 88 from phthisis, and 51 from kidney disease.

Bilharzia Ova.—At a recent meeting of the London Pathological Society, live *Bilharzia* ova in the process of hatching were shown under the microscope. The parasites were obtained from a soldier invalided home from Mashonaland, where it is supposed he contracted the disease while bathing.

Healthfulness of Cycling.—After a prolonged consideration of the subject, the Paris Medical Society has come to the conclusion that cycling is excellent exercise for healthy people, is very beneficial for those suffering from nervous disorders, but is undesirable for delicate people who are liable to suffer from over-fatigue.

Milk and Disease.—In a communication made by Professor Delépine at a recent meeting of the Pathological Society of Manchester, England, in regard to the conditions under which cow's milk becomes pathogenic, *time* and *temperature* were given as the most important factors in rendering milk unfit for consumption.

American Association for the Study and Cure of Inebriety.—The twenty-seventh annual meeting of this Association will be held December 8, 1897, in the Hall of the Washington Home, 41 Waltham street, Boston, Mass. Many men prominent in the study of this question both in this country and abroad, will take part in the meeting.

Obituary.—The death is announced of Dr. P. Castells y Bellespi, Sanitary Inspector of the Province of Barcelona, Spain. Death was due to typhoid fever, which he contracted while engaged in combating an epidemic of this disease. He was much interested in preventive medicine, was editor of the *Revista de Higiene y Policía Sanitaria*, and was also secretary of the Editorial Committee of the *Gaceta Medica Catalana*.

Yellow-Fever Statistics.—The Marine Hospital Service reports the total number of cases of yellow fever up to November 19th as follows: Louisiana, 1847; Mississippi, 1625; Alabama, 740; Tennessee, 52; Texas, 16; Illinois, 4; Georgia, 3; Florida, 1; Kentucky, 1. Total number of cases, 4289, of which 446 proved fatal, or an average of about 10½ per cent. In Mississippi the death-rate was less than 6 per cent.; at New Orleans, 14⅓ per cent., and something less than 13 per cent. at Mobile.

An Antiseptic Dwelling.—Dr. W. van der Heyden, the bacteriologist, has recently had constructed an antiseptic residence at Yokohama, Japan, the walls of which are made of large blocks and slabs of glass mounted in metal and hermetically closed. Ventilation is provided for by small openings near the ceiling of the upper story, which allow egress of air without permitting the entrance of the outer air, which is exclusively supplied through a pipe, extending some distance beyond the house, into which it is forced, filtered, and sterilized by passing through glycerin.

Obituary.—Dr. Cornelius Olcott died recently of pneumonia at his home in Brooklyn, N. Y., in the sixty-ninth year of his age. He was born in Jersey City, N. J., of English parents, and was a descendant of Thomas Scott, one of the first settlers of Hartford, Conn. He studied medicine at the University of the City of New York, graduating in 1849. During the war he was a surgeon under General McClellan at Fortress Monroe, and later under General Grant at Fredericksburg. At the time of his death he was a member of the Kings County Medical Society.

The Philadelphia Medical Journal.—It is announced that the opening of the new year will witness the commencement of a new weekly medical periodical in Philadelphia, to be issued under the auspices of the leading members of the profession, including a number of gentlemen whose reputation is world-wide as teachers in the various colleges of that city. The editorial management will be entrusted to Dr. George M. Gould, whose experience and well-known ability give assurance that the new periodical will make its mark. We extend to our forthcoming contemporary the right hand of fellowship, for the harvest field is wide and there is room for all earnest laborers.

OBITUARY.

RESOLUTIONS ON THE DEATH OF CHARLES H. AVERY, M.D.

AT a stated meeting of the Medical Society of the County of New York, held at the New York Academy of Medicine, Monday, November 22, 1897, the following resolutions were adopted:

WHEREAS, Dr. Charles H. Avery, our esteemed and honored Secretary, has been removed by death, which occurred November 2, 1897,

Resolved, That we hereby express our deep sense of the loss which our Society has sustained in his decease; that we desire to bear testimony to the sterling integrity of his character, to his genial social qualities, and to his devotion to the interests of this Society, which he has so long, faithfully, and efficiently served in the capacity of secretary; that a copy of these resolutions be transmitted to the medical journals of this city, and an engrossed copy be sent to the family of our deceased associate.

JOHN L. WARREN, M.D.,

WILLIAM E. BULLARD, M.D.,

Committee.

CORRESPONDENCE.

TAPEWORM AS A CAUSE OF INTESTINAL PERFORATION.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: At the suggestion of Dr. H. N. Mateer, Professor of Biology in Wooster University, I enclose a short description of an instance of intestinal perforation in a rabbit by means of a tapeworm. I consider the case an odd one, and so submit it to your criticism with the hope that it may be deemed worthy of publication.

Upon opening the abdominal cavity of a wild rabbit a broad tapeworm, twenty-two or twenty-four inches in length, was found in the anterior, left, lateral portion of the cavity, between the colon and the greater curvature of the stomach.

Examination proved that the worm had escaped from the alimentary canal through a hole in the small intestine at a point about eighteen or twenty inches from the duodenal

loop. The wound from which it had escaped included half the circumference of the small intestine, the edges of which had the appearance of having been lightly attached to some other portion of the viscera, and were everted and resembled a circular lip. Very slight inflammation was present at this spot, but no other indications of an inflammatory process could be found elsewhere in the abdominal cavity. Fecal matter which had escaped from the wound was found in all parts of the cavity, about the stomach, and in the recesses surrounding the bladder and uterus. The greater part of the fecal matter consisted of minute, clean particles of cellulose whose cleanliness would seem to indicate that they had been free in the cavity for a considerable time. The cecum, colon, and rectum all contained the normal quantity of matter. When killed, the rabbit was running rapidly and gave no outward appearance of being weak or disabled.

Biological Department, University of Wooster.
WOOSTER, OHIO, November 20, 1897.

SEWAGE FARMS.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: The editorial which appeared in THE MEDICAL NEWS of November 6th fails to point out a very important factor: A sewage farm cannot be successfully maintained when established haphazard upon soil of every sort. It makes a great difference whether or not the latter is sandy, and if so, of what variety. If established upon an impervious clay subsoil, which is nearly level, the results will be entirely different from those attained when the surface has a greater slope and is capable of soaking up and draining away such materials.

Furthermore, certain soils are the natural habitat of the nitrifying organisms, the office of which appears to be the destruction of pathogenic bacteria. There is great danger that the crude method of taking water from any source which happens to be convenient as the basis of a public water-supply, will be repeated in attempting to dispose of sewage by the method proposed.

M. A. VEEDER, M.D.

LYONS, N. Y., November 27, 1897.

MEDICAL REQUIREMENTS IN THE STATE OF WASHINGTON.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: I am in receipt of many inquiries concerning the medical laws of the State of Washington. In reply I would say that all persons intending to practice Medicine or Surgery in this State are obliged to pass an examination before the State Board of Medical Examiners.

These examinations are held the first Tuesday in both January and July. The January examination is held on the west side of the Cascade Mountains and the July on the east side. No temporary certificates are granted, and no exception is made to the rule.

F. H. COE,

Secretary of the Medical Society of the State of Washington.

SEATTLE, WASHINGTON, November 25, 1897.

A CORRECTION.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: In my article published in your journal of November 13th, it was stated that during 1896 252,548 steerage passengers were inspected at this station. It should have read that this was the total number of passengers of this class who came to the United States during that period (1896), and out of this number 190,928 were inspected at this station. I desired to show that the great bulk of these people came to the Port of New York.

Very truly yours,

A. H. DOTY, M.D.

NEW YORK, November 23, 1897.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

THE HEALTH PROTECTIVE HOSPITAL FOR CONTAGIOUS DISEASES—DEATH OF DR. HARRISON ALLEN—COLLEGE OF PHYSICIANS OF PHILADELPHIA; SECTION ON OPHTHALMOLOGY; SECTION ON GYNECOLOGY—THE NEW KENSINGTON HOSPITAL FOR WOMEN—FREE LABORATORY DEMONSTRATIONS AT THE PHILADELPHIA POLYCLINIC.

PHILADELPHIA, November 29, 1897.

A MEETING was held on November 15th, in the office of the Mayor of Philadelphia, by a number of prominent laymen and physicians interested in the establishment in this city of a pay hospital for contagious diseases, and such advance in the project was reported that it is believed that the institution will be built in the near future.

The sudden death on November 14th of Dr. Harrison Allen, Emeritus Professor of Comparative Anatomy in the University of Pennsylvania, has removed another of the fast thinning group of men to whom Philadelphia owes much of her prominence in scientific matters. The local scientific bodies with which Dr. Allen was connected have passed appropriate resolutions upon his death.

A stated meeting of the Section on Ophthalmology of the College of Physicians was held on November 16th. Dr. William Campbell Posey presented a case showing metastatic iridocyclitis in both eyes, causing blindness; the exciting cause of the iridocyclitis was held to be an intense inflammation of the nose and its accessory sinuses resulting from long-continued inhalation of sulphuric-acid fumes to which the patient had been exposed. The determination of the exact cause of the blindness in this instance happened to be important, inasmuch as the patient had been an unsuccessful plaintiff in a damage suit against her employer, in whose factory she was obliged to expose herself to the acid fumes. Dr. William F. Norris exhibited a patient having a cyst of the orbit, causing a downward and outward dislocation of the eye on the affected side. Dr. H. F. Hansell showed a case of traumatic paralysis of the third nerve due to a gunshot wound on the nasal side of the orbit, without injury to either the eyeball, or to the optic nerve; a skiagraph of this case showing the foreign body (a No. 4 shot) *in situ* was shown by Dr. W. M. Sweet. Dr. George C. Harlan reported a case of transient pulse in the retinal artery, induced by the application of homatropin; and in his dis-

cussion of the case drew attention to the possible employment of this drug in the diagnosis of doubtful cases of glaucoma. Dr. G. E. de Schweinitz made some remarks on cases of central amblyopia, and showed field-charts of five different varieties of this condition. One class of monocular central amblyopia in certain cases of compound hyperopia without the presence of squint was referred to as being a likely cause of reduced vision. Dr. Edward Jackson read a paper on the technic of needle operations upon the lens and capsule, suggesting that most of the aqueous humor be allowed to escape, and as the lens comes close to the cornea to enter the needle through the capsule, making as small an opening as possible, and stirring up the lens substance freely with the point of the needle. By this maneuver the lens substance does not escape into the anterior chamber and set up an irritation.

At the last stated meeting of the Section on Gynecology of the College of Physicians of Philadelphia, held on November 18th, Dr. Edward P. Davis reported a Cæsarian section for impossible labor, in a woman with a contracted pelvis, 7½-months pregnant, with recovery of the mother, and safe delivery of the child. He also reported a symphysiotomy for a similar condition of the pelvic canal, and in this operation it was found that it was impossible to separate the pubic symphysis by the use of either the Galbati knife, or the bistoury, so that a saw, made after a model devised by the speaker, was used for the purpose, with immediate effect; ten months after the operation firm union had taken place. Dr. George E. Shoemaker reported the clinical histories and operation-notes of three cases of fibroid uterus, of an instance of pyosalpinx intermittently draining through the uterus, and of two cases of ovarian cysts. Dr. H. D. Beyea reported a case of acute strangulation of a prolapsed uterus and vagina, for the relief of which condition vaginal hysterectomy was performed; and Dr. J. M. Baldy related two similar cases, in both of which he had preferred to operate by the abdominal, rather than by the vaginal route.

Final touches to the new Kensington Hospital for Women, which has been reconstructed during the past summer, have been given, and the building has been formally thrown open for inspection. The new structure is of fire-proof construction throughout, provides for the accommodation of forty patients, and contains every improvement for the conduct of gynecologic surgery under the best auspices. It will be recalled that the hospital was founded in 1883, by Dr. H. A. Kelly of Baltimore, and at present is under the direction of Dr. C. P. Noble, his successor as surgeon-in-chief.

A series of laboratory demonstrations, free to physicians and students of medicine and lasting from November 15th until December 11th have been begun at the Philadelphia Polyclinic.

For the week ending November 20th, the total number of deaths reported in this city was 339, of which 103 occurred in children under the age of five years. Compared with last week, the mortality showed a decrease of 45, and with the corresponding week of last year, a decrease of 35. There were 230 new cases of contagious disease reported, as follows: scarlet fever, 56 cases, 3

deaths; diphtheria, 140 cases, 28 deaths; and enteric fever, 34 cases, 4 deaths.

The number of deaths occurring in this city for the week ending November 27th, reached a total of 394, an increase of 55 over the preceding week, and an increase of 5 over the corresponding week of last year. Of the total deaths 124 occurred in children under five years of age. New cases of contagious disease numbered 239, as follows: Diphtheria, 130 cases, 32 deaths; scarlet fever, 55 cases, 4 deaths; and enteric fever, 54 cases, 3 deaths.

OUR BERLIN LETTER.

[From our Special Correspondent.]

DR. FRANK OF CHICAGO READS A PAPER BEFORE THE BERLIN MEDICAL SOCIETY—ATTENDANCE AT THE MEDICAL SOCIETY'S MEETINGS—TWO JUBILEES OF PROFESSOR VIRCHOW—A CASE OF SPONTANEOUS DELIVERY IN THE COFFIN AFTER DEATH AND BURIAL—THE TREATMENT AND BACTERIOLOGY OF WHOOPING-COUGH.

BERLIN, November 20, 1897.

DR. FRANK of Chicago recently read by special invitation a paper before the *Berliner Medicinische Gesellschaft* on his absorbable button or coupler for intestinal anastomosis. It was discussed by Professor Landau, who has witnessed several experiments with the button upon animals. He has employed it in one case upon a human being, and was very much pleased with the result.

Since Czerny's announcement at the Congress at Moscow that he considered the Murphy button the best procedure for intestinal anastomosis the question of adopting some such mechanical aid has been a living one in Germany. *Magni nominis umbra*—the shadow of a great name stands for much in German surgery, and it is probable that for some time to come most anastomoses will be accomplished with the aid of some such coupling apparatus. Dr. Frank's invention is like Murphy's button in most respects, except that it is made of an absorbable material—decalcified bone—which ought to prove a very advantageous addition to the good qualities of the Murphy button, and so has attracted a good deal of attention here in Berlin.

The Berlin Medical Society has about 1100 members, and holds its meetings once a week. They are invariably presided over by Professor Virchow, begin exactly on the minute announced, 7.30 P.M., and are regularly attended by from 500 to 800 members. There are a good many qualities here that medical societies in other countries, especially our own, may well envy. This is particularly true of the large attendance which is really typical of the profession in Berlin, and is an index of the intense earnestness of purpose and lively interest in things medical which characterizes German physicians in general. Not the least noteworthy item is the invariable presence of the President, Professor Virchow, who, at the age of seventy-six, is still ready to learn, but even more ready to encourage others, by his personal example, to keep up with the advances in medicine by hearing the latest discoveries described and discussed.

Two Virchow Jubilees have been celebrated within the last few days. The one the celebration of the fiftieth year of his career as a teacher in the University of Berlin, the other the appearance of the Jubilee number of *Virchow's Archives*.

A committee was chosen to present congratulations to the aged Professor. It was composed of a number of distinguished teachers in the University, and was headed by the Rector Magnificus and the Dean of the Medical Department. Professor Virchow, when congratulated by the Dean upon the wonderful success of his teaching career, answered with characteristic modesty. His success, he said, had not been due so much to his own work as to the early realization that the field of scientific medicine was so great that one man, single-handed, could accomplish nothing that would produce an effect upon the current of medical thought, and so he had drawn around him a school whose work had been wide and important enough to make an impression. He had been more fortunate than others in the associates who had come to him, but it was to them and not to him alone that the glory of success was due.

The Jubilee number of the *Archives* contains as a frontispiece a picture of the Master himself, and opens with a few words from him commemorative of the fiftieth year of the existence of the *Archives*. He says, with pardonable pride, that it has accomplished much more than its prospectus dared claim; that its long series of volumes (150 in number) form a rich and ever richer source of scientific medical instruction; but more than all this has been its influence in making clear to the world the essential unity of medical science. It is this that has been the main aim of its editor during the long years of its existence, and it is the accomplishment of the purpose that is his pride and strength in his old age.

As he states, the Jubilee number appears without pomp or ceremony. Its scientific spirit is too serious for that, but it constitutes, in the articles contained, the best proof of how it has ever combined the practical with the purely scientific in medicine. While founded on original work of the highest order, the articles on "The Production of Amyloid Degeneration," "The Pathological Anatomy of the Malpighian Bodies in the Kidney," "The Mechanism of Urination and of Bladder Closure," "The Connection between Section of the Vagus and Changes in the Heart-Muscle," and finally, "The Quantitative Estimation of Glycogen in the Liver" (by a compatriot, by the way, Dr. A. E. Austin of Boston), are all such as must be of lively interest to the general practitioner as well as to the scientific seeker after truth for its own sake.

An account of one of the rare cases of spontaneous delivery of a child some days after the death of the mother appeared in the last number of the *Vierteljahrsschrift für Gerichtliche Medizin*, and has given rise to considerable comment. The case is very well authenticated, as the body passed through the hands of medical and legal public officials before burial, so that the details are a matter of legal evidence.

The woman had been found dead in the river under

circumstances which seemed to point to suicide. Careful examination of the body was made to be sure that there was no evidence of injury previous to the immersion, and it was noted that she was in an advanced stage of pregnancy. Ten days later circumstances came to light which seemed to point to foul play, and the body was exhumed for further and detailed examination.

A tumor was found projecting from the vulva which had not existed at the time when she was placed in the coffin. This was found to consist of the completely inverted uterus and vagina. A little below it, lying upon the lower limbs, was a fetus 36 cm. in length.

Dr. Bleich, who reported the case, discussed the possible causes of the delivery, and considered that the usual causes do not afford a sufficient explanation. Neither the development of gas within the abdomen and the consequent pressure exerted upon the fundus uteri nor tonic contraction of the uterus due to *post-mortem* rigidity are sufficient explanation of this remarkable phenomenon, as far as he is concerned, neither nor both of them can account for it, if one is to consider the uterus as being in its ordinary *post-mortem* condition. He considered it probable that during the death agony there had been active contractions of the uterus which had almost accomplished the extrusion of the child, and then, that the pressure of putrefactive gases in the abdomen and the further tonic contraction of the uterus were sufficient to have completed the process of delivery.

In any case, the occurrence of an authentic instance of delivery after burial where there is not the slightest chance for doubt as to the mother's death before burial ought to prove a great source of consolation to those who have found in the published reports of such cases some confirmation of their fears as to the dread possibility of being buried alive.

Professor Hübner, in a recent lecture on whooping-cough, began with the question of treatment by asking the student who was going over a case with him (it is a regulation of the University here that a student must always study the case with the professor at a clinic), "What is the best remedy we have for whooping-cough?" The immediate answer was, "Bromoform." "But does it do any good?" Almost as immediate came the answer, "No," at which there was a titter promptly suppressed by the Professor, who said, very seriously, "That is just the state of the case; it is our best remedy, but how much good it really does is problematic. In some cases it seems to be of real service, but there are many in which it does not seem to have the slightest effect on the course of the disease."

To the question, "How long does whooping-cough usually last?" the answer was the usual text-book formula, "Four to six weeks"; but Professor Hübner assured the embryo doctor that "if all his patients with pertussis were better in two to three months he would be indeed lucky, while some of them would last the year out, despite his best efforts." Notwithstanding advances in medicine, the therapeutics of most of the children's diseases are no better than they were half a century ago. It was hoped that the demonstration of the bacteriologic cause of whooping-cough

would give a foundation for rational therapeutics; but the bother seems to be, so far, that the discoveries of the microbe of the disease have been too frequent and varied to be of practical value, and the claims of discoverers too little substantiated by later investigators to as yet awaken the hope that specific treatment may soon be possible. There are claims for two microbes of the disease here in Berlin. The last one described resembles the diphtheria bacillus, and has been found in the sputum of patients. The secular press have taken it up, and considering that morphology corresponds to pathogeneity, have been exploiting the fact that the diphtheria bacillus, under two different forms, produces both diseases to no little discomfort of anxious parents whose children, or neighbor's children, have whooping-cough. Verily, the press has become a wonderful disseminator of truth!

The other microbe described here, and assigned as the cause of whooping-cough, is a coccus. It is not easily found in the sputum, but may be cultivated by inoculating tubes of agar with portions of the minute, clump-like masses which occur in the sputum of patients having this disease. These are usually coughed up at the end of a paroxysm, and it is generally considered that it is their tendency to persistently cling to sensitive portions of the mucous membrane which causes the paroxysms.

The colonies are closely agglutinated together in cultures. A whole colony must be taken for examination, and is found to consist of closely packed cocci. The agglutination in the media, resembling the tenacity of the clumps in the sputum, is one of the characteristics of the microbe, and is considered proof of its connection with the disease.

In France, however, another form of coccus is claimed as the bacterial cause of the disease, while it may be noticed in the report of the recent meeting of the British Medical Association at Montreal that there is an English claimant for the specific pathogeneity of a short bacillus—*Si quid vis excipias*.

TRANSACTIONS OF FOREIGN SOCIETIES.

London.

INVESTIGATION OF SOME OF THE DISORDERS OF THE HEART—LOCALIZATION OF RHEUMATISM AND CHOREA—PERMANENT CURE OF PYLORIC STRICTURE BY LORETA'S OPERATION—HEMIPLEGIA IN WHOOPING-COUGH—ONE-SIDED BLUSHING—TREATMENT OF UTERINE DYSMENORRHEA.

AT the opening session of the Medical Society, October 11th, the president for the coming year, SANSOM, gave an address upon the *Investigation of Some of the Disorders of the Heart*. In the examination of the heart it is important to keep the patient as tranquil as possible. On this account it is better to examine patients who come to a physician's office in their ordinary clothing before asking them to disrobe. More attention than is usual should be directed to the nervous system, especially to its relation to the cardiac reflex. Some practical points were given which are worthy of especial notice:

(1) Protrusion of the eyeballs, retraction of the upper lids, or tremor of the latter when the patient is told to

gently close the eyes, are often present in the early stages of Graves' disease, being associated with the tachycardia. They may also be found in other conditions, and are indicative of disorder or distress of the heart. (2) An examination of the auditory mechanism and of the pharyngeal tract is important, as trouble in one or the other of these situations may cause reflex irritability of the heart. (3) The pulse at the wrist should be carefully palpated, and its lessons supplemented by auscultation at first practised with the clothing undisturbed. (4) If fine muscular tremors of the trunk, limbs, or face are observed, there is probability of the existence of a disorder of the nervous mechanism of the heart, such as Graves' disease. (5) Afterward the chest should be examined with all the clothing removed. The author also discussed the significance of the different varieties of cardiac murmur.

At the meeting of the same Society, October 25th, CHURTON read a paper on the *Localization of Rheumatism and Chorea*. Nearly six hundred cases were tabulated, the points noted being the state of health before the attack, the assigned causation, the joints first affected, the occurrence of acetonuria, indicanuria, and constipation. The previous health was not good in the large majority of the cases. The causes assigned were chiefly exposure to the weather and injuries, the joints of the limbs which were chilled or injured being the first to suffer. The "toxin-local-injury" theory has been held by Duckworth and others. The toxin may be glycocin; if so, the micro-organisms will not be found in the blood, joints, etc., where they have been sought. From a study of 150 chorea patients no light was thrown upon the connection of arthritis and chorea, nor was any explanation advanced why the toxin settles in the brain when the latter disease occurs in rheumatic individuals. In the tabulated cases, however, there was no instance of chorea primarily caused by a chill, and no case of arthritis primarily caused by fright.

MACKENZIE said that rheumatism is expressed not only by arthritis and pyrexia, but also by inflammations of the serous membranes, cutaneous eruptions, subcutaneous nodules, and, of course, chorea. As a rule chill and wetting acting as localizing factors determine affections of the joints, while chorea is chiefly excited by fright. Age is another localizing factor. Chorea is common in children; arthritis is rare.

SANSOM disagreed with the opinion of Duckworth that arthritis and chorea are two manifestations of the same morbid process.

At a meeting of the Clinical Society, October 8th, WHITE and LANGTON related a case in which Loreta's operation was performed for relief of stricture of the pylorus. The patient was a man aged twenty-eight years, who during four years after recovery from typhoid fever, suffered from severe gastritis. Medical measures did not improve his condition, and upon opening the stomach, the pylorus was found to be so contracted that it admitted only a No. 1 catheter. Larger and larger instruments were cautiously passed, until the pylorus admitted two fingers. The wound in the stomach was then closed, and the patient entirely recovered. At the present time,

three years after operation, he is still in perfect health, and able to eat anything. The case was brought forward to show the success which might follow Loreta's operation; though it has been superseded by pyloroplastic procedures.

GOULD said that the chief objection to Loreta's operation is the probability of a speedy recurrence of the symptoms. He operated three times upon a patient for simple stricture of the pylorus, at intervals of a few months. Each time there was temporary relief, but later return of symptoms, and each time he found that the adhesions were more extensive than before. The patient, a few months after the third operation, was in a worse condition than at first.

ABRAHAM showed a *child aged two years suffering from hemiplegia*, which began in the first days of a whooping-cough of moderate severity. One evening she was suddenly seized with an attack of right-sided convulsions and became unconscious. The pupils were dilated and insensitive to light, and there was marked nystagmus. The temperature during the attack was 103° F. Two days later she presented complete right-sided hemiplegia, from which she has since partially recovered. The case was considered to be one of cerebral hemorrhage.

WEBER showed a *curious case of one-sided blushing following eating*. The blush involved the cheek and ear, and in the cheek it was associated with perspiration. The young man so affected, had formerly a suppurating gland behind the ear, and Weber explained the blushing by the supposition that some of the vasoconstrictor branches of the cervical sympathetic were involved in the scar, and that when the parotid gland became distended during mastication it dragged upon or compressed these branches.

At a meeting of the British Gynecological Society, October 14th, KEITH read a paper on the *Treatment of Uterine Dysmenorrhea*. The pain in these cases is caused not by the stricture, but by the bending of the uterus *plus* the thickening of the uterine mucous membrane, and also by the congestion naturally present at the commencement of menstruation. General treatment should first be employed, chiefly with a view to keeping the patient warm and thus preventing internal congestion. For the severe cases in which all remedial measures have failed, attention was directed to local treatment by stem pessaries, dilatation, and division of the cervix (Dudley's operation), and by division with stitching (Apostoli's operation). The advantages of the last two procedures are not so well known as they should be. A number of the members of the Society mentioned good results which they had obtained from combined dilatation and suture of the cervix.

Berlin.

CLINICAL EXPERIENCE WITH LUMBAR PUNCTURE, AND THE CONDITIONS IN WHICH IT IS OF VALUE IN DIAGNOSIS AND TREATMENT.

At the session for Internal Medicine, October 18th, STADELMANN described his *clinical experiences with lumbar puncture*. The observations extended over about one hundred cases. In tuberculous meningitis (sixteen cases) the fluid in the spinal canal is usually under high

pressure, but there is very little of it. The spinal fluid is sometimes clear, containing only a few flakes of fibrin or more rarely leucocytes, but it is sometimes cloudy or even purulent or bloody. Proof of the existence of tubercle bacilli in the fluid may be of great diagnostic value. The speaker had found them in only twenty-two per cent. of the cases; either because the tubercles were still intact, or situated only in the meninges of the brain, or in the deeper portions of the pia, or else because these were instances of the so-called *meningitis serosa*, which latter is with difficulty distinguished on clinical grounds from tuberculous meningitis.

In purulent meningitis (seven cases) the fluid is under pressure and contains various kinds of cocci, but it is occasionally free from bacteria, and the case can then with difficulty be differentiated from one of tuberculous meningitis. The clinical symptoms are far more reliable than the lumbar puncture, the value of which from a diagnostic point of view, is at present over-estimated. The bacteriologic examination must be made at once, otherwise the bacteria will die and not appear in the cultures. Also, in cases of suppurative meningitis, the fluid will sometimes be sterile for reasons similar to those given above; hence, only in those cases in which a positive result is obtained can the differential diagnosis be made.

In abscess of the brain the amount and character of the fluid and the pressure under which it exists are subject to variations. Even a complicating meningitis cannot be determined with accuracy. A negative result is no indication that it does not exist. Sometimes the spinal fluid is increased in thrombosis of the sinus.

In acute infectious diseases, especially in pneumonia, suspicion of a complicating meningitis may be confirmed by lumbar puncture, if pus or pneumococci can be proven to exist in the spinal fluid. In cryptogenetic septicemia, streptococci are found in the spinal fluid just as in the blood. Lumbar puncture is sometimes of value in obscure cases without history; for example, in unconscious or delirious patients. In tumors of the brain, lumbar puncture as a therapeutic measure has been vastly over-estimated. Its action is in fact unfavorable, not to speak of the sudden death which may follow. The diagnostic value of this procedure is never greater than that of the clinical symptoms.

In cerebral hemorrhage, if the spinal fluid contains blood, one must first assure himself that it is not derived from an accidentally punctured vein; hence, the puncture must be repeated in several places. In cerebral hemorrhage, the blood may be from the surface of the brain or from a ventricle. An evenly tinged spinal fluid may be looked upon as evidence of such bleeding. It may be of prognostic value to determine in this manner that the blood has burst into a ventricle. It is not possible to make a differential diagnosis between apoplexy, softening, and embolism by means of lumbar puncture. The bad effect of brain-pressure, as the result of hemorrhage, cannot be relieved by this means. In fact, puncture may cause the hemorrhage to begin again.

In hydrocephalus, encephalitis hemorrhagica, uremia, encephalopathia saturnina, etc., lumbar puncture gives

only unsatisfactory results. Puncture shows that in epileptic attacks pressure is increased. In pneumonia, scarlatina, typhoid, and other diseases, the spinal fluid is increased. The observer has never seen any therapeutic result follow lumbar puncture. To reiterate, it has a diagnostic value only if a positive bacterial cause is isolated. Unless bacteria are proved to exist, one dare not conclude from the cloudiness of the fluid that meningitis is present. Above all things lumbar puncture is not to be depended upon as a means of diagnosis to the neglect of clinical symptoms.

REVIEWS.

THE DISEASES OF THE MALE URETHRA. By R. W. STEWART, M.D., M.R.C.S. New York: William Wood & Co., 1896.

IT would be manifestly unjust to expect in a work of the compass of that before us a complete and exhaustive treatise on the fruitful subject with which it deals. In a work, however, in which it was the declared "object of the writer to place before the reader the diseases of the urethra as viewed from the standpoint of modern knowledge," it is decidedly disappointing to find no mention of the Gram stain as a differential test for the gonococcus, and only the most meager references, without any description of the methods, to the possibility of cultivating that organism on culture media.

Not less disappointing are the chapters on the treatment of gonorrhea. It is eminently proper, eminently conservative, but it might all have been written twenty years ago. Surely, the modern treatment of gonorrhea has gone beyond the Lafayette mixture and sulphate of zinc! The chapters on chronic urethritis, and on stricture, may, on the whole, be commended as a just and conservative presentation of the subject.

Most of the illustrations in the work are antiquated, and those copied from a well-known atlas of anatomy should be credited to Heitzmann, not Hitzmann. In general, however, the book is typographically satisfactory.

THE ESSENTIALS OF OBSTETRICS. By CHARLES JEWETT, M.D., Professor of Obstetrics in the Long Island College Hospital, Brooklyn, New York. Illustrated. New York and Philadelphia: Lea Brothers & Co. 1897.

IN this volume of 356 pages Dr. Jewett has embodied what he considers the needs of the student for the acquisition of his groundwork of obstetric knowledge. No one doubts the value of a work of this character, limited as its field is. When the manual, too, is written by one who has so long and favorably been known as a teacher of obstetrics, the worth of its contents is more than doubly enhanced.

The surprising thing in regard to the book is that Dr. Jewett has covered so much ground so well in so little space. We have here anatomy and physiology, embryology, the phenomena of labor, the pathology of pregnancy, of labor, and of the puerperium, and obstetric surgery. Contrary to the title, more than mere essentials are included.

It is only necessary to mention that the scientific feeding of infants, and the chlorinated soda-method of disinfecting the hands, are discussed to show how thoroughly up to date Dr. Jewett's book has been brought.

The black and colored illustrations are admirably chosen, and the book presents a handsome typographic appearance.

NOTES ON PATHOLOGY. For Students' Use. By W. A. EVANS, B.Sc., M.D., Professor of Pathology, Medical School of the University of Illinois; Professor of Pathology, Milwaukee Medical College. Etc. Chicago: The W. T. Keener Co., 1897.

AS this work is not intended as a treatise on the subject of pathology, but simply as a manual for the student, a detailed description of the subject cannot be expected, but the book should certainly have been a safe guide. There are many sweeping statements without necessary justification, and much carelessness in arrangement and in the literary construction. Parts of the book we can heartily endorse, but where the student is concerned there should be nothing which can be criticized. The book is made with blank pages for notes, alternating with the text, and for advanced workers may occasionally serve as a work for quick reference.

THE LIVER OF DYSPEPTICS, AND PARTICULARLY THE CIRRHOSIS PRODUCED BY AUTO-INTOXICATION OF GASTRO-INTESTINAL ORIGIN. By DR. EMIL BOIX. Authorized Translation from the Latest French Edition, by PAUL R. BROWN, M.D., U. S. Army. New York: Putnams, 1897.

AFTER a brief general introduction, Boix discusses in detail the auto-intoxication of gastro-intestinal origin, separate chapters being devoted to the poisons of the alimentary tract, and the conditions which favor their production. These poisons are the result of fermentation; they are much more numerous than is commonly supposed. Among them he includes lactic, acetic, butyric, valeric, propionic, oxalic, the various fatty acids, aldehydes, acetones, the various derivatives of albuminous digestion, indol, skatol, etc. The causes which favor their production are especially motor insufficiency and stagnation of the ingesta.

In Part II. the liver of dyspeptics is considered at full length. Although many objections might be raised against the use of the term "dyspeptics," yet our language possesses no other word which can readily replace it. The body of the work is devoted to a very elaborate study of the hepatic congestion and cirrhosis which occur in the course of gastric diseases; many cases of his own and others are cited. A large amount of original work is described in the next two chapters on the etiology and pathologic anatomy of these lesions. Many striking conclusions are reached which are entirely opposed to currently accepted opinions. Boix's views on the effects of alcohol are especially striking; for these the reader is referred to the book itself which will amply repay a careful perusal.

The translation is excellent and Dr. Brown deserves our thanks for having given English physicians the op-

portunity of studying this work at first hand. The letter-press and the colored plates reflect credit upon the publishers.

A PRACTICAL MANUAL OF THE DISEASES OF WOMEN AND UTERINE THERAPEUTICS. For Students and Practitioners. By H. MACNAUGHTON JONES, M.D., M.Ch., Master of Obstetrics (Honoris Causa), Royal University of Ireland; Fellow of the Royal College of Surgeons of Ireland and Edinburgh. Seventh edition, revised and enlarged, with 565 illustrations. New York: William Wood & Co., 1897.

THIS is a handy little volume of 900 pages, and is the result of an effort on the part of the author to "provide an epitome of the teachings and opinions of the greatest living gynecologists." It is profusely illustrated. Its teachings have a strong English flavor, and English and German methods are presented rather than those of French or American operators. The author recognizes the sway of gynecology over the bladder, ureters, and kidneys, and devotes a chapter to Kelly's method of catheterization of the ureters, and the treatment of affections of those organs. That a seventh edition has been necessitated at so early a date indicates the popularity of the work.

A TEXT-BOOK OF MEDICAL AND SURGICAL GYNECOLOGY. For the Use of Students and Practitioners. By R. W. GARRETT, M.A., M.D., Professor of Obstetrics and Gynecology in the Medical Faculty, Queen's University, Kingston; Gynecologist to the Kingston General Hospital. Containing over 100 illustrations. Toronto: J. A. Carveth & Co., 1897.

THIS work is designed as a means for ready reference, and an index to the standard writers on the subject of gynecology. The chapters are based upon the notes of the author from which he has given his lectures to a medical class. These notes have been extended so that the volume may be of service to the general practitioner. The author not only presents his own views, but also those of the standard authorities on the various subjects discussed. The volume consists of 419 pages, and briefly covers the entire subject.

A QUIZ MANUAL OF HISTOLOGY, GENERAL AND DENTAL. By CHARLES B. REED, M.D., Professor of General Histology, Northwestern University Dental School; Assistant Obstetrician, Chicago Lying-In Hospital, Etc.; and FREDERICK B. NOYES, B.A., D.D.S., Professor of Dental Histology, Northwestern University Dental School. Chicago: The W. T. Keener Co., 1896.

THE authors of the little volume before us have published this work as a guide to the student in histology. While we believe that this important branch of medicine can only be satisfactorily studied by individual use of the microscope, still, a book of this kind is of value to the student as an aid in his work. The authors have arranged in compact form all the essential facts to be memorized, and the work is a fairly complete and concise

summary of histology. About one-fifth of the book is devoted to dental histology, which is a unique addition to works of this kind. All in all, the book is a useful one, and is creditable to its authors and publishers.

THERAPEUTIC HINTS.

For Contusions.—Wash the injured part, and then paint twice daily with menthol in collodion (1-8 or 1-4). Pain will be relieved, and the resulting constriction of the vessels diminishes the discoloration and swelling. This treatment should not be used in case of contusion of a joint.

The Use of Tannoform.—Both the internal and external employment of tannoform is highly praised. In doses of $\frac{1}{6}$ - to $\frac{1}{2}$ -grain it has a rapid and favorable action in the enterocolitis of children, and, following the administration of castor oil, it is of equal service in dysentery. Externally, applied as a powder, it is useful as a remedy for hyperidrosis, and also for chronic ulcer in which it relieves the pain and energetically stimulates the granulations.

For Gastric Hyperacidity.—

℞	Tr. gentianæ	}	aa	3 ii.
	Tr. cascariillæ			
	Tr. cardamomii			
	Tr. absinthii			

M. Sig. One teaspoonful ten minutes before the two principal meals.

Iodoform as an Antiseptic.—In the treatment of infected wounds, furuncles, and gonorrheal inflammations, this drug is said to have no unpleasant systemic effects, and to be an improvement over iodoform. It should be used in the form of a powder in gonorrheal vaginitis, and for urethritis, in the form of a bougie, containing 20 per cent. of the drug.

It may also be employed as a salve, according to the following prescription:

℞	Iodoform	.	.	.	.	gr. xlviii
	Bals. Peru.	}	.	.	.	gtt. xv
	Lanolini anhyd.		.	.	.	
	Vaselini	.	.	.	.	q. s. ad. $\frac{3}{4}$ i.

M. Ft. ungt. Sig. For external use.

For Infantile Tetany of Gastro-intestinal Origin.—

℞	Bismuthi salicyl.	.	.	.	.	3 i
	Benzonaphthol.	.	.	.	.	3 ss
	Sacchr.	.	.	.	.	q. s.

M. Div. in chart. No. XII. Sig. One powder four times daily.

In conjunction with above administer the following:

℞	Potass. brom.	.	.	.	.	gr. xlv
	Chloral hydr.	.	.	.	.	gr. xv
	Syr. aurant. cor.	.	.	.	.	$\frac{3}{4}$ iss
	Aq. dest.	.	.	.	.	$\frac{3}{4}$ iii.

M. Sig. One teaspoonful three times daily for a child two to three years of age.

THE MEDICAL NEWS.

No. 24.

ORIGINAL ARTICLES.

*THE CLINICAL AND PATHOLOGIC INTERPRETATION OF TIC, WITH SPECIAL REFERENCE TO ITS TREATMENT.*¹

By JOSEPH COLLINS, M.D.,
OF NEW YORK;

PROFESSOR OF NERVOUS AND MENTAL DISEASES IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; VISITING PHYSICIAN TO THE CITY HOSPITAL.

THE condition to which the term "tic" is applied is one which has great interest for me; first, because I see much of it, and, second, because its interpretation is difficult and its explanation unsatisfactory. It is a subject which has received entirely inadequate consideration. In this communication I have two objects in view: (1) To lay before you for your consideration some thoughts on the significance and pathogenesis of tic, and (2) to urge a more determined plan of treatment than is usually adopted. The word tic means literally a twitching. It is applied to an abrupt, rapid, and usually uncontrollable movement, the result of abnormal contraction of individual muscles or groups of muscles which normally act together to fulfil some physiologic purpose. The designation "tic" is a most appropriate one, though it has stood in the way of a more universal recognition of the condition as a pathologic entity.² It has been difficult for some to believe that the ordinary tics are not in reality habits, one variety having been described as a habit-spasm, while others have unfortunately considered the tics as atypical manifestations of chorea, and the dreadful phrase "a kind of chorea" has been applied to them. I should venture to state that tic has no more in common with chorea, be it acute or chronic, than it has with epilepsy; indeed, I am inclined to believe that it has much less. The atmosphere of the tics has been very much obscured by the use of the word choreiform to describe the movements, and also by their consideration with chorea in systematic medical treatises. I appreciate that we cannot drop the terms choreic and choreiform, but if we could when speaking of the tics it would be a decided gain.

It is important to understand that the term, although it suggests only the most prominent symp-

tom, oftentimes bespeaks an abnormality of the nervous system quite as demonstrable as that to which the terms epilepsy, hysteria, or migraine are applied. When the latter words are used, a certain well-defined significance is attached to them, and they call to the minds of the users clearly cut clinical pictures and well-known data concerning etiology and pathology. It is unfortunate that the word tic does not do as much. The only reason why the names hysteria and epilepsy have a more decisive application is that the conditions for which they stand have been more carefully and persistently studied. A similar amount of labor expended upon the tics would be followed, I venture to believe, by a corresponding amount of information.

In the definition which I have given nothing is said of the pathogenesis of tic or of the morbid conditions upon which it is dependent, for as yet but little is known of them. The twitchings to which the term tic may be applied vary in severity from the slightest movement of a part up to the most complex coordinated movement associated with obsession and the externalization of mental activity.

All tics may be classified primarily into (1) senile (acquired) tic, and (2) early tic, the last being further divided into two varieties, *viz.*, (a) degenerative and (b) acquired.

The senile variety is a convulsive or spasmodic manifestation in one part of the body or another, usually in the face, almost invariably due to, or at least accompanied by, degeneration of the blood-vessels, arteriocapillary fibrosis. The twitching is usually of the fronto-orbicularis or facial musculature, and pathogenetically it is an entirely different affection from the early or degenerative types. In short, it is usually the symptom of a well-understood pathologic condition, and the treatment which it requires, aside from that which is symptomatic, is none other than the treatment of this condition. To this form we shall not again revert. It is mentioned to give completeness to the classification.

Early tic, degenerative or acquired, may be divided into two groups: (1) Motor tic, which may be further divided into (a) localized tic, (b) generalized tic, and (2) psychomotor tic, which may also be further divided into (a) tic which is a response to a compulsory idea or obsession, (b) tic caused by coordinated movement, associated with intellectual or emotional externalization, orderly or disorderly.

¹ Read before the Section on Pediatrics of the New York Academy of Medicine, November 11, 1897.

² Dr. Landon Carter Gray of this city recently suggested the name palmus instead of tic. This term is preferable for etymologic reasons, but universal usage gives tic a great claim for its retention.

The motor tics, although in all likelihood oftentimes the expression of a similar abnormal condition as the psychomotor tics, are much less complex, but despite this fact they have been much less studied. One reason for this is that the localized varieties have usually been regarded as habit-spasms and the generalized tics as forms of chorea. The psychomotor tics, and particularly group *b*, have been rather extensively studied since Gilles de la Tourette turned his attention to them, and since it has been recognized that a condition very similar to the psychomotor tics occurs in certain parts of the world as tribal and family affections, and under other conditions as apparently the result of some toxic or infectious agent. Such, for instance, are the "jumpers" found in that portion of New England bordering Canada, Myrachit of the Siberians and Kamschatkans, and Latah of the eastern coast of Africa. The psychomotor tics, especially in this country, are, moreover, relatively uncommon when compared with the purely motor form.

Motor tic may be further subjected to topographic classification. Such a classification facilitates recognition of the condition. Thus we have (*a*) fronto-orbicular tic, (*b*) nasal and naso-orbicular tic, (*c*) facial tic, (*d*) nuchal tic, sometimes called spasmodic torticollis; (*e*) tic of the diaphragm, often called respiratory tic; (*f*) bowing tic, or *tic de salaam*, as it has been called; (*g*) string-halt tic. Further extension of this classification could be made, but this suffices to indicate the purpose and direction of such a division.

What do we know of the etiology of tic? Very little definite and positive information is to be had in response to this query. We know that tics of all kinds occur in early life, in childhood, and in early adolescence. That the disease afflicts males more commonly than females, and that the victims not infrequently have neuropathic parents and brothers and sisters who manifest other forms of nervous disease. It is known, furthermore, that occasionally the twitching follows emotion, fright, bodily and mental fatigue, and that it is often associated with somatic and psychic defects. In other words, to put it briefly, tic is frequently a possession of the superior and inferior degenerates, and it manifests itself during the formative period of the individual's character. I should fail to convey my meaning were it understood that it is my belief that tics are invariably stigmata of degeneration. The simple motor tics may occur in individuals who have nothing in their antecedents to suggest an inherent neuropathic constitution, and no bodily or mental attributes which can be called stigmata. Indeed, the simple motor tics may, I believe, be the result of many different con-

ditions which induce some change in the motor areas of the brain or in the subcortical motor stations. The immediate antecedent condition is, in all likelihood, a nutritional depravity. This harmonizes with our experiences that tic is not infrequently encountered in rachitic children, in young individuals who have acquired a rheumatic diathesis, and occasionally after acute disease.

In this connection I would like to say a word in reference to so-called habit-spasm or habit-tic. That twitching movements occur in individuals who voluntarily imitate them as an affectation, or to ridicule or tantalize others cannot be denied. Many habit movements are pure, emotional, and gesticulatory manifestations, and can by no means be considered tics. Tics may occur in individuals who have voluntarily imitated the twitching movements of others, and if such are not possessed of a stable nervous system, the tic often develops so dominantly that it cannot be controlled. Such persons are abnormal when considered from a neural standpoint. In the opinion of the writer the departure from the normal indicated by the word tic is in the majority of cases akin to that indicated by the words epilepsy or hysteria. It is unnecessary to say that epilepsy may be caused by toxic states of the blood; that it results occasionally from causes termed reflex, and that states of the nutrition have a direct traceable relationship to the frequency of the epileptic attacks. Notwithstanding this, when we speak of epilepsy in ordinary parlance, we mean epilepsy which is not associated with any of these, but which is conditioned by unknown, prenatal influences. I am, therefore, inclined to the belief that tics taken as a whole bespeak, with greater uniformity than any other one condition, a state which may be designated, at the present time, only as degenerative, using this word in its biologic and proper sense as signifying a loss or impairment of the qualities peculiar to the race or type and not in its pathologic sense as synonymous with decay. A number of nervous diseases whose pathogenesis is obscure and whose morbid anatomy is a closed book have come to be considered as degenerative neuroses, that is, symptom-complexes which have been so frequently found, statistically, to be associated with bodily and mental stigmata or departures from the normal, as to justify us in classifying them as degenerate diseases. Of these, we may take the three just mentioned and tic as exemplars. The fact that we have already found, or shall eventually find, that one or all of them is associated with definite anatomical lesions does not interfere with the conception of them as degenerative diseases. The degenerative nervous diseases by the very reason of there being have no individual causative factors, such as have

the infectious or toxic diseases of the nervous system, and unless our understanding of biology and the underlying principles of heredity be all at fault, such diseases do not stand in genetic relationship to factors operative after the complete development of the individual. The forces which determine the existence of such a disease are antecedent to the life of the individual, and they may be traced directly, indirectly, or not at all through many generations, although the exciting cause, the one which apparently determines the tic is effective only during life.

Tic itself is not inherited but the neuropathic predisposition may show itself in other almost innumerable conditions, mental or physical, indicating a departure from the normal. This is true of all the degenerative nervous diseases. If we examine what is known of the etiology of the diseases which have been enumerated as examples of nervous degenerative diseases, we will find that, although it is uncommon to discover the same disease in the immediate or remote ancestry, it is extremely frequent that some collateral or related nervous disease is found. And so it is with the tics. It is very rare to learn that a patient's parents or immediate relatives have suffered from some twitching disorder, but it is not uncommon; indeed it is the rule to find that there is some allied neurosis or psychosis in the family.

In what, may be inquired, are we justified in placing tic among the degenerative diseases? To this, our answer is, that particular investigation of the cases which have come under personal observation during the past four years, since my attention was first attracted to this view, has shown that tic is associated with somatic and psychic stigmata of degeneration in greater proportion than any other nervous disease. I have full notes of fifty-seven cases of tic, and have seen a much larger number of which I do not possess notes. On looking through the histories of these cases I find that such stigmata of degeneration were sufficiently obvious in thirty-two of them (about sixty per cent.) to call for specific notation. In others, I recall such stigmata, even though there is no note of their existence.

It would carry me beyond the self-imposed limits of this paper were I to dwell upon the variety and form which these stigmata assume. It is taken for granted that every one admits that all abnormal individuals may be divided into two great classes, *viz.*, superior and inferior degenerates, that the superior degenerates are those who, though possessed of individual qualifications to command notoriety and fame, are lacking in the possession of such mental equilibrium as prevents the term normal from being applied to them. Such often contribute to the number of names that live forever, particularly if their indi-

vidual and superior qualifications lie in the direction of externalizing emotional states, supported by, but not solidly based upon, intellectual possessions. They are the decadent artists, poets, and esthetes. The inferior degenerates, on the other hand, are a dependent class. Their intellectual possessions are all below the normal. Some of them may be but slightly so, while others may be so lacking that they are as good as absent. Naturally, this class includes the idiot and the idiot savant. It includes the individual with congenital clubfoot, the polydactylus, and the web-fingered. Although the superior degenerate is of the independent class, he not infrequently has quite as many and as striking stigmata of degeneration as has his brother, the inferior degenerate. These stigmata are, as is well known, certain definite departures from the normal, occurring with sufficient frequency to constitute types. They are both of the body and of the mind. Those of the body are much more easily detected, the more important being changes in the relative shape and contour of the extremities and their accessories from what is normal for an individual, considered as a member of a race. I say considered as members of a race or people, for what is normal in a Mongolian would be decidedly pathologic in a Caucasian, and likewise, cranial conformations habitual to the Teuton would, occurring in a Celt, constitute a decided departure from the normal.

Patients who have one of the different forms of early tic, which is not a symptom of peripheral irritation, will be found, I believe, to have some of these bodily stigmata of degeneration with sufficient frequency to justify us from this evidence alone in placing it among the degenerative diseases. They will be found to have malformations of the cranium, exemplified by too large, too small, or asymmetrically developed heads; defective lobulation, formation, and relative position of the ears; the occurrence of a Darwinian tubercle, or an absence of the helix; a deficient tragus or antitragus; change in the shape of the ocular aperture, an approximation to the circular, a tapering internal canthus, an approach to the Mongolian eye; an unduly developed, prognathous lower jaw, with an accentuation of the inferior angular process, constituting the Lamarckian hypophysis; defective conformation of the palate; an excessively vaulted arch, the development of a ridge through the center, constituting the *torus palatinus*; asymmetrical or bifid uvula; disproportionate length of the upper extremities, and particularly of the index-finger, a remnant of the prehensile finger in the early stages of evolution; undue projection of the os calcis; excessively arched feet, constituting the *pes cavus*, and a number of other defects of corporeal evolution

which have been statistically shown to be the natural possession and attribute of the degenerate. Moreover, these deficiencies are as likely to be found in the superior as in the inferior degenerate who develops tic. I have seen them conspicuously developed in an individual with tic whose ancestors contributed to the constitutional and formative history of this country, as well as in the individual devoid of sufficient mind to be cognizant of ancestors. The psychic stigmata of patients with tic are much more difficult to enumerate, principally because they are ill defined. Indeed, the mental phenomena constituting a part of the psychomotor tics may be looked upon as such stigmata. In other instances they manifest themselves by intellectual limitations, by obsessions, by pathologic intolerance of ordinary environmental conditions, and by some manifestation of defective mental balance.

Not infrequently tic patients have certain abnormal bodily conditions which are attributed as causative of the twitching movement, and which some writers have been so illogical as to contend would allow or cause cessation of the tic if remedied. I speak now particularly of ocular, including refractive, anomalies. I am very certain that patients with tic not infrequently have misshapen eyeballs which call for corrective glasses; that the musculature of their eyes is sometime badly balanced; and that other peripheral sense organs may show departures from the normal, but I am quite as firmly convinced that these are the legitimate possessions of an individual whose evolution toward the type which at this stage of the world's history is looked upon as normal has been imperfect. Moreover, as I shall say under treatment, no means should be left untried to correct these shortcomings, but their existence should not be said to be causative of another manifestation of the degenerate state. An examination of the statistics of epilepsy shows that ocular anomalies are more common in those who suffer from this disease than in normal individuals; yet no one whose opinion is of any considerable value now contends that such abnormalities of the peripheral visual apparatus are the causes of epilepsy, or that their correction has any particular influence on the course of the disease.

To recapitulate, and to summarize in a few words my conception of tic, I may say that, leaving out acquired motor tic, both the early and later varieties, it is one of the degenerate diseases; that its association with somatic and psychic stigmata of degeneration entitles it to classification in this category; that it conforms in its occurrence, in its development, in its progression, and in its attitude toward treatment with all the degenerative diseases; it occurs in the early years of life, and develops gradually; its unin-

fluenced tendency is toward progression, and it is disappointingly responsive to therapeutic measures.

The clinical phenomena of tic are so very familiar that I hesitate to attempt to depict them. I shall, however, quote very briefly the notes of a few cases illustrative of types of the disease, and particularly bearing on the topographic classification given in the beginning of this article. The most common form of simple motor tic is of some group of muscles of the face. The twitching may be limited to this locality, or may extend to involve other muscles and groups of muscles concerned in the performance of a motion requiring coordination. Such a type is well illustrated by the following case:

CASE I.—M. H., ten years old, a school-girl, was brought to my clinic at the Post-Graduate Medical School, because of the grimaces which the mother said she indulged in. The only family history bearing upon the disease was that the father had had twitching of the shoulder and of the side of the neck as long as he could remember. The child had many stigmata of degeneration, including most of those enumerated above as commonly found in the cephalic extremity. In addition, she had a considerable degree of astigmatism associated with myopia, for which she wore glasses. The twitching movements consisted of a number of sudden, rapid closures of the eyelids, with corrugation of the forehead, followed by short, rapid elevation of both corners of the mouth and distension of the nostrils. Occasionally these movements would alternate with a few rapid twitchings of the head toward the right side, while at other times these lateral movements of the head would follow the facial movements. After the child had been under observation for some time she added to her complex of movements that of spasmodic sniffing, to which was sometimes superadded a slight inspiratory sound or stridor. For a considerable time the symptoms made no response to the customary therapeutic measures. She was then given belladonna in sufficient doses to produce a pronounced effect, and this condition was maintained a fortnight. At the end of this time she was put upon sulphate of copper in large doses ($\frac{1}{2}$ gr., three times daily), and at the end of five months all manifestations of the tic had ceased, with the exception of inconsequential blinking movements. She remained away from the clinic for six months, and has recently returned with the story that the symptoms all returned after a month of attending school.

The second case, one of tic of the diaphragm, is in decided contrast to the first:

CASE II.—The patient, a girl fifteen years old, was suffering from a condition which gave her and her family almost intolerable annoyance. This symptom consisted of a sudden ejaculatory inarticulate sound which resembled "heim," if forcibly said without moving the lips, and which was repeated from eight to fifteen times per minute, and was sufficiently loud to be heard through the walls of a closed

room or throughout an entire railroad car. This case might be considered a type of barking-girl. Examination showed that there were no departures from the normal save a number of the stigmata of degeneration. The present attack, which had lasted nearly two years, was separated from the first by an interval of three years. After she had been under Dr. L. C. Dana's care for some time, he requested me to carry out certain plans of treatment, which I did. The first consisted of isolating the patient, and keeping her in a stuporous condition for a number of days, three or four weeks, indeed, with opium; no amelioration resulted. The next was to give large and gradually increasing doses of dilute hydrocyanic acid, hoping thus to blunt the terminal filaments of the phrenic and pneumogastric nerves; treatment unavailing. It was then decided to intubate the larynx, hoping, at least, to so minimize the annoying symptoms of her infirmity as to make life tolerable. If the spasmodic expiration could be robbed of its intonation by preventing the vocal cords from vibrating, it was hoped that she might become less of a "pariah." This procedure was quite as futile as its predecessors. It was then suggested that an endeavor be made to overcome the intolerable manifestation of her disease by making a suggestive appeal to the mind. She believed the seat of the trouble was in the throat. No attempt was made to deceive her; on the contrary, she was told that a serious operation would have to be performed, and that the result, if her life was spared, could only be gratifying. She was placed under ether, the throat scarified, and her neck very voluminously and stiffly bandaged; then put back to bed, provided with a nurse, and fed on liquid diet, just the same as though she had had a most serious operation. The irrepressible "heim" continued as before. She was then sent to the country, and made to live a rollicking, out-of-door life, and after a few months returned to California. Nothing more was heard from her until one day when lecturing upon a patient, similarly afflicted, at the Post-Graduate School, one of the audience volunteered the information that she had come under his care in the Occident; that he had administered sulphate of copper in large doses, and that the convulsive phenomenon had ceased while she was taking this drug. I am unable to say just how long a period she took the treatment.

The next case is one of the degenerative forms of torticollis:

CASE III.—The patient was a young woman, twenty-six years of age, who had been comparatively well until the twentieth year of her age. She was of a nervous and excitable disposition. The first manifestation of tic was a persistent sense of fatigue in the left side of her neck, which was somewhat relieved by turning the head toward the right side. This was followed after an indefinite time by intervals of twitching in the neck which turned the head quickly and convulsively toward the right side, and at the same time elevated the chin. When she was fatigued or depressed this symptom was very severe and annoying, but when she was well and in good spirits it

was more tolerable. She was treated for the first few weeks with antispasmodics and restoratives, but with very slight improvement. After this the head was suspended by the modification of the jury-mast used in the treatment of tabic patients. At first this procedure seemed to be of some avail, but its ameliorating efficacy was soon exhausted. She was then given hypodermic injections of atropin, later fluid extract of conium, and restoratives, with no gratifying result. After having been treated with galvanism for a time she sought a more propitious Mecca.

The following case is a striking example of generalized tic:

CASE IV.—The patient is a boy seventeen years old, of good family history. There were no accidents attending his birth, nor has he ever had convulsions. He did not walk until he was two years old, but this was attributed to infantile corpulency. He always had a tendency to fall. When about three years old he was taken to an orthopedic hospital because of incontinence of urine. Despite treatment this continued for a number of years. When he was five years old he was taken to another hospital on account of a tendency to fall and of an unsteadiness in standing. When eight years old he was run over by a wagon, and a fracture of the left thigh resulted. When he was eleven years old he broke the right knee-cap. During these years the unsteadiness of station was ever present. During the last two or three years he has been getting worse. When he is asked to tell what is the matter, he says "I can't walk like other people, and I cannot straighten my legs properly to walk. I am very nervous, and I can't keep still when sitting or standing. My strength is all right, but I sweat more than other boys. When I try to sit still I have to brace myself, and then my head twitches toward one side, or my face gets turned upward. When I try to stand still, my body keeps on twitching."

Examination shows a well-nourished boy who is capable of helping himself in every way and who is ordinarily dextrous. He is of splendid muscular development. When he stands both knees are somewhat flexed, the right more than the left, and while he stands, his body, particularly the trunk, is in a state of continual agitation, more twitching than rhythmic, and which impresses one of the never-ceasing change in state of muscular contraction to be observed in a person trying to balance, let us say while walking a rope. The gait is very peculiar, a flexed-knee, spastic, claw-toe gait. The trunk showing the agitation just referred to. As he walks one is reminded of the gait of a Shanghai rooster. In addition to these, there are twitching movements of the hands, not rhythmic, nor the dance movements of chorea, but similar to those he shows in the face and in the neck. If he is tired, hurried, or excited, the movements are exaggerated and his capacity for locomotion is diminished. The voice has a peculiar intonation, and there is an interruption of the rhythm of vocalization. He can articulate properly, but the intonation is jerky. There is no ataxia, no diminution of

muscular strength, and the reflexes are quite normal. When the eyes are closed, the irregular movement of the extremities and the twitching movement of the trunk are exaggerated, but they cease when he sleeps. The course of the disease has been uninfluenced by treatment, and it seems to be an elementary and progressive one.

The next case is an example of psychomotor tic:

CASE V.—The patient is now a young man twenty years old. His family history is rather peculiar. His father, although apparently sane, never took any interest in the labors and pleasures, the indulgences and anticipations which are reputed to make life worth living, even when a comparatively young man, forty-five years old, and after that lived the life of a recluse. He became neither miserly nor religious, neither paranoic nor demented; simply tolerant of his days. If he had convictions, he did not attempt to share them; if he had complaints he kept them to himself. Our patient was, so far as he remembers, a child like other children; but he was very morbid and introspective during all his youth. He says that he has always been easily fatigued, and has not had much brain power, although there are no evidences of mental shortcomings when one converses with him, even on abstruse subjects. He is of a scientific turn of mind and very inventive. When he has completed some mechanical contrivance, however, he has not the executive power to patent it, although he sees the necessity for so doing and reproaches himself for his deficiency. The complaint for which he seeks advice and aid may be best described in his own words: "I may be engrossingly engaged in work, or I may be doing nothing, when without thought or warning, I feel compelled to lift my eyes heavenward three or four or more times in rapid succession, which movement is accompanied with slight turning and elevation of the face and head. Sometimes it is necessary to do this every few minutes, and sometimes only a comparatively few times in an hour or in a day. When I am worried or perplexed, hurried or confused, it is worse. Sometimes I can resist it for a short time, but it can only be put off for a few minutes. Then I must come to it, the same as one must cough when he has a tickling in the throat. Although this movement of looking toward the sky, just over the rim of the hat is the most common one, not infrequently it alternates with a compulsory movement of looking down beyond the left elbow."

On inquiry, it is found that when he was ten years of age he had a sniffing tic for quite a long time, and afterwards had what he calls a "spasmodic grunting sound," coming from the throat. The patient is of a very peculiar disposition, a combination of excessive frankness and reticence, of confidence and distrust, of ability along certain mechanical lines, and of serious limitations along others, particularly those involving the execution of any task. Although a skilled electrician, he receives less for his labor than an ordinary workman; because of his unwillingness to assume any responsibility. These brief remarks will convey some idea of his intellectual possessions. I was not able to suggest any treatment which was

of benefit to him during the few weeks he was under my care. He was convinced that hypnotism was the remedy, and we could not agree.

The next case is an example of a variety which, fortunately, is not of common occurrence:

CASE VI.—A female child, eleven years old, of fairly good family history, save that the mother is nervous. She had an uneventful childhood, and save for a temper which was violent and which swayed her when aroused, she was of good disposition. She is a very intelligent child, and learns with ease and readiness. She has been carefully brought up and is naturally modest, and without any tendency to vulgarity. She chafes and frets under restraint and, when disciplined, and gets excited easily. Without a noticeable prodromal or developmental stage the child began to have twitchings, short and uncontrollable, of the face and shoulder. She did not seem to be cognizant of these movements, and the parents first looked upon them as an affectation. They continued, however, and became more severe until one day she upset the family equanimity by punctuating her speech with obscene, profane words, which seemed to fall from her mouth without emotion or passion, and without particular notice or comment on her part. She was not shocked nor remorseful until she was reproached, but then she was much grieved and very contrite. Notwithstanding this, the tic of the face and the coprolalia continued for some time. Under the influence of isolation, tonics, hydrotherapy, and increasing indulgence in exercise, the distressing symptoms disappeared, and so far as I know they have not recurred.

Such cases of coordinated tic with coprolalia, with echolalia, with profanity, etc., are not very uncommon. It is difficult to interpret the significance of the compulsory language in these cases. Profanity as ordinarily used is an emotional manifestation and not an intellectual one. In other words, it is a content of emotional consciousness. It is probable that the obscene words, except when they are used by depraved persons to incite sensuality, are psychologically of the same nature.

It is quite possible that the psychogenesis of coprolalia and the like is that the words constituting it have been heard on the street or elsewhere and are registered upon the auditory tablets of the brain; but they never become a part of our conscious vocabulary because they are not passed through the speech areas of the brain to the intellectual areas. Nevertheless, they may be externalized by uncontrollable forces in a way that makes their manifestation analogous to the twitching movements of tic. Indeed, the motor impulse may be a very similar one, acting however, through the entire articulatory apparatus to produce words. As a whole, coprolalia, echolalia, etc., may be considered stigmata of psychic

degeneration. Psychologically, they are rudimentary forms of speech, and in no wise comparable to intellectual word production.

CASE VII.—The last case to which I shall refer is that of a youth who is afflicted in the most distressing way. He is a superior degenerate, and has a mildly neurotic family history. The years of childhood were passed in a fairly satisfactory way, but at puberty he developed twitching movements in the cephalic extremity which turned the head abruptly and rapidly to one side, and then finished with a few short, jerky movements of the chin in the air, accompanied with sniffing. For a long time it was not suspicioned by anyone that these twitchings did not constitute all of the patient's complaint; but one evening while in the theater he blurted out in rapid succession the vulgar Latin derivative synonym of the word copulation, and thereby paralyzed that part of the audience within hearing. He afterwards told me that he had struggled against this tendency for quite a time; that the explosion had often occurred before, but until that occasion he had been able to avoid polite society when freeing himself from the unknown demoniacal grasp which seemed to be fastened upon him. This patient was likewise benefited by isolation, hydrotherapy, etc., followed by travel abroad. The twitchings have not ceased, and it is likely that they or other evidences of his neurosis will cease only with the span of life.

Taking the salient features of these cases from these brief notes of the histories and scrutinizing them, we find that the majority of the patients are entitled to the designation degenerates. Almost without exception they have the accompaniments of the degenerate state. The twitching movement, the tic, is an externalization of such degeneracy. In one case it assumes the form of an uncontrollable grimace, in another it results in a barking sound, and in another it passes through the gradations of a rhythmic-like spasm of the muscles of the trunk to a twitching of the muscles of the head and of the neck. In brief, all these forms of tic have certain general features in common, but these features merge by gradation one into another, and it is quite impossible to say what form they will take in this case or to what extent they will go in that. When we come to analyze the psychomotor tics, we at once experience great difficulty in separating them by hard and fast lines from the manifestations of other degenerate diseases. It is difficult to say just wherein they differ from the aborted types of rudimentary paranoia, from the obsessions which accompany the neurasthenic state developing in children and in early adult life, which I am inclined to believe is another manifestation of degeneracy, and from the manifold psychic compulsions and accompaniments of hysteria. But there are certain general features accompanying the tics which

one soon learns to associate with this condition and not with the degenerative disorders just mentioned. In the first place, the twitching movements themselves, if carefully studied are readily differentiated from hysteric motor manifestations. In the latter disease the motor phenomena are tremor, contracture, tonic convulsions, or flaccidity. None of these occur in tic. Above all, we must not delude ourselves into thinking that it has anything in common with chorea. That term should be restricted, except when used as a descriptive adjective, to designate an acute, humoral disease whose pathogenesis is primarily in the blood, a self-limiting disease known as Sydenham's chorea, and a hereditary chorea, dependent upon chronic parenchymatous degeneration of the cortex of the brain and known as Huntington's chorea. The tendency of many physicians to diagnose these cases as examples of chorea reminds me of the impassioned words of Charcot. On being told by a patient with generalized tic that he had been treated for chorea, Charcot exclaimed: "Chorea! And always chorea! As if that word chorea swept aside magically and majestically all difficulties of interpretation and comprehension."

With simple habit-spasms the physician has little to do unless he happens to be personally afflicted. The twitching or spasm, the result of habit, is rarely sufficiently annoying to be considered pathologic.

Occupation tic, such as "watchmaker's tic," is an occupation neurosis, and should be interpreted and treated as any other affection of this class.

The majority of the acquired motor tics are curable when their cause is discovered and removed. It is the degenerate form of which I wish to speak.

In estimating the prognosis of tic, a number of factors are to be taken into consideration. If our conception of the disease is approximately correct, then it would seem almost a contradiction to speak of tic as inimical to the life of the patient. Tic is a condition which disorders life, but does not destroy it, and when we consider the prognosis we consider in reality the chances which the patient has of ridding himself of this manifestation of developmental or evolutionary shortcomings. Like all elementary troubles the natural tendency of the tics is to progression, and it is this progression that may diminish the potentiality of health preservation. In general it may be said that the earlier the tic develops the less are the chances of its amelioration and cessation. Likewise, it may be stated that the more extensive the development and the more vital the parts in which the tic phenomenon occurs, the less are the chances of cure. In other words, it is my experience that a generalized motor-tic is almost always progressive, no matter what is done for it, and

that a tic of the diaphragm is more stubborn to treat than a tic of the face. Again, it may be said that the greater the number and the intensity of the stigmata of degeneration—in other words, the further the patient is removed from the normal, the less are the chances of assisting him to approximate normality. And, lastly, the longer the symptoms have existed, the greater is the difficulty in terminating them. Patients with tic who have psychic stigmata rarely ever become normal individuals. They may be bettered, but the mental accompaniments are every now and then likely to show their dominancy. In reality, there are few diseases in which the physician is obliged to temper his prognosis with so little assurance of recovery as in the psychomotor tics.

The treatment must be considered under two headings: (1) The treatment of the most annoying symptom, *viz.*, the twitching and its psychic accompaniment, if there be any. (2) The treatment of the neurosis, of which the main symptom is but a manifestation.

The treatment of the twitching varies according to the nature of the tic, that is, whether it be an acquired or a degenerative condition. If it be an acquired condition, the treatment is very simple, and means the removal of the cause. If it be removable, the symptom will disappear with it, although oftentimes it is necessary to utilize at the same time measures which will build up the nervous system, particularly as such simple acquired tics are commoner in neurotic subjects. Orthopedic and surgical measures have a service in the treatment of certain forms of both acquired and degenerative tic. Spasmodic torticollis is sometimes ameliorated if the patient be suspended by means of the head-piece of the apparatus constructed to suspend tabic patients, and practically the same as that used by the surgeon in applying the plaster-corset splint. It will be understood that none of these measures are curative in the degenerative forms of tic. To overcome the disease in these cases, it is necessary to go behind the symptoms and to direct treatment immediately toward the general health and the maintenance of as normal a state of health as the neural conditions with which the patient is born will allow. The necessity of putting all the bodily functions at their best is apparent to every one. This is so obvious in the treatment of all chronic and degenerative diseases that it seems trite and puerile to again refer to it; but as this is one of the diseases in which the utility of such measures is oftentimes more manifest than in its congeners, it is perhaps permissible to mention it. To accomplish this end no one measure can be successful. If the patient be a child and in school, he or she should be removed and encouraged to lead a rol-

licking outdoor life, and be given a course of tonics, while the various hydiatic and hygienic measures which may be utilized for the betterment of the health are employed. In some instances the discipline of partial isolation and the removal from parents and members of the family, particularly if the tic be associated with an emotional state, or occurs in a very nervous individual, is of considerable service.

All sources of pathologic reflexes should be investigated; the eyes, the ears, the nasopharynx, and the genital organs should be passed in review, and any deviation from the normal corrected; but the physician who sees in tic one of the manifestations of the degenerate state will not beguile himself into the belief, nor mislead others by the promise that such patching can replace the evolutionary work of centuries. He will learn to differentiate the simple tics which are symptomatic of some local departure from the normal and the degenerative tics, and shape his words and course accordingly.

Spasmodic wryneck is sometimes alleviated by the administration of large doses of fluid extract of conium, 60 drops in twenty-four hours, and by the hypodermic administration of atropin. The galvanic current applied to the side of the neck oftentimes gives relief, particularly if the condition be painful, and massage is often of real service. Stretching of the facial nerve for facial tic and resection of the spinal accessory nerve and of the posterior branches of the four upper cervical nerves has been resorted to many times. If the procedure be thoroughly done, naturally it overcomes the spasm even though the tic be of the degenerative variety.

Simple facial tic in children is oftentimes found associated with some disease of the nasopharynx, and treatment directed immediately to this condition and kept up persistently will overcome the twitching in the facial musculature. I have notes of a number of cases in which such treatment has been efficacious. The indications for treatment are as direct as they are in the treatment of what has been called watchmaker's tic, a tic of the orbicular muscles following the use of the glass which these artisans hold in the orbit. In short, the source of the twitching being removed, and the general health of the patient cared for, recovery follows.

The treatment of the neurosis of which the tic is a manifestation is practically the same as the treatment of any other degenerative condition subject to individual and selective variation. The measures to be utilized are hygienic and medicinal. The hygienic should have in view, first, the development of the body, and, second, the development of the mind, and the medicinal should find its object in increasing the potentiality of life in the cellular elements of

the higher tissues. If we recall for a moment the treatment which is most serviceable in other degenerative diseases, and if we apply the results of our ratiocination to the treatment of this disease, we will be led, I believe, to formulate certain definite rules which should guide us in the theoretic handling of tics. For instance, let us take, as examples of degenerative disorders, the diseases which were enumerated in the beginning of this article, and see what is to be learned from a consideration of their up-to-date therapy. Will anyone gainsay the statement that there is any measure in the treatment of epilepsy which approaches the employment of the bromids, and will any one deny that in order to secure their fullest efficaciousness that they must be given in doses which will produce at least slightly poisonous symptoms? One of the first tasks which the physician sets himself, when face to face with the treatment of a case of epilepsy, is to determine the largest possible dose of the drug which may be continuously administered without injury to the patient, and after he has determined it he reaches out for every means at his command to so maintain the patient's vitality that such administration may be continued without injury. This treatment of epilepsy gives the best results. It is the same with hysteria, with migraine, with chronic chorea, and, indeed, I may say it is the same with all the degenerative conditions of the nervous system, using the word degenerative here in its pathologic sense. There has yet to be discovered a drug which is as efficacious in staying or delaying the basic process of locomotor ataxia as nitrate of silver. But, in order that benefit may be derived from it, it must be given in large doses, and the patient must consent to take the chances of argyria. So, I might go on and enumerate a number of other degenerative conditions in which, in order to derive any lasting beneficial effect, it is necessary to give a drug in large doses, in short, it is necessary to poison the patient. I am a believer in the use of drugs, in the efficaciousness of drugs, and in the use of therapeutic aids which are not drugs, but more than this, I believe that when it is elected to give drugs that they should not be given half-heartedly, but with a definite object in view, and that our strife should be to secure that object or demonstrate that it is not obtainable. A consideration of the therapy of chronic diseases of the nervous system has led me to one or two well-defined convictions which I have endeavored to apply in the treatment of the tics, and which I shall take the liberty of now laying before you. I have already spoken of the necessity of giving drugs in adequate doses. Experience has taught me that for the chronic nervous diseases of the slowly progressive

order the salts of the metals are of greatest service, and that in chronic diseases conditioned through the vascular system, the vegetable poisons and their alkaloids are of similar service. In support of this statement, I would cite again the use of the bromids in epilepsy, of silver in tabes, and strychnin in tic-douloureux.

I believe that I have witnessed the efficaciousness of the sulphate of copper and of the nitrate of silver sufficiently often in cases of degenerate tic to warrant me in calling anew your attention to them, when they are given in sufficient doses and for a prolonged period. It is impossible, of course, to say how these alteratives act or what they do to influence the progress of the neurosis. If they are administered in a desultory fashion, or if they are given for a short time only and in a more or less haphazard way, their use will be very disappointing. They should never be alone relied upon to benefit the neurosis, but should be employed as adjuvants to the disciplinary, hygienic, and moral treatment which has already been referred to.

The education of children with tic should be along the same lines as that of children who have hysteria or epilepsy, and with the same object in view, *viz.*, to increase the stability of the nervous system while the nutritional state is kept as near to perfection as possible. In these diseases the moral and disciplinary treatment calls for the intelligent collusion of the physician and pedagogue. The details of such treatment must suggest themselves to every physician. All manifestations of precociousness are to be discouraged, childish coquetry, affectation, and self-indulgence should be exterminated, and the epochal periods of puberty and menstruation should be jealously guarded. As in hysteria, the cultivation of outdoor sports and plenty of refreshing sleep for children are inimical to the development of the tics. Inculcation of the precepts of self-control, generous feeling, altruistic sentiment, and intolerance of affectation, all have due influence in the disciplinary training of such a child.

In the minor forms of tic, it is sometimes possible for the patient to control the twitching, partially or completely, by an effort of the will, and they should be encouraged to do so. In the more severe forms, and in cases of generalized motor tic, the twitchings are materially lessened, or indeed they may cease, while the patient is indulging in absorbing occupation or sport. I have seen marked benefit follow the use of the bicycle. The patient with generalized tic whose history has been epitomized in this paper indulges in this form of sport to considerable advantage. The tic movements often stop entirely at such times and the longer they cease the better for the patient.

Summary.—In conclusion, I would like to repeat that I have endeavored to show that tic is, in the majority of cases, a degenerative neurosis; that its most prominent outward manifestation, *viz.*, the twitching, the one from which it takes its name, is a stigmata of degeneration, just as hemi-anesthesia is a stigmata of degeneration in hysteria; that its next most common stigmata are psychic and consist of compulsions, obsessions, and possessions; that tic occurs in individuals who have stigmata of degeneration; and that it is one of the degenerative diseases which develops early. I have not contended that all forms of tic are of the degenerative kind or the concomitant of a degenerated neurosis. On the contrary, I have desired to emphasize that simple motor tic, let us say tic of the musculature of the seventh nerve, oftentimes is a reflex condition dependent upon irritation of some of the branches of the fifth nerve, that in elderly persons it is often associated with degeneration of the blood-vessels, and that in the young it is sometimes seen with perverted states of nutrition, and that it recovers when these are overcome. Furthermore, I have reiterated that it has absolutely nothing in common with acute, humoral, Sydenham's chorea, nor with degenerative, parenchymatous, Huntington's chorea, and that the term chorea should never be thought of in connection with this disease, and finally, that tic being in a majority of instances a degenerative neurosis, it conforms in occurrence, in development, in progression, in obstinacy, and unresponsiveness to treatment with other degenerating diseases; that the form of treatment of greatest avail is like that which has been shown to be of service in the class of diseases of which it is a type; that the same principles should guide us in the treatment of tic, as in the treatment of hysteria, epilepsy, and of congenital defects in general, and that in my experience the salts of copper and silver, when given in comparatively large doses and for a prolonged time, while the bodily health and the general morale are cared for, are more efficacious in the degenerative form than other therapeutic measures.

THE SOURCES AND DIAGNOSIS OF PYURIA.¹

By HOWARD A. KELLY, M.D.,
OF BALTIMORE.

If I were asked what subject of all others in the range of medicine I considered it most important to bring prominently before the profession at this juncture of the advancement of our art, I think I would reply, on the spur of the moment, pyuria. Let me emphasize the importance of my subject by saying that there are to-day thousands of women in our

country going about with a pyuria of undetermined origin; that in most instances the disease is progressive, going from bad to worse, and for this reason valuable time is being lost; and that the investigation of the source of a pyuria is not difficult to make, simply requiring some special instruments and a little practice in using them. It is my desire to speak to you briefly of the methods at our command for investigating and tracing a pyuria to its source, of determining the point at which the pus enters the

FIG. 1.

Showing a number of the sources of pyuria from the extreme lower urinary tract up to the area surrounding the kidney. The circles indicate the location of the abscess and the arrows the direction in which the abscess discharges. The character of the abscess is described on the diagram.

urine, its cause, and the extent of the involvement of the urinary tract.

Pyuria signifies nothing more nor less than the presence of pus in the urine, a sign common to a variety of affections of the urinary passages. It is, therefore, but a symptom of an involvement of some portion of the urinary system, from the external urethral orifice up to the capsule of the kidneys.

The investigation of the cause of a pyuria must be *analytic*, taking the symptom and tracing it to its source by a process of exclusion. This is the natural procedure in the routine investigation of most diseases. Your patient comes to you with a more or less definite complaint of a disturbance along the urinary tract, often exceedingly vague, and you examine the urine and find that it contains pus, you then naturally conclude that if you can find the source of the pus you will locate the disease. While the question

¹ An address delivered at a meeting of the Southern Surgical and Gynecological Society, held at St. Louis, Mo., November 9, 10, and 11, 1897.

presents itself in this way, the means which we have hitherto had at our command for making such a determination have been generally most unsatisfactory.

FIG. 2.

Showing the finger in the act of expressing a drop of pus from Skene's gland on the right side. The index-finger is introduced within the vagina and engaged in compressing the ureter up under the symphysis pubis, which is represented by a dotted line. The direction of the pressure is from above downward.

If an enlargement is not found in the loin suggesting a kidney containing pus, or if a point of tenderness is not found somewhere along the accessible part of the urinary tract, how is it to be determined where

FIG. 3.

Showing the appearance of a suburethral abscess occupying the anterior wall of the vagina. The abscess is exposed by retracting the posterior vaginal wall.

the pus comes from? Moreover, the clinical signs themselves may be most misleading; for a stone in the kidney or a tuberculous kidney may give no

other sign than a vesical tenesmus; and then, too, if both kidney and bladder are inflamed, how is one to ascertain this fact and to determine the extent of the involvement of each? The question, as it stands to-day, with better means at our command, is much like the case of a man who comes to you complaining of a sore throat and purulent expectoration, and you try to determine the exact location and extent of the malady by a series of questions and by looking at the sputum, without once asking him to open his mouth, and thus looking down his throat, seeing exactly what is wrong. It is my desire, therefore, to emphasize the importance of the direct methods of

FIG. 4.

inquiring into the sources of pus in the urine, and I shall, for this reason, but briefly refer to the other accessory diagnostic procedures at our command.

The history of the case must be carefully considered, and the duration of the disease, the exact character and location of the pain, the frequency of urination, the existence of morbid processes elsewhere, such as phthisis, etc., must be noted. The microscopic characteristics of the urine are of the utmost importance, as the quantity of pus present, variation in the amount, the character of the pus-corpuscles themselves, the presence of blood, crystals, or cellular debris in the urine are all factors liable to afford a clue to the source of the pus.

An infection is almost always the basis of a pyuria, and this may be due to any one of the pus-producing

organisms. A scientific investigation will aim to determine which one of a large number of such organisms is present. Such a determination is not without a high degree of practical importance, as some of them exhibit a marked predilection for a special portal of entry; the gonococcus, for example, enters the urinary tract by the urethra, and the colon bacillus is more apt to be an invader from a neighboring bowel.

Pyurias may differ in the following ways: In the quantity of pus; in the reaction of the urine, which may be alkaline or acid; whether or not pus is constantly present, and whether it varies in quantity at different times. A little pus, found microscopically, associated with an irritable bladder, may mean nothing more than a hyperemia of the vesical trigonum or a ureter which is irritated by a concentrated or an intensely acid urine; a large amount of pus almost invariably proceeds from the kidney. Renal pus is usually acid, while pus from the bladder walls is often strongly alkaline; an intermittent or remittent flow of pus is most likely to come from an extravascular source, either from a kidney or an outside suppurating area communicating with the urinary tract.

In investigating a pyuria, we should always bear in mind that it may originate in one of two ways: either in a diseased condition of some portion of the urinary tract itself, or it may depend for its continuance upon a disease located outside the urinary tract and simply discharging through it as an avenue of exit from the body. The principal portals of entry for such an affection are by the pelvis of the kidney and by the bladder; in the vast majority of cases by the latter (Fig. 1).

Let us now see what we can do to clear up a diagnosis by a direct examination, which, in order that it may be complete, must pass in review the possible diseased conditions of the entire urinary tract from the external urethral orifice to the kidney, as well as the contiguous structures as far as they are accessible. I can perhaps best illustrate what I wish to inculcate by citing typical cases from my practice, proceeding in our investigation in an anatomic order from below upward.

Urethra.—To begin with, the urethra furnishes three possible sources from which pus may enter the urine: (1) Skene's ducts; (2) a urethritis or ulcer of the urethra; (3) a suburethral abscess.

A small amount of pus, a drop or two lodged in Skene's glands, may easily escape observation unless it is made a part of the routine of every examination to milk them out by pressing first one side then the other up under the pubic arch and squeezing downward and outward. A drop of thick yellow pus may exude from the external orifice of the gland

or duct of the side from which it originates. The diagram (Fig. 2) serves to illustrate one of my cases in which this condition existed unsuspected.

A urethritis or a urethral ulcer will also afford a source of pus-contamination of the urine, which is easily detected by using a two-glass test in passing the urine; the first urine escaping brings with it the pus, and consequently that which follows will be clear. The inflamed ulcerated urethra is readily observed through the cystoscope as it is withdrawn. One of the most marked cases of this kind I ever had was due to a gonorrheal ulcer of the posterior wall near the neck of the bladder where Littre's glands are found.

A suburethral abscess (Fig. 3) is a rare but most in-

FIG. 5.

Showing a dermoid cyst adherent to the peritoneal surface of the bladder, suppurating, and discharging by a sinus into the bladder.

teresting condition, and one which is easily overlooked. This is the only source of urethral contamination which occasionally yields considerable quantities of pus. Two cases of this kind have passed through my hands, in both of which there was a little pouch projecting into the anterior vaginal wall, which was not otherwise altered in appearance. This pouch was full of pus, and communicated by a slit with the posterior wall of the urethra, into which it intermittently discharged a teaspoonful or more of pus. Through the urethroscope I could see the slit and introduce a probe which could be felt in the bottom of the sac.

Bladder.—The vesical sources of pyuria are three in number: (1) cystitis and trigonitis; (2) foreign body, and (3) ulcer.

All of these various affections may readily be diagnosed by examining the bladder through a simple

cylindrical cystoscope, with the patient in the knee-chest posture, under which condition the bladder becomes distended with air. A small electric head-light or an electric light is held close to the sacrum and the rays reflected by an ordinary head-mirror into the bladder, when this viscus may easily be examined. I wish to call particular attention to the fact that it is important in order that the base of the bladder may be satisfactorily inspected to let air into the

FIG. 6.

Showing an abscess of the vermiform appendix discharging by a fistulous orifice into the bladder.

vagina before dilating the bladder. This brings the floor of the bladder almost into the plane of vision, and makes the trigonum easily accessible. Ulcers are most apt to be found here, and an inflammation localized in this neighborhood—a trigonitis—is the commonest form of localized cystitis.

Extravesical Sources of Pyuria.—There are several extravesical sources of pyuria, the commonest being those connected with inflammatory diseases of the Fallopian tubes, of which I have observed a number of instances. In one of my cases (Fig. 4) a small tuberculous abscess broke into the right horn of the bladder near the base of the broad ligament, while all the rest of the urinary tract remained un-

affected. I discovered its presence by means of the red mammillated edematous mucosa surrounding the concealed opening, from which, during examination, a bubble of air escaped, and when I introduced a

FIG. 7.

Showing a carcinomatous fistula at the base of the bladder surrounded by secondary nodules.

searcher at this point its withdrawal was followed by the escape of pus. A rarer avenue of entrance is by the adhesion of a suppurating tumor to the free peritoneal surface of the bladder, subsequent to which perforation occurs. A case of this kind came into my hands a year ago through her brother, a prominent physician in New York State. The diagnosis of a tuberculous kidney had been made, but I was able to at once relieve the extensive pyuria by removing a dermoid cyst attached to the vault of the bladder and dissecting out and closing by suture the long sinus of communication between the tumor and the bladder (Fig. 5).

Let me also illustrate these extravescical sources of pyuria by citing a brief history of the following case in which the cause operated from the vagina: My patient had an atresia of the vagina. I found embedded in the perivaginal tissues the stem of a hard-rubber stem-cup pessary, the cup of which lay concealed in the upper part of the vagina above the atresia, where it had eroded a little opening into the base of the bladder through which a quantity of fetid pus was constantly discharged with the urine.

I shall not pause longer to dwell upon examples of abscess originating in extra-uterine pregnancy, or acetabular, or psoas-abscess, or an abscess from the vermiform appendix, also emptying in this way (Fig. 6), or the intense cystitis evoked by an intestinal fistula, or a carcinoma extending from the uterus.

The Ureters.—If a direct examination and analysis of the evidence presented does not reveal a source of the pus in the lower urinary tract, the whole upper urinary tract still remains to be investigated. May the source, and often the nature of a pyuria originating

in a ureter, pelvis of the kidney, or the kidney itself, be easily determined? This may be accomplished with facility in two ways, both of which depend upon

FIG. 8.

Showing a tuberculous strictured left ureter with a pyo-ureter and pyelonephrosis above the stricture.

the fact that the turning of the vesical speculum about thirty degrees to the right or to the left, and dropping the handle so as to bring the floor of the bladder into view, will readily afford a good view of a ureteral orifice.

Too much has been said about the difficulty of doing this. It is not difficult; it only requires practice. I have just said that there are two ways of locating the source of a pyuria above the bladder. When an abscess breaks through into this viscus from any of the extravescical sources just pointed out the opening through which it discharges is always plainly indicated by an area of intense congestion; in like manner, when the pus comes down one of the ureters into the bladder, in many instances, the ureteral orifice of that side is intensely reddened, mammillated,

or even ulcerated. The second way consists in determining at just what point in the upper urinary tract the infection is located, by passing ureteral or renal catheters so as to investigate the entire length of the ureter and the pelvis of the kidney. I have located in this way the source of a pyuria in a pyo-ureter due to a gonorrheal stricture at its vesical end, and when I succeeded in passing a metal catheter through the tortuous stricture 150 cubic centimeters of pus at once escaped. I have located the infection in a tuberculous pyo-ureter where the pus had accumulated above a stricture near the brim of the pelvis (Fig. 8). I located another in a pocket above a stricture in the upper third of the ureter (Fig. 9) and the patient recovered after its evacuation and the dilatation of the stricture.

Renal Pyuria.—Finally, we have to distinguish, in the absence of any source of contamination below, those pyurias (a large group) which have their origin in the pelvis of the kidney, usually associated with an obstruction at the renal opening of the ureter, causing the pus to dam up in considerable quantities.

FIG. 9.

Showing an abscess in the upper part of the ureter just below the pelvis of the kidney.

This obstruction may be due to a catarrhal puffy mucosa of the renal pelvis, or to an oblique entrance of the ureter into the pelvis causing its compression as

the latter distends, or to a rotation of the kidney, which twists the ureter, or to the obstruction caused by a stone or a new growth which plugs the orifice, or to the fact that the pus is too thick to readily escape down the small ureteral channel. The source of the pus may be readily distinguished by passing a long renal catheter, which enters the pelvis of the kidney and permits of its slow escape. If the pus is too thick to run out of the narrow lumen of the catheter, it may be sufficiently thinned by injecting some boric-acid solution, and in some cases even assisting the mixture of the fluids by manipulating a large kidney between two hands. By repeated washings in this way all the pus will be evacuated.

The nature of a pyelitis of this sort must be determined by a bacteriologic examination of the pus,

FIG. 10.

Showing a pyelonephrosis with compression and thinning out of the renal substance due to the presence of a renal calculus. The ureter enters the kidney at an acute angle as often found in simple pyelonephrosis.

by an investigation of the history to determine whether the patient has had any previous hydronephrosis, and by a further examination to detect the presence of a calculus. I find that some cases of intermittent pyonephrosis are due to the unsuspected existence of a hydronephrosis of a low grade, the pelvis of the kidney containing at the utmost not more than from ten to twenty cubic centimeters of fluid. Following some undetermined cause or an attack of grip, or other depressing illness, the patient has a chill followed by high fever and general aching with more or less pain in the loins, associated with the appearance of pus in the urine. After washing out the kidney the symptoms all subside, but a simple hydronephrosis remains.

When there is a stone in the kidney (Fig. 10) the use of the catheter may bring down a little black *débris* which sinks to the bottom of the vessel, and should

always be looked for. A bit of the stone may stick in the eye of the catheter, or best of all, if the end of the catheter is coated with a mixture of dental wax and olive oil, the soft polished surface of the wax will be scratched by contact with the stone, and the scratch marks may be seen by examining the wax with a low-power lens.

Other sources of pus in the urine are from tuberculous (Fig. 11) or other abscesses of the kidney substance itself, discharging into the pelvis of this organ and thus into the ureter. When tubercle bacilli are found in urine taken from the upper urinary tract, it almost always indicates a tuberculous affection of the

FIG. 11.

Showing a tubercular abscess discharging into the pelvis of the kidney, the shaded area showing the sound portion of the kidney.

renal substance. In rare instances a perinephric abscess, such as a suppurating hydatid cyst, breaks through into the renal pelvis, and so finds its exit from the body through the urethra. In all cases of renal origin the diagnosis will be made, and in some the exact cause determined, by using the ureteral catheters as recommended.

SPYROCOLON AND SYPHILIS IN GREECE.

By ACHILLES ROSE, M.D.,
OF NEW YORK.

No country in all Europe is less afflicted with syphilis than Greece. The reasons for this remarkable fact are the following:

1. The majority of the population, namely, 55.27 per cent., are peasants.
2. Houses of prostitution, except in some but by no means in all cities, do not exist. This is the

more honorable to the Greeks of to-day when one recalls the ancient cult of Aphrodite Pandemos. Even Athens was without a brothel until the French introduced their morals, or lack of morals, during the blockade of the Piræus at the time of the Crimean War (1854-1857).

3. The restricted communication between many districts with large cities or foreign lands.

4. The strict morals of the majority of the population. All witnesses agree that chastity is law in Greece. The bitter enemies of this country cannot deny that Greek women are virtuous women; that women are nowhere more highly respected.

All that we know about syphilis in Greece at a period previous to our century, is that this disease was comparatively common in the principal Ionian Islands and in Crete, where houses of prostitution existed and where morals were somewhat more lax. It appears that in the cities and maritime stations where, toward the end of the last century, navigation and commerce had developed to a greater extent, and from which places many Greeks visited Western Europe, syphilis was more frequently met with. But in addition to this appearance of the disease, which can easily be explained, there occurred in Continental Greece and in the Peloponnesus, at a time which cannot exactly be stated, one or more formidable invasions of syphilis, or rather of *spyrocolon* *scerlievo*. Since a part of Greece has regained her independence several villages of Acarnania, of Æbolia, of Phthiotis; and of Bœotia of Continental Greece, and of Messinia in the Peloponnesus have also had such invasions.

According to information from physicians of a preceding generation, there can be no doubt that these invasions came from Albany. This statement is confirmed by the fact that the disease showed itself more frequently, in some parts almost exclusively, among Albanians, and among Valachian nomads or others who had intimate relations with the Albanians. It has been established that in Acarnania and Eurytania, where the occurrence of the disease had been very rare before the War of Independence, it was introduced by Albanian troops, and that it likewise made its appearance in Aetolia and Acarnania, to which places several Albanian families had migrated.

During the year 1841 Dr. Carl Wibmer, physician to King Otto of Greece, published his observations on *spyrocolon*, a new disease, which made its appearance in the northern part of Greece about 1821 or 1826. This disease showed itself first in the province of Bœotia, and in the Baltos, and later on in almost all of the other provinces of the northern part of the new kingdom. While there existed a few

cases only, the few physicians who at that time lived in Greece did not pay much attention to it; neither did the inhabitants. The symptoms resembled those of syphilis and lepra. Only later on, when it began to spread rapidly, did physicians and sanitary officers become alarmed. For the greater part they diagnosticated it as syphilis, or a yet undefined form of lepra. The inhabitants called it *spyrocolon*, or *orchida*. Dr. Wibmer was of the opinion that it was the same disease which the Italians called *scerlievo*, the Scandinavians *radesyge*. Wibmer and Kalogeropoulo describe the symptoms as follows:

“Generally the disease begins with an attack of vertigo, which in some cases is so violent that the patient drops down; in some cases there is an initial chill. Occasionally there occurs, instead of the vertigo, or associated with it, severe headache. After headache and vertigo have persisted for days, weeks, or even months, the headache ceases, and suddenly pains in the arms, legs, especially in the ulna, finger-joints, and also, in some instances, in the back and in the shoulders make their appearance. Within a few days the pains extend over all parts of the body, especially in the joints. They become aggravated during the evening and night. Sometimes they are not preceded by headache and vertigo. These pains in the bones and joints last, as a rule, weeks or months. The periosteum becomes swollen. After this condition has lasted a longer or shorter time, there appear suddenly upon the skin at different parts of the body, especially on parts covered with hair, often at different regions simultaneously, round, unequal, copper-colored pustules, resembling those of smallpox. They secrete offensive pus, and change, after a few days, into red, psoriasis-like scales. Having fallen off, they leave dark brown marks. In some instances there is no suppuration; the skin only shows tiny red nodules. After some weeks there are noticed round, large ulcerations with a whitish base in the mouth, on the lips, palate, tongue, in the nasal cavities, and on the genital organs, and condylomata around the anus. As soon as these make their appearance, the pains in the bones and joints, as a rule, become less, or disappear altogether. At this time the voice undergoes a change and becomes hoarse to such a degree that patients cannot make themselves understood. Some also suffer from dyspnea. The digestive organs do not seem to be involved. In women the catamenia discontinue from the beginning of the attack. In the course of years, while the disease lasts, the ulcers spread and cause considerable destruction; then the skin becomes covered with reddish scales, and the patients present a swollen, demented appearance. The periosteum swells, the dyspnea becomes aggravated, and at last the disease

ends with the development of tabes. The most constant of these symptoms is the progressing hoarseness. In some cases it is the only symptom noticed, while in some exceptional instances, however, it may be wanting. No age or condition of life is exempt from attack. Antisyphilitic treatment will control the disease within some weeks or months. Hoarseness is generally the symptom which lasts the longest."

During the endemic which existed at the time of the War of Independence, the symptoms were indeed grave, and this can easily be explained. We know from history how the Greeks at that time suffered for want of food, and how poor the quality of the food was. The disease made its appearance without warning. Physicians were few, and in most cases patients received no treatment.

The above described irregularity in the succession of symptoms, and some other differences or apparent differences from typical syphilis, which were observed in places where the disease reached its height, have given rise to doubts as to whether it was really syphilis or some other affection. Crosinis and Pallis insisted upon the syphilitic character of *spirocolon*. Dr. Albanarius has written an exhaustive treatise on the subject. He was for some years director of the Hospital of the *Spyrocolics*, at Calamas.

During 1847 special hospitals for sufferers from the disease were opened in Acarnania, Phthiotis, Parnassidis, Boeotia, Achaia, and later on, at Calamas. A law was passed compelling the segregation in these hospitals of all persons afflicted, thanks to which measure the disease became extinct. Aside from this endemic appearance of syphilis or *spirocolon* in the rural regions, real, unmistakable syphilis appeared in the cities. Then it was met with elsewhere, principally in the Ionian Islands, especially Zante and Corfu, and in Athens, Piræus, Hermopolis, Nauplia, Lamia, Patras, and Calamas. It was also frequently encountered in certain islands where the inhabitants were sailors, especially Hydra and Spetsa, while in other islands, inhabited also by sailors, very few cases were known to exist. In the agricole islands of the Archipelagos, in the greater part of Eubœa, in the different places of Mantinea and in Megara, the disease is almost unknown. With the development of syphilis in different cities, which has taken place since a part of Greece became independent, the disease was transmitted to other localities where it had not before existed. On the other hand, it disappeared from the rural districts, and even from some cities where it had been introduced during the war.

RAPID DISINFECTION WITH HIGH PERCENTAGES OF FORMALDEHYD; RESEARCHES CONDUCTED AT THE HYGIENIC LABORATORY OF THE UNITED STATES MARINE HOSPITAL SERVICE.

BY EZRA KIMBALL SPRAGUE, M.D.;
PASSED-ASSISTANT SURGEON UNITED STATES MARINE HOSPITAL SERVICE.

IN recent years, when we have learned to place a proper estimate upon the value of disinfection as a means of preventing the introduction and spread of infectious diseases, there has arisen a demand for an agent which, without injury to fabrics, will promptly destroy the most resistant pathogenic organisms. The ruinous effects of steam, mercuric chlorid, carbolic acid, and sulphur dioxide upon certain articles are too well known to require comment. But in formaldehyd we have at last found an efficient disinfectant which, according to the results of experiments, seems to be practically non-injurious.

Dr. J. J. Kinyoun, Passed-Assistant Surgeon, Marine Hospital Service, says in *Public Health Report*, January 29, 1897, "At this juncture it might be well to remark upon the effects of formaldehyd gas and its solutions upon textile fabrics, hair, fur, and leather. Experiments were made by subjecting samples of wool, cotton, fur, and leather goods, to crucial tests, using solutions of various strengths, and also a saturated atmosphere of the gas. The results obtained were in every way satisfactory. Of over 225 different samples of wool, silk, cotton, linen, leather, and hair, employed in the tests, there was no change observed in textile character, even when they were soaked in a strong solution of the gas. Little, if any, change occurred in the colors of the fabrics, only three of the number showing any change whatsoever—two shades of violet, and a light red. The affected colors were a product of coal-tar, and were also quickly bleached by the sun."

From the above there can be no doubt that we now have in formaldehyd a disinfectant which may be used upon all articles without injury thereto. Hitherto, most of the experiments with formaldehyd have been made with a small percentage of the gas, and with a long exposure, twelve to forty-eight hours. There can be no question regarding its efficiency when thus employed, but its field of usefulness would be greatly limited were the minimum time of exposure to be twelve hours. The fact that no apparatus had been constructed on a plan such that a high percentage of gas could be secured and maintained compelled the employment of relatively small quantities. With the Kinyoun-Francis formaldehyd disinfector, manufactured by the Kensington Engine Works, Philadelphia, it is possible to

make use of as high a percentage as may be desired, and the chamber being air tight, the quantity of gas is not decreased during the time of exposure.

It has been urged against formaldehyd that in practical application its effects are uncertain, because the percentage of gas generated cannot at all times be accurately determined. This objection holds good against all other generating apparatus with which the writer has had experience, because of an inherent inability to so regulate the heat that formaldehyd alone is generated without the production of comparatively inert polymeric forms; but with a thirty-per-cent. solution of calcium chlorid in formalin, heated by a steam coil, these polymers are not produced, and consequently with an apparatus thus equipped this objection is removed, and the percentage of gas generated can be calculated with mathematic certainty.

The Kinyoun-Francis apparatus consists of a disinfecting chamber, a boiler-iron cylinder without a jacket, with a capacity of 1090 liters. To the cylinder is attached a vacuum apparatus, a formaldehyd generator, and an ammonia generator. The cylinder is also fitted with a rack in which the various articles for disinfection are placed. The formaldehyd and ammonia generators are attached at the middle of one side of the cylinder and, although distinct, are covered with a Russia-iron jacket, which would conceal their identity were it not for the fact that to each is attached a brass plate, one marked "Formalin" and the other "Ammonia." The formaldehyd generator is a copper boiler, containing a copper coil, and its capacity is 3.21 liters. The ammonia generator is of the same construction and capacity, with the exception that the copper is replaced by iron. The coils are connected with a steam boiler, and the generators communicate with the disinfecting-chamber by means of small pipes which are fitted with the proper stop-cocks.

The articles to be disinfected are placed in the rack or car which is rolled into the chamber, the door is closed and secured, and a vacuum of fifteen to twenty inches obtained. The formaldehyd generator having been previously supplied with 200 cubic centimeters of a thirty-per-cent. solution of calcium chlorid in formalin, steam is turned into the coil, and, by means of a gage, the pressure of formaldehyd is recorded in atmospheres. By comparing the capacity of the generator thus filled (2.71 liters) with the capacity of the chamber (1088.72 liters) we find that it corresponds very closely to 1-400. Consequently, with a pressure of twenty atmospheres of formaldehyd in the generator, if the gas is turned into the disinfecting-chamber we will have very nearly five per cent. formalde-

hyd therein. Working, as we did, upon the above basis, forty atmospheres equaled ten per cent. in the chamber, and eighty atmospheres, twenty per cent. The percentage of formaldehyd having been decided upon, the gas is turned into the chamber and allowed to remain in contact with the various articles contained the desired length of time, at the end of which the vacuum is opened and the air rushes in. This mixture of air and formaldehyd is then exhausted, and the ammonia generator, previously supplied with about 500 cubic centimeters of aqua ammonia, is operated in the same manner as already described for formaldehyd. The latter having been in a great measure removed with the air, one to two per cent. of ammonia will neutralize the residue. Air is again allowed to enter the chamber and the door may now be opened. It is usually found that there is a slight excess of ammonia, but not enough to cause any annoyance. In order to test the efficiency of the apparatus sterile cover-slips were respectively smeared with a drop of bouillon culture of anthrax, diphtheria, and typhoid bacilli. These slips were dried, wrapped in sterile lens paper, the package being then placed in a sterile envelope and marked. Plate-cultures of the same organisms were also prepared in order to show the effect of formaldehyd on both dry and moist bacteria. Before exposure the envelopes were cut open to permit access of the disinfecting-agent. One set of slips was placed free in the chamber, one between the leaves of a large book, one buried in a cotton mattress, one in a hair pillow, one in a feather pillow, and still another was tied up in a bundle of letters. The last was sealed in a non-perforated envelope. The covers of the plate-cultures were removed and two thicknesses of sterile cheese-cloth tied over the top, after which a set of them was placed in the mattress and in each of the pillows.

EXPERIMENT 1.

Exposures were made as follows:

- 5 per cent. formaldehyd, 15 minutes.
- 5 per cent. formaldehyd, 60 minutes.
- 10 per cent. formaldehyd, 30 minutes.
- 10 per cent. formaldehyd, 60 minutes.
- 20 per cent. formaldehyd, 30 minutes.
- 20 per cent. formaldehyd, 60 minutes.

The first exposure of fifteen minutes with five per cent. formaldehyd may be dismissed with a few words. It was the first time the apparatus was used, and only thirty-eight cubic centimeters of the formalin and calcium-chlorid mixtures was placed in the generator.¹ Mechanically the trial was successful, and the

¹ Note. This experiment is of practical interest because it confirms the truth of the estimate that a pressure of twenty atmospheres in the formaldehyd generator will fill five per cent. of the space in the chamber. By the rule of three it is readily seen that if one liter of formalin will generate 1425 liters of gas, thirty-eight cubic centimeters of formalin should generate fifty-four liters or five per cent. of the capacity of the chamber.

five per cent. of formaldehyd was generated, the gauge showing a pressure of twenty atmospheres before the gas was turned into the chamber, but the organisms were not killed in a single instance. In the succeeding experiments a larger quantity of formalin was placed in the generator, and the volume of gas estimated from the pressure. Proceeding in this manner only two charges were required for the entire work.

EXPERIMENT II.

Percentage of formaldehyd, 5; time, 1 hour.

(A) Cultures on Petri dishes covered with two thicknesses of cheese-cloth:

Typhoid.....	no growth

In each experiment a package of letters, in the center of which was placed dried cultures in sealed envelopes, was securely tied and thrown into the rack. Growth occurred in all cases. In all probability, if the packages had been perforated they would have been disinfected in some instances, but the trials were made with sealed letters for the express purpose of ascertaining whether or not it were possible to avoid mutilating them with a punch.

The above experiments were performed by direction of Surgeon-General Wyman of the Marine Hospital Service, and were conducted under such conditions as would obtain at a well-equipped quarantine station. While surface disinfection was accomplished with twenty per cent. of gas after thirty-minutes' exposure, as well as after one hour, the results in the interior of the mattress and pillows were not entirely satisfactory. The destruction of the organisms between the leaves of a large book after one-hour's exposure demonstrates that formaldehyd turned into a vacuum chamber possesses no considerable power of penetration.

We know of no one, heretofore, who has claimed that disinfection with formaldehyd could be secured in less than four hours. But even that is too long a time to render its use practical at a quarantine station, where results must be obtained with the least possible delay.

At the National Quarantine Stations formaldehyd lamps are now in practical use for the disinfection of cabins, forecastles, etc. In the recent epidemic of yellow fever, disinfection of mails, baggage, and freight has regularly been performed with formalin generators or lamps, and with the best results. They have also been used at the detention camps established at Fontainebleau, Mississippi, Mount Vernon Barracks, Alabama, Camp Hutton, and other points. As rapidly as possible, all the quarantine stations under the control of the Marine Hospital Service are being equipped with the most approved and complete appliances for the use of formaldehyd in in-

stances where it would be preferable to other methods.

While the specific time for exposure in vacuum with twenty per cent. of gas is one hour, and for the present it will not be lessened, the foregoing experiments demonstrate that the disinfection of clothing and articles of like nature can be accomplished in thirty minutes. It is not improbable that with higher percentages better results will be obtained, and in a future article it is intended to give the results of further experimentation; but enough data have already been given to prove that with formaldehyd rapid and efficient disinfection may be secured, and that, without injury to the most delicate fabrics.

CLINICAL LECTURE.

HEMORRHAGIC INFARCTION OF THE LUNGS; SUDDEN DEATH FROM HEART DISEASE.¹

By R. C. M. PAGE, M.D.,
OF NEW YORK;

PROFESSOR OF GENERAL MEDICINE AND DISEASES OF THE CHEST
IN THE NEW YORK POLYCLINIC MEDICAL SCHOOL
AND HOSPITAL.

Hemorrhagic Infarction of the Lungs is a circumscribed pulmonary apoplexy due to embolism. Though it may occur in several ways it usually results from the plugging of a branch of the pulmonary artery by an embolus, which is followed by diapedesis or transudation of blood into the parts formerly supplied by the obstructed arterial twig. More rarely it is due to rupture of a branch of the pulmonary artery from intense hyperemia around the obstruction and subsequent fatty degeneration of the vessel. According to Rindfleisch, in such cases the blood finds its way into the air-cells and bronchi in the vicinity, rapidly coagulates, and the process ceases. In some cases no cause of the infarction can be discovered, as all traces of an embolus have disappeared.

When a twig of the pulmonary artery is completely occluded by an embolus, the parts beyond the obstruction, *viz.*, the air-cells, bronchioles, and interstitial tissue, become the seat of hemorrhagic infarction. Cohnheim says that, "this is accomplished by the arterial blood being forced backward or regurgitated from the capillaries of the pulmonary veins into the excommunicated capillaries of the obstructed twig of the pulmonary artery." As a rule, the latter do not rupture, but permit a diapedesis or transudation of blood-elements through their walls, which are abnormally permeable owing to the fact that their integrity has been impaired by embolism. It is also probable that they allow leakage of arterial blood more readily than venous blood, on account of their being accustomed to the latter. Formerly it was thought that infarction in these cases is invariably due to rupture of the capillaries from intense hyperemia alone, as might occur in mitral disease, without taking into account the embolus. This,

¹ A clinical lecture delivered at the New York Polyclinic Medical School and Hospital.

however, does not explain why the infarction is limited to such sharply defined areas, sometimes to a single lobule. The true explanation is as follows:

Sooner or later, in diseases of the heart, there occurs dilatation of the right ventricle as a result of mitral obstruction or regurgitation. In the beginning it is dilated hypertrophy, but later the dilatation becomes prominent and, not being properly compensated by hypertrophy, the blood-current becomes sluggish. In such a condition thrombi or venous clots may form in the right heart, especially in the muscoli pectinati of the right auricular appendix, or between the columnæ carneæ of the right ventricle near the apex. Emboli become detached from these thrombi and cause infarctions in the lungs by their direct transmission along the pulmonary artery. Besides originating in the right heart from dilatation, emboli may enter the systemic venous circulation from any part of the body, and produce infarction in the lungs after passing through the right-heart. Emboli may also enter through the superior vena cava into the right side of the heart as a result of fractures or other severe injuries of the skull affecting the diploe.

As occasionally happens in typhoid or other fevers, emboli may become detached from thrombi formed in any of the peripheral veins, or in thrombosis of the uterine or ovarian veins, and even of the iliac or renal veins from pressure caused by large uterine fibroids and other tumors. If the emboli are septic, metastatic abscess, instead of infarction, usually occurs, or rapidly follows the latter. Emboli which originate in the portal circulation are apt to produce infarctions of the liver; those which originate in the lungs or left side of the heart affect the brain, spleen, or kidneys.

Hemorrhagic infarction may involve but a single lobule, or several infarctions may occur simultaneously in one or both lungs. They are more commonly found at the periphery than in the interior of the lung, because of the fact that the pulmonary artery and its branches become smaller as the surface of the lung is approached. For the same reason, when central infarctions occur, they are more extensive than the peripheral. As a matter of course, the infarcted areas are slightly pyramidal in form, their bases being toward the periphery. The condition may affect either sex at any age.

Sudden dyspnea is a constant symptom of this disease, and it is proportionate to the area of pulmonary tissue involved. The dyspnea is accompanied by cough and a characteristic expectoration, brownish-red and darker than that of lobar pneumonia. If the infarction is due to thrombosis in the right-heart from any of the causes mentioned, there may also be a corresponding sudden irregularity of the heart's action which, of course, is reflected in the pulse. The sudden occurrence of hemoptysis of the above-mentioned character in connection with long-standing heart disease, is usually due to infarction, even though the prominent symptoms of irregular cardiac action and intense dyspnea are absent. In other cases the infarction may give rise to pleurisy with its attending pain. Sometimes pneumonia is developed to a varying extent, and even gangrene may result. Frequently the symp-

toms are so vague or lacking that the condition is entirely overlooked. As a rule, there is a slight increase in temperature, which occasionally rises to 102° F. Septic infection is often unrecognized on account of the general condition of the patient.

On palpation, vocal fremitus, as a rule, will be found to be increased, unless the infarction is central or complicated by pleurisy. Percussion will elicit dulness in proportion to the extent of the affected areas; there may be little or none if this area is small or centrally located. If the infarcted area is sufficiently large, auscultation will reveal bronchial breathing and bronchophony over it. As a rule, crepitant and subcrepitant râles may also be heard. In some cases, owing to the small extent of the area involved or to the co-existence of pleurisy, no physical signs can be detected. In such a condition the heart should always be examined.

The diagnosis is easily made by means of the sudden dyspnea, localized spots of dulness, crepitant and subcrepitant râles, a slight rise in temperature, cough, and the characteristic brownish-red sputa, which continues a longer time than in pneumonia, the co-existing heart disease, especially an old mitral lesion, and the etiology in general.

The sputa in patients with cancer of the lung resembles that in infarction, but cancer-cells will be found in the former, and there will be present cachexia and other familiar signs. According to Loomis the sputa in hydatid disease of the lung may also resemble that in infarction; in the former, however, the discovery of hooklets will determine the diagnosis.

The prognosis is always unfavorable when the condition is dependent upon cardiac thrombosis or septic emboli. It is also unfavorable in proportion to the area of lung tissue involved and the number of infarcts present. On the other hand the prognosis is generally good in the case of a small, single, peripheral infarct of aseptic origin, although even here much depends upon the original cause.

The treatment is purely symptomatic. Hemorrhage is rarely so profuse as to require the use of hemostatics. Absolute rest in bed and regulation of the heart's action, in case of disease of that organ, may be necessary. For this purpose digitalis may be employed when the heart is acting weakly. If signs of collapse develop, such as cold extremities, etc., alcoholic stimulation and the applications of sinapisms to the body and extremities are indicated. Extensive dry cupping will relieve the dyspnea better than anything else. For the dyspnea and the cough, as well as for the enfeebled and irregular cardiac action, 5 to 10 minims of Magendie's solution of morphine may be given hypodermically with good effect. Pleurisy and pneumonia, should they occur, must be treated independently of the infarction.

The following is a most interesting example of this affection:

A. D. H., a physician, aged 44 years, had acute articular rheumatism at the age of thirteen. This was complicated by endocarditis, which resulted in mitral regurgitation. At first, hypertrophy fully compensated for dilatation, and so long as this was the case he experienced no symp-

toms of valvular lesion. Later on, however, owing to secondary enlargement of the right ventricle which always occurs in these cases, he began to suffer from dyspnea, especially on exertion, such as walking rapidly or going upstairs. At the age of forty he began to notice edema of the lower extremities—a bad omen in cases of mitral lesion. This edema was occasional, and depended upon treatment. During the last year of his life, however, it became continuous, the dyspnea increased, the right ventricle became more and more enlarged, until finally jugular pulsation was noticed at the base of the neck on the right side, showing that tricuspid insufficiency had become a complication of the already bad condition. He improved very much under the administration of the infusion of digitalis with acetate of potash, but only temporarily. He experienced the greatest relief from his dyspnea from the extensive use of dry cups to the back, which were applied by means of fire, the ordinary rubber-bulb apparatus having failed to give any relief whatsoever. Cardiac stimulants of all kinds were now of no assistance. Finally, owing to enlargement of the right ventricle, a blood clot formed in that cavity, especially about the trabeculæ and columnæ carneæ, and a considerable thrombus resulted. Suddenly, he sent for me, and I found him suffering from great dyspnea and excruciating pain in the chest. There was also cough, attended with dark expectoration. Although dulness was not marked at any particular point, auscultation revealed the presence of râles in several places. Suspecting hemorrhagic infarction, I immediately sent for the late Dr. Alfred L. Loomis, who at once confirmed the diagnosis. This condition was due to emboli carried directly into the lungs through the pulmonary artery, having originated from the thrombus in the right ventricle. Very soon what may be called cardiac pneumonia set in, as evidenced by the signs of consolidation of lung tissue over a considerable area. This, with the hemorrhagic infarctions which had already occurred, resulted in death within a few days in spite of most eminent consultation and the most careful treatment.

In concluding this case, I would like to state that hemorrhagic infarction of the lungs may be regarded as an evil omen, on account of the danger of pneumonia supervening. In such cases an extensive pneumonia will be almost certainly fatal.

Sudden death from heart disease is not so common as the laity generally suppose. There are, however, certain forms of disease of the heart which do undoubtedly cause sudden death, while other forms, although fatal, give rise to complications which produce death indirectly, rather than directly through the heart itself.

Sudden death may occur in aortic regurgitation, not only from apoplexy due to the force with which the blood is driven from the left ventricle by reason of the enlargement of that part of the heart, but it may also occur in some way which is not yet thoroughly understood. It is thought by some that death in such cases is due to failure of the circulation in the nutrient vessels of the heart. The coronary arteries are so pressed upon by an enormous enlargement of the left ventricle, which sometimes

occurs in this disease, that blood cannot enter them, and heart-failure results from lack of blood-supply. Such a condition existed in a case which came under my observation, a brief history of which is as follows:

The patient was a man thirty-five years of age, of excellent habits, and apparently in good health. At my request he was seen by Dr. Francis Delafield, who confirmed the diagnosis which I had made. The patient died suddenly while going upstairs. There was no cerebral lesion.

In stenocardia the patient may suddenly die, not of spasm, but of paralysis of the heart, due to failure of the coronary circulation as a result of arterial sclerosis and shock caused by the terrible pain of angina pectoris. In fatty metamorphosis, otherwise known as Quain's fatty degeneration of the heart, death may occur at any time as a result of heart-failure or rupture. The heart may suddenly fail or rupture in cases of attenuated dilatation, although some complication, such as dropsy, is likely to cause death before this occurs. Sudden death due to rupture of the heart may occur in cardiac aneurism. The latter is usually situated in the wall of the left ventricle near the apex, and is due to thinning of the cardiac wall from previous inflammation and fibroid changes. At times it is almost impossible to differentiate this condition from mitral regurgitation. An apex systolic murmur is present in both, and both are accompanied by enlargement of the left ventricle. In mitral regurgitation, however, the murmur is usually louder than in cardiac aneurism and more frequently heard posteriorly. Enlargement of the left auricle and right ventricle with accentuation of the second sound in the pulmonary interspace is usually present in mitral regurgitation, but not in cardiac aneurism.

In fibrosis of the heart due to syphilis, alcoholism, gout, rheumatism, and lead-poisoning, the muscular fibers are gradually replaced by connective tissue until finally the heart fails to act, or cardiac aneurism and rupture ensue.

Hypertrophy of the left ventricle, when the arterioles throughout the body are fibroid and brittle, as, for example, in chronic interstitial nephritis, predisposes to cerebral apoplexy, and sudden death from this cause not infrequently occurs. In many cases this condition is preceded by retinal apoplexy, which is plainly shown by ophthalmoscopic examination.

Other forms of heart disease may be indirectly fatal, but rarely of themselves cause death.

Dr. Hare again at Work.—Dr. H. A. Hare of Philadelphia, who returned a few days ago from Bristol, R. I., where he has been spending some weeks, has so far convalesced from his late illness as to be able to resume his lectures at the Jefferson Medical College.

Epileptics Poisoned.—Two hundred and fifty patients at the Epileptic Hospital of Gallipolis, Ohio, were suddenly stricken with symptoms of ptomain poisoning on the 1st inst. Bacteriologists are making careful analyses of the food which was served during the few preceding days.

CLINICAL MEMORANDUM.

A REMARKABLE CASE OF ECTOCARDIA WITH DISPLACEMENT, THE HEART BEATING IN THE ABDOMINAL CAVITY.¹

By L. EMMETT HOLT, M.D.,
OF NEW YORK;

PROFESSOR OF PEDIATRICS IN THE NEW YORK POLYCLINIC; ATTENDING PHYSICIAN TO THE BABIES' HOSPITAL, AND TO THE NURSERY AND CHILD'S HOSPITAL; CONSULTING PHYSICIAN TO THE HOSPITAL FOR RUPTURED AND CRIPPLED.

THE patient who presented this unique condition was brought to my office October 16, 1897, by Dr. E. M. Raynor of this city, to whom I am indebted for the early history and for the privilege of recording the case.

At the time of my examination the infant was five months old, a male, and had been under Dr. Raynor's observation since its birth. As soon as the child escaped from the uterus, an abdominal tumor, about the size of a goose egg, and only partly covered by normal skin, was discovered. Manual pressure was applied until the mass could be kept reduced by a retaining bandage and pad. The greater part of the tumor was evidently intestinal—an ordinary umbilical hernia; but in it there was a small, hard, pulsating body. In other respects the child appeared to be normally developed. During the early weeks of its life nothing unusual was observed, except a severe degree

FIG. 1.

Showing two abdominal tumors: the lower the hernia; the upper the heart.

of cyanosis. At first this was almost constant, but it gradually lessened in intensity and for some time before my examination had been noticed only on exertion. The cord had fallen off and healed normally. The child had gained steadily in weight, and by means of an abdominal pad the umbilical hernia had been easily kept reduced.

At the time of my examination I found a fat, well-developed infant, much above the average in weight. While perfectly quiet nothing unusual was observed, but when disturbed, and especially when crying, it became intensely cyanotic and continued so for some minutes after the exertion ceased. The recti muscles of the abdomen were widely separated. In the median line was a circular area, about two inches in diameter, where normal integument was wanting, and where only a thin membrane covered the abdominal contents. At the lower border of this area was the umbilicus. This surface resembled that often seen over a spina bifida. When the pad was removed the hernial protrusion became about the size of half an orange. In the epigas-

tric region, in the median line, extending from the ensiform cartilage into the upper part of the area previously mentioned, was a pulsating tumor of conical shape, $1\frac{1}{4}$ inches broad at its base, which was at the ensiform cartilage, and two inches in length. It was covered only by integument and subcutaneous tissue, the muscles being separated at

FIG. 2.

Also showing both abdominal tumors.

this point fully an inch. This body was evidently the heart. Through the thin covering all the cardiac movements could be easily observed, diastole and systole being almost as well defined as in an animal when the chest is opened. By placing the tips of the fingers beneath the apex, the heart could be lifted until the apex was at the ensiform cartilage, the body of the heart disappearing

FIG. 3.

Showing the relative size and position of the heart. (B) the heart; (C) the part of the abdominal wall where the skin was undeveloped; (A) the point where the murmur was loudest.

completely behind the sternum. This movement did not seem to cause the child the slightest disturbance. A loud systolic murmur was present and could be heard in front all over the chest. It was most distinct a little to the left of the ensiform cartilage. It was not distinct behind. A respiratory murmur was present anteriorly over the whole chest, even in the area usually occupied by the

¹ Reported to the New York Clinical Society, October 29, 1897.

heart, but was not very loud. There was moderate clubbing of the fingers. Examination of the abdomen and chest elsewhere disclosed nothing abnormal.

This case appears to me to admit of no other explanation than that of a large congenital deficiency in the diaphragm as a result of which, instead of the usual one of protrusion of some of the abdominal contents into the thorax, the heart had become displaced downward to the remarkable degree described. This had doubtless been favored by the imperfect development of the abdominal walls which also led to the umbilical hernia. This cardiac displacement must have occurred quite early in the fetal development, since the organ had become so well adjusted to these abnormal conditions that the circulation was fairly sustained.

Interesting speculation might be indulged in as to the relation and position of the pulmonary arteries, pericardium, etc. It is to be hoped that at some time these may be definitely given as a result of a *post-mortem* examination. At present, however, there does not appear to be any condition which interferes with the growth of the body, and the circulation is so well maintained that life may be indefinitely prolonged. The cyanosis and systolic murmur doubtless depend upon some other abnormality in the development of the heart, probably pulmonic stenosis.

A fairly careful search through medical literature has failed to reveal any case on record which resembles the one described. I believe it to be unique. Ectocardia is a name which is usually applied to a condition where the heart is covered only by integument and subcutaneous tissues. Quite a number of cases have been recorded, but all of them, so far as my investigation has gone, have been associated with some congenital deficiency of the sternum or chest-wall.

The accompanying illustrations will perhaps give a better idea of the position and relation of the heart than the description.

HOSPITAL REPORT.

A TEN-YEARS' RECORD OF ANESTHESIA AT MT. SINAI HOSPITAL, NEW YORK.

BY WM. H. LUCKETT, M.D.,
OF NEW YORK.

IN an editorial which appeared in the *Medical Record*, October 30, 1897, a few figures were quoted from the statistics compiled by Goult as a result of an investigation of anesthetics made by the German Surgical Society of Berlin. Some of these figures, taken from the editorial mentioned, are given in Table I.

TABLE I.

Anesthesia.	1890 to 1895.	
	Cases.	Deaths.
Chloroform.....	2286	88
Ether.....	6020	7
Chloroform and ether.....	10,162	1
Alcohol, chloroform, and ether.....	5744	1

"Would it not be more scientific to have an honest report of deaths from anesthetics and a more careful study of the subject of anesthesia?" This is a question which naturally arises after reading Goult's enormous mortality statistics. In answer to this question I have carefully compiled and tabulated the statistics which are given in this communication. These figures are taken from the record of all anesthetics, both general and local, which might result in death, and which have been induced in the Surgical Division of Mt. Sinai Hospital during the last ten years. I have omitted local anesthesia by a spray of ether or ethyl chlorid on account of non-poisonous effects. I have also purposely omitted a few ether anesthetics per rectum, which occurred early in the decade, as, there being no fatal results, they are without special importance. No reference is made to the Medical Division.

In the table, under the heading "Anesthetics," chloroform to ether means that the anesthesia was started with chloroform and, as the patient did not take it well, ether was substituted, *vice versa*, ether to chloroform. This is true up to the year 1893; but from this time on no record was kept as to which was used first, ether or chloroform, and so they are placed under the head of chloroform and ether. Indeed, it frequently occurred that, from 1893 on, the anesthesia was started with chloroform, and then ether was substituted; not because the patient took the chloroform badly, but because this method proved convenient in numerous instances. Cocain to chloroform and cocain to ether means that an operation was attempted under cocain, but the patient's suffering was so intense, or the lesion turned out to be so much more extensive than supposed, that, of necessity, general anesthesia was induced. The cocain statistics are interesting as showing 706 cases in which this drug was employed without a single instance of anything approximating severe poisoning.

During the ten years one case occurred in which anesthesia was started with chloroform, the patient taking it so badly that ether was substituted, which acting even worse than the former anesthetic, it became necessary to again employ chloroform, under which the operation was completed. Not once during the period mentioned was the "alcohol-chloroform-ether" mixture used.

Table II. is presented with the permission of the proper authorities.

The circumstances which attended the single death which occurred during this period are worthy of notice: The patient was a very healthy adult. He did not use alcohol, but used tobacco to excess. He acted as a porter about the hospital, and as such was allowed more liberty than a regular patient. He abused this freedom by smoking his pipe on the morning of the operation for which he had been prepared. The patient suffered from a cellulitis of the thumb which required incision. According to custom his heart and lungs were examined previous to the anesthesia, and nothing abnormal discovered; urinary examination also negative. The anesthetic was administered with the patient upon a wheeling-stretcher. He took the chloroform nicely, almost without a struggle,

and was wheeled into the operating-room. He was in good condition just before being lifted from the stretcher to the operating-table; that is, his respiration, pulse, and general appearance was that commonly observed in an ordinary chloroform narcosis, pupillary and conjunctival reflexes being present. While being lifted from the stretcher to the table the patient died; he was dead before he reached the table, death having apparently resulted from simultaneous respiratory and cardiac paralysis—whatever that may mean.

The anesthetic, in this instance, was administered by a most careful, conscientious, and competent physician, one whose record as an anesthetizer was excellent. This lat-

bright yellow and contains almost all of the antitoxin. The two may be easily separated.

The Disinfecting Power of Benzine in Cleansing Establishments.—RUEPP (*Corres. Bl. für Schweiz. Aerzte*, October 1, 1897) has tested the disinfecting power of the ordinary methods of benzine cleansing of clothing, etc. He finds that the common pyogenic cocci, typhoid and diphtheria bacilli, as well as the germs of cholera, tuberculosis, and anthrax are not destroyed by soaking in benzine during the usual length of time the clothing is treated in such establishments. It is worth while, therefore, to remember that this process of cleansing cannot be relied

TABLE II.

Anesthetics.	1887.	1888.	1889.	1890.	1891.	1892.	1893.	1894.	1895.	1896.	Total Number of Anesthesias.	Deaths.
Chloroform.....	152	172	315	457	534	316	366	498	616	837	4263	1
Ether.....	307	421	468	395	387	589	610	503	615	378	4673	0
Chloroform to ether.....	15	8	12	46	41	19	0	0	0	0	141	0
Ether to chloroform.....	7	4	19	19	36	31	0	0	0	0	116	0
Chloroform and ether.....	0	0	0	0	0	0	48	27	25	64	164	0
Cocain to chloroform.....	0	1	0	1	0	1	1	1	0	1	6	0
Cocain to ether.....	0	0	5	1	1	1	1	1	0	0	10	0
Cocain.....	27	10	126	97	70	63	71	83	45	114	706	0
Nitrous oxid gas.	0	0	0	3	10	0	2	62	35	30	142	0

ter fact is emphasized because it shows that such an unfortunate accident may result when all possible precautions have been taken.

The boastful, over-confident anesthetizer is an exceedingly dangerous one, and one in whose hands anesthesia, from lack of proper precautions, is more than likely to prove fatal. Such should remember that death under these circumstances has occurred in the practice of Simpson, Sands, Agnew, and many other distinguished surgeons. However, there is no doubt that by a proper study of the patient, careful preparation, care in the choice of anesthetics, and last and most important by the exercise of every possible precaution in the actual administration, a much lower death-rate may be reasonably expected than that evidenced by the statistics of Goult. Such figures only prove (88 deaths in 2286 chloroform anesthetics, and 7 deaths in 6020 instances of ether narcosis) a shamefully reckless disregard of legitimate precautions.

MEDICAL PROGRESS.

A Method of Concentrating Therapeutic Serums.—BUJWID (*Centralbl. für Bacter.*, September 24, 1897) has experimented with diphtheria and tetanus antitoxin preparations in order to obtain concentrated solutions. The dried preparations are unreliable and under certain circumstances may be dangerous. Partial evaporation of serums at a low temperature gives a cloudy product. A better method consists in freezing the remedy. The ice is clear and there remains only a small amount of a brownish fluid in the bottom of the glass. If the glass of serum is allowed to thaw slowly the upper layer is without color and contains little beside pure water. The lower layer is a clear,

upon to sterilize infected objects. Such articles must also be subjected to heat or to some chemic disinfectant before it is safe to use them again.

Influence of Alcoholism in the Father upon the Life of the Child.—ANTHONY (*Centralbl. für Gynäkol.*, October 16, 1897) mentions a case of a healthy woman who was married at the age of seventeen years to a notorious drunkard, and who had by him, in her nine years of married life, five miserable little children of whom four died within the first ten days after birth. The fifth one, by great care, was raised to the fourth year when it also died. After this the woman was separated from her husband. She then married a healthy man, and had by him two children. The elder of whom grew to be four years old, and the younger, at the time of writing, was fourteen days old. Both were in perfect health. This great contrast between the children of different fathers plainly shows, inasmuch as syphilis was not present, that the alcoholism of the father of the first children destroyed their vitality.

Reasons for Being a Cannibal.—According to PETRIE (*Bull. Gen. de Therapeut.*, September 30, 1897) twenty per cent. of all cannibals eat the dead in order to glorify them; nineteen per cent. eat great warriors in order that they may inherit their courage, and eat dead children in order to renew their youth; ten per cent. partake of their near relatives from religious motives, either in connection with initiatory rites, or to glorify deities, and five per cent. feast for hatred in order to avenge themselves upon their enemies. Those who devour human flesh because of famine are reckoned as eighteen per cent. In short, deducting all these there remains only a proportion of twenty-four per cent. who partake of human flesh because they prefer it to other means of alimentation.

THERAPEUTIC NOTES.

Treatment of Diabetic Albuminuria.—ROBIN (*Rev. de Therapeut.*, October, 1897) gives some practical rules for the treatment of albuminuria occurring in connection with diabetes. The primary disease should first be treated, and in no case ought the dosage of antipyrin, if this is given, to exceed 30 grains a day, on account of its unfavorable action upon the kidneys. If the albuminuria is due to faulty digestion, this should be remedied; if to a lack of minerals in the system, then milk, meat bouillon, or salines should be administered to make good to the system its loss in this direction. If the albuminuria is phosphatic, as is most frequently the case, arsenic should be given to diminish the phosphatic loss, the patient taking twice daily, half an hour before meals, a tablespoonful of the following mixture in a small glass of milk:

R	Sodii arsen.	.	.	.	gr. ss
	Potass. iodid.	.	.	.	gr. xlviii
	Aq. dest.	.	.	.	$\frac{3}{4}$ vj—m.

Tonics are also indicated, such as the following:

R	Ext. cinchon.	.	.	.	gr. jss
	Quin. sulph.	.	.	.	gr. iss
	Ext. nucis vom.	.	.	.	gr. $\frac{1}{2}$.

M. Ft. pil. No. I. Sig. One pill at breakfast and at dinner.

After two weeks these remedies should be discontinued, and glycerophosphates begun in the following proportions:

R	Calci et magnes.	} aa	.	.	gr. jss
	Glycerophosphat.		.	.	
	Ext. nucis vom.		.	.	gr. $\frac{1}{2}$.

M. Ft. chart. No. I. Sig. One powder at breakfast and at dinner.

In two weeks this also should be discontinued, and a mixture of the hypophosphites prescribed, each tablespoonful of which, taken before breakfast and dinner, should contain the following:

	Strychn. hypophosphit.	.	.	gr. $\frac{1}{3000}$
	Quin.	.	.	gr. $\frac{1}{2}$
	Magnes.	.	.	gr. $\frac{1}{2}$
	Potass.	.	.	gr. ss
	Calci	.	.	gr. $j\frac{1}{2}$
	Sodii	.	.	gr. j
	Ferri	.	.	gr. ss.

Abortive Treatment of Influenza by Calomel.—After an experience of several years, FREUDENTHAL (*Ther. Monatshäfte*, October, 1897) heartily recommends the use of several large doses of calomel in the beginning of an attack of influenza. In order to abort the disease the calomel must be given before the third day. The dose for a man is $1\frac{1}{2}$ grains, for a woman about $\frac{3}{4}$ grain, for a child, as many sixths of a grain as the child is years old. Either two or three doses are required. Within six to ten hours after the last dose, the high fever abates, the headache and pain are favorably influenced or entirely disappear. The coryza and cough never become purulent and are soon overcome. For persistent nervous symptoms it may be necessary to give an antipyretic. At the close of the treatment, on account of the loss of appe-

tite, tonic bitters are indicated. In a great many cases no medicine except calomel is required. Freudenthal says that the season of the year has nothing to do with the effectiveness of this treatment, but that the sole factor determining success is the day of the disease upon which treatment is begun. Twenty-five per cent. of the cases were cured within two days. The longest duration of the disease after treatment was six days. The average duration of the disease after treatment was three and one-third days. No complications traceable to the influence of calomel were observed.

Vomiting in Pregnancy.—PAGE (*The Med. Times*, October, 1897) says of vomiting in pregnancy that "the first indication of nausea or lack of appetite, not to say vomiting, should warn a prospective mother that she is getting a little ahead of her stomach, so to say; and, then, all she has to do is simply to sip a few swallows of moderately hot water occasionally during the day, fasting, to make short and easy work of restoring the balance to the system. I have never known a single case of failure when this plan has been intelligently carried out. It may be necessary to skip only a couple of meals or it may be necessary to fast two or three days. Wait until the patient is again really hungry before giving food. Meanwhile it will be necessary to give from a quart to three pints of soft warm water daily to fulfil the requirements of the system." The writer believes that many cases have terminated fatally in which life might have been saved by the adoption of this simple plan of treatment.

The Treatment of Fissures of the Anus with Cocain and Ichthylol.—CHERON (*Prakt. Dermatol.*, No. 7) proceeds as follows: The anal fissure is first made insensible by laying upon it, during five minutes, a bit of cotton soaked in a five- or ten-per-cent. solution of cocain. As soon as the fissure is anesthetised one or two drops of pure ichthylol are allowed to run into it. This treatment is repeated daily during four or five days, by which time improvement will have progressed so far that dilatation of the anus is easily accomplished, and the fissure may now be treated throughout its whole extent. As a rule complete healing follows about ten applications.

Influence of Hydrastis Canadensis and Ergotin upon the Uterus.—As a result of the very exact experiments, SCHATZ (*Central. für Gynäkol.*, September 11, 1897) has found that hydrastis Canadensis and ergotin, whether injected into the veins or used subcutaneously, produce marked contractions of the uterus. The influence is direct, not an indirect one, produced by an influence upon the blood-vessels. The contractions after the use of ergotin are more powerful than those after hydrastis, follow more quickly upon one another, and are longer continued, and of a tetanic character; while the contractions after the administration of hydrastis are always separated by considerable intervals, which tend to grow greater after the drug has been used for some time. If used in excessive doses both remedies tend to produce a paralyzed condition of the uterine muscles. Both of these preparations produce an increase of blood pressure and of cardiac activity.

THE LAPORTE CASE.

THE trial and conviction of a Paris physician on a charge of homicide has roused the indignation of both the medical and lay press of Europe, and particularly of Paris, to a most commendable degree. On September 11th last, a midwife who had charge of a confinement and had met with difficult complications advised the husband to send for a physician. He concluded to wait until evening in order to take advantage of the free night medical service. Dr. Laporte, a member of the night-service staff, was called, and, after ineffectual attempts to deliver the woman of a large child, the forceps having been applied three times, he told the husband that craniotomy would be necessary to save the mother's life. This being agreed upon, he asked for some sharp instrument, as he had nothing suitable with him. A tool-chest was produced, and he selected a curved needle used for sewing mattresses, with which he punctured the head and soon after applied the forceps for the fourth time, with the result that the delivery was accomplished. He then saw that the patient was comfortable, and, leaving the necessary directions, went home.

Three days later the woman died in a hospital.

The physician who made the autopsy gave as the cause of death peritonitis following a perforation of the bladder. Laporte was arrested, tried, and, partly on the testimony of the physician, but still more on that of the midwife, the husband, and the neighbors who watched the proceedings through a half-open door, was convicted of having "committed an imprudence, an operative neglect which constitutes a grave error, *faute lourde*, which was the direct and involuntary cause of the death of the woman."

The unfortunate young man was sentenced to three-months' imprisonment, but was allowed to go free on the condition that during the next five years no further charges are made against him.

Public interest was aroused not merely by the sensational facts of the case—the extreme poverty of the defendant—the bitter attack of one neighbor who testified, for example, that the doctor would have used a hammer and chisel had not the husband snatched them from his hand—but even more by the understanding, which seemed to exist on the part of the medical profession as well as among the laity, that the court was making law for physicians in general, and that hereafter to fail in an operation will be a criminal offense. This was recognized by the daily press as well as by the medical journals. The *Echo de Paris* said of the trial, "During more than three hours this man, who has worked more than twenty years to get his diploma, whom misery has rendered timid, whom an unfortunate accident and a detention of several weeks has weakened and chagrined, was tortured by a magistrate who was blinded by professional hardness and by witnesses resolved to destroy the defendant—the same witnesses who would have sounded his name to the skies if the unfortunate operation had proved a success."

The medical press was even more emphatic in denouncing the proceedings. "Laporte was condemned," said *La Médecine Moderne*, "because he did unskilfully that which he attempted. That is to say, that the magistrates, establishing upon this point a new jurisprudence, declared themselves competent to decide that an accused physician had unskilfully performed his professional duties. . . . Rejoice, brothers in medicine! The times have changed. Heretofore we have had as protection against the attacks of the vulgar, two guarantees: The first was

our diploma. The medical faculties once determined a man's fitness to practice medicine. Now, every one who calls a doctor will determine whether he has been benefited or the reverse, and in the latter case he will exact justice. . . . The second guarantee . . . was a vague sentiment of respect and affection which surrounded the physician. This has also vanished."

"If Laporte had been a common assassin," said the *Journal de Médecine*, "he would have been treated with more consideration. It is a sign of the times. . . . It is not a physician who was vilified in a criminal court, but the whole body of medical men."

These quotations show something of the feeling which has been expressed regarding this affair. It is not wonderful that medical men resented such a remark on the part of the presiding magistrate as that made in answer to Laporte's claim that in order to save the patient's life, it was necessary to do something at once. "My God! she died just the same," was the brutal reminder of the magistrate that the operation had been unsuccessful.

After the decision had been announced, indeed before the end of the trial, public opinion turned in Laporte's favor. Several papers started subscriptions in the young man's behalf and with such success that his financial condition at least will be considerably better than it was at the time of his arrest, when, having missed his dinner for lack of funds, he had only 15 cents in his pocket.

INJURIES OF PARTURITION, OLD AND NEW.

UNDER this title Dr. Sinclair of Manchester, England, contributed to the British Medical Association at its recent meeting one of the most interesting of its addresses. With the evident belief that "confession is good for the soul" (of him who hears it), Dr. Sinclair described a state of practice in England which he deeply deplored. He has for some time been investigating the frequency with which the obstetric forceps is used, and has learned that in the manufacturing districts of England as many as seventy-five per cent. of the labors are terminated by this means. Recalling Cullingworth's recent investigations, which showed that puerperal septic infection had not materially diminished, the inference points to a connection between the two facts. Turning to the great hospitals of

the world, Sinclair finds that the frequency of forceps application is subject to great variation (from 22.6 per cent. at Winckel's clinic in Munich to less than two per cent. in other clinics). In the Manchester Infirmary, under Sinclair's charge, the forceps is not used more commonly than in many of the large Continental maternities.

We quite agree with the writer of the address in deprecating the carelessly frequent use of forceps. Those who have more business shrewdness than conscience in the practice of obstetrics are able to produce a very great mental and financial impression upon patients by giving them anodynes until the os is sufficiently dilated to apply forceps, and then delivering them with instruments. This shortens labor, produces all the theatric effect of a surgical procedure in a private house, and if it be followed up by a timely suggestion that nothing but the superior skill of the physician has saved the mother and child, the immediate returns to the doctor may be, in some instances, very considerable. That such, however, is the practice of the best obstetricians in America we do not believe; neither do we think that general practitioners of extensive experience in this line condescend to this sort of chicanery. Since medical students have been taught diagnosis by palpation the mistake is not so often made of applying forceps until the head has passed well through the pelvis. We are glad, however, to join Dr. Sinclair in his warning, and to urge that the natural forces of labor be aided and awaited with judgment and patience.

The author of the address, however, proceeded to express his distrust and disappointment in the use of antiseptic solutions and in the repair of recent injuries caused by forceps delivery. In this we are surprised at his unfortunate experiences, and regret that he should lead his readers to believe that such poor success follows the obstetrician's efforts to repair injuries. He does not recommend immediate suture of the cervix, even in extensive lacerations, and we infer that he does not practise this procedure. In striking contrast to this is the custom of the prominent maternity hospitals of this country, in which it is the routine practice to promptly repair injuries to the pelvic floor, and extensive lacerations of the cervix, especially when attended by hemorrhage. The results in both private and hospital work commend this practice.

There is every reason to believe that antiseptic solutions, when soap and water are used for preliminary cleansing, render the hands practically aseptic and greatly assist in preventing infection of the genital tract. Equally important is the invariable use of antiseptic vulvar dressings, and latterly, we have found nothing but good results follow the insertion of antiseptic gauze within the uterus and vagina in cases of instrumental delivery when the uterine cavity had been entered by either hand or instrument, and in which relaxation of the womb was threatened.

In our experience the obstetrician often faces a choice of two evils: If he allows labor to be prolonged in an ill-nourished, ill-developed, or neurotic patient, exhaustion, relaxation of the uterus and hemorrhage threaten, with danger of fetal asphyxiation through pressure; if he interferes, the patient may sustain injury or infection. The risk is less and recovery follows more promptly and completely when exhaustion is anticipated and prevented by judicious interference under surgical antiseptics.

But if we understand Dr. Sinclair rightly, it is the surgical tendency in modern obstetricians which he depreciates. He regrets the application to the parturient patient of the same prompt and thorough methods which enable the surgeon to deal successfully with other cases. We cannot agree with him in this. His own illustration is against him; for the text of his address is the case of a young woman dying of septic infection with lacerations of the vagina, and probably of the cervix, unrepaired and infected. Had this same patient been carefully delivered under thorough antiseptic precautions, her injuries closed by suture, and had suitable dressings been employed, she should have recovered.

The writer truly and wittily remarks that "modern medical students learn surgery which but few of them ever practice, while nearly all practise obstetrics which they never learn." He has hit one of the errors of modern medical education squarely on the head. We do not criticize the modern teaching of surgery, but we regret that one of the most complex conditions which the physician meets is often relegated to undergraduate students and ignorant midwives. The dangerous half-truth, "Labor is a physiologic process," has shielded the indolence and greed of many obstetric teachers. When the modern student goes to his cases of labor with a competent instructor,

with efficient and simple means for sterilizing his necessary instruments, with surgical dressings, and with the same discipline which obtains in the teaching of minor surgery, he will then begin, not only to learn, but to practice modern obstetrics. As a general practitioner, he will reduce suffering and disability among women very largely, and do much to diminish the excessive number of operations upon women, many of which may be rendered unnecessary by the judicious practice of obstetric surgery.

EDWARD P. DAVIS, M.D.

ECHOES AND NEWS.

Medical Society of the County of Kings and the Druggist.—A druggist of Brooklyn, N. Y., was convicted on November 3d of practising medicine without a diploma. He was committed to jail to await sentence.

Second Attacks of Measles and Infection.—An English physician writes to the *Lancet* (London) expressing his belief that second attacks of measles are not infectious, and cites several cases to substantiate his theory.

The Bacillus of Acute Articular Rheumatism.—Thiroloux, a French investigator, asserts that since March last he has five times found the pathogenic bacillus in the blood of persons suffering from acute articular rheumatism.

Hospital for Cornell University.—The two sons of the late Mr. Sage of Ithaca, N. Y., have presented his former residence to Cornell University to be used as a hospital for the students of that college, together with an endowment fund of \$100,000 to be used solely for its maintenance.

Lead Poisoning Due to Patent Medicine.—Two cases of lead poisoning following the use of an English proprietary mixture known as "Dr. Priestley's Compound" have been reported in the English medical journals of recent date. Upon analysis the mixture was found to contain lead, bismuth, magnesia, soda, and ammonia.

A Hospital Masonic Lodge.—The Masons of St. Mary's Hospital, London, England, have organized a new lodge, No. 2668, the "Sancta Maria," and H. R. H., the Prince of Wales, has consented to act as Worshipful Master during the coming year, having appointed Mr. Edmund Owen, the senior surgeon of the hospital, his deputy.

Siamese Twins in Yonkers.—A triple birth was recorded recently at the Health Office of Yonkers, N. Y., in which two of the children were united face to face by a ligament extending from the neck to the lower part of the abdomen of each. Both were boys of small size and they lived but an hour after birth. The third child, a healthy girl, survives.

Vaccine Virus and the United States Army.—President Wilson of the Health Department of the City of New York

has been notified by Assistant Surgeon-General Alden that the offer of that Board to supply the army with vaccine virus has been accepted, and that the contract to supply virus for the frontier posts of the United States has been given to it.

Bogus Dentist Fined.—At the instance of the New York State Dental Society, a man who has been practising dentistry in New York City without a license was brought last week before Justice Hayes in the Court of Special Sessions and fined \$350. The man is the proprietor of a "dental parlor" on Eighth avenue and was fined \$100 for a similar offense in 1893.

Responsibility of Water Companies.—A jury at Steven's Point, Wis., recently returned a verdict in favor of the plaintiff the sum of \$5000 damages against the Ashland Water Company. The cause of action was the alleged negligence of the water company in furnishing impure and unwholesome water, containing typhoid germs, to the plaintiff's husband, thereby causing his death.

Tulane University.—The fall term of Tulane University at New Orleans, which was delayed on account of the prevalence of yellow fever in that city, was opened November 29th. The faculty has announced that the session will continue until June 20, 1898, with no vacations and only occasional intermissions on holidays, in order to get in a full year's work before the next commencement.

Serum Treatment of Snake-bite.—An expedition in charge of M. Raoul, Pharmacist-in-Chief of the Colonies, which was sent by the French Government to make researches in Malaita in regard to indigenous plants, has returned to Paris. Several of the party were bitten by snakes while making their investigations, and they declare that their lives were saved by injections of Dr. Calmett's serum, of which they carried a liberal supply.

New York Academy of Medicine.—At its meeting on the 2d inst. the following nominations were made: Vice-Presidents, O. B. Douglas and W. H. Katzenbach; recording secretary, L. F. Bishop; corresponding secretary, M. Allen Starr; treasurer, H. E. Crampton. The Board of Trustees reported the gift by Mrs. Anna Woerishoffer of \$15,000 to the library endowment fund, and it was decided that this sum be set aside as a special fund to be known as the "Anna Woerishoffer Fund."

A New Hospital for New York City.—There were recently filed at Albany articles of incorporation of an institution called the Cooper Hospital of New York. According to the laws of the State no certificate of hospital incorporation should be filed until it has been approved by the State Board of Charities. Inquiry at the New York office of the inspectors of the State Board revealed the fact that the institution under consideration is a private hospital designed to treat skin diseases, and has a capital stock of \$1000 and a paid-up capital of \$500. The irregularity in the application for articles of incorporation and the extraordinary capitalization, have induced the State Board of Charities to make an investigation.

Opium Habit among Children.—*Pediatrics* calls attention to the fact that the British Opium Commission has discovered that from sixty to ninety per cent. of Hindoo babies are dosed with opium. The drug is given almost from birth up to the end of the second or third year, when it is usually discontinued. The labors of the Commission tend to show that no ill effects are felt by these children in after-life. The contention is that this tolerance on the part of native children is congenital. In support of this view, the fact is cited that opium when administered to English children in India (it is often given to them secretly by the native nurses) has a most disastrous effect. The immunity of the native children cannot, therefore, be ascribed to the climate.

Typhoid Fever in Paterson, N. J.—During the latter part of November several cases of typhoid developed at the Paterson Orphan Asylum, and shortly after the disease made its appearance among the inhabitants of the city. Sixty-two cases have been reported. Investigation showed that the asylum and many of the families in which the disease occurred were supplied with milk by a certain milkman, and that three sons of this milkman have been ill for a month with what was termed "remittent fever." It was then discovered that the water used in the dairy to wash cans, etc., was drawn from a small stream through a pipe which is situated twelve feet below the outlet of a drain from an outhouse. This pipe was removed by order of the health authorities and the man ordered to send out no more milk until he received official permission to do so.

CORRESPONDENCE.

AN IMPROVED METHOD OF GENERAL ANESTHESIA.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: In the issue of your esteemed journal of November 27th, I find an article by Dr. M. L. Maduro of this city, in which he describes the new anesthetic mixtures of Dr. C. L. Schleich of Berlin, whom he visited when abroad during the last summer.

Last week I addressed a letter to the editor of the *New York Medical Record*, asking that he kindly give space to a preliminary communication of mine on this same subject (Schleich's anesthetic mixtures) in the columns of the next issue of the *Record*, which will appear December 4th.

I stated in my remarks that I had employed the mixtures in all my hospital and private operations since September 15th of the present year, the time of commencing my fall service at the German Hospital.

I have carefully studied the narcosis produced by these mixtures in all its phases (nearly 100 cases), and am more than delighted with it; all the colleagues who witnessed the operations were impressed in the same way. My results fully confirm what Schleich claimed two years ago, and again this year. There is no stage of excitation, no cyanosis, no accumulation of mucus or saliva in the throat during the narcosis; nor was there a single instance of subsequent bronchitis, or bronchopneumonia. I am sure

that whoever will carefully try the "mixtures," regardless of whether the patient be old or young, with or without bronchitis, consumption, heart disease, etc., will never return to the former methods of inducing general anesthesia with chloroform or sulphuric ether.

I would especially emphasize that the petroleum-ether (benzine) as used by Schleich must have a boiling-point of 60-65° C. (140-148° F.). In order to always obtain a reliable mixture I have tried to interest a great number of druggists throughout the city in the matter. They will keep a petroleum-ether with this boiling-point. It may also be obtained of any first-class wholesale chemist.

That Schleich should have used only one ounce of his mixture for a complete narcosis, as Dr. Maduro states, is a mistake; one ounce is the amount he first pours upon the mask, or rather, into the funnel of the mask, devised by himself. The average amount used during an operation differs according to the mixture which is selected. For an operation lasting from forty-five to sixty minutes I have found the average quantity required to be six to eight ounces.

On the basis of a promise given me during the early part of November by the President of the Medical Society of the County of New York I shall have the honor of presenting to this Society at its next meeting, December 27th, my observations upon the practical application of Schleich's mixtures in general anesthesia.

WILLY MEYER, M.D.

NEW YORK, November 27, 1897.

OUR BERLIN LETTER.

[From our Special Correspondent.]

GERMAN INTEREST IN THE LAPORTE CASE — THE QUESTION OF A JURY OF MEDICAL MEN FOR MEDICAL OFFENDERS — COUGHING AND THE DISSEMINATION OF TUBERCLE BACILLI—THE BREMER COLOR-TEST FOR DIABETIC BLOOD CONFIRMED IN BERLIN—SOME RECENT WORK ON THE EXCRETION OF PATHOGENIC ORGANISMS IN MILK.

BERLIN, December 4, 1897.

A GREAT deal of interest has been shown in the Laporte case by the German medical press, and medical men generally here in Europe seem to have realized that the questions involved in the trial at Paris are not merely local in their bearings, but are of wide professional interest. In the case in question a young doctor was called out at night to attend a woman seriously ill. He was unprovided with all the instruments which might have been of service, and made the best of the available means to accomplish the delivery of a dead child. Two days later the patient died, and on the testimony of neighbors who watched the proceedings from the next room he was thrown into prison and, after trial, condemned to fine and imprisonment on the charge of manslaughter.

The condemnation came in spite of vigorous protests from all the medical societies of Paris, and the positive evidence of one of the great obstetricians, Professor Pinard, that the lesions found *post-mortem* were probably due to necrosis from pressure during the long-continued labor. Further, it seemed to be clear that the husband had been

criminally negligent in the matter of sending for a physician. To avoid certain charges and inconveniences attached to application for medical attendance by day, he had waited until evening before going for a physician in order to receive the benefit of the free night medical service furnished by the city.

On all sides it has been pointed out that errors of judgment when not occasioned by criminal ignorance of medical principles cannot be imputed to a physician as a crime, though the results may be serious. While not every one can approve, nor would most physicians be ready to imitate, the young doctor's readiness to avail himself of extraneous means in a medical emergency, still it is only the principle of medical responsibility which is at stake.

The opinions of the German medical press bring out clearly the position taken by the profession here: That physicians must resent the judgment of their actions in an emergency by those who do not understand the circumstances and the necessities of the case. The presence of non-medical witnesses at surgical and other operations has always been considered not only inadvisable but as liable to be productive of serious misunderstandings. When, as in the present instance, they are unavoidably present their lack of technic knowledge is apt to make them, in serious operations, translate procedures which are only ordinary surgical manipulations into unnecessary or cruel mutilation of the patient. Their evidence needs the most careful sifting by a medical expert before it is worthy of credence, even in cases where the witnesses have the best of good will in the matter.

Professor Mendel, at the last meeting of the Berlin-Brandenburg Arzt-Kammer, the Department Medical Council, called attention to this case, and to some of the questions involved. He advocated for medical men in medical matters a jury of their peers. He considered that in cases involving the reputation of a physician, especially when punishment may follow an action performed in pursuance of duties as a physician, that then medical men should be the judges of the facts in the case, the interpretation and application of the law being left to follow the usual course. The profession has always shown itself ready to uphold its own dignity in the matter of violations of law, and could be thoroughly trusted to see that actual criminals receive their proper punishment. To consider that one's actions may be judged by those utterly incapable of understanding the circumstances of the case is paralyzing to the best effort in an emergency.

That some such suggestion as that of Professor Mendel will have to come sooner or later is clear from the constantly growing number of malpractice suits which are too often only a species of blackmail. The profession itself will have to assert its right to be judged by its own standards and not left to the mercy of the ordinary jurymen, whose sympathies, in such suits, are notoriously apt to be against the defendant, and who in any case has not the proper sort of knowledge to logically consider the facts.

Some time ago, Professor Flügge, the Director of the Institute of Hygiene at Breslau, announced, as the result of a long series of experiments, that the ordinarily accepted mode of the conveyance of tuberculosis is not the

true one. One of his conclusions was that dried sputum rubbed into dust and blown around in the atmosphere is not only not an evident mode of contagion in tuberculosis but that it is even improbable. For him the consumptive loosens from his infected mucous membranes during a spasm of coughing numbers of bacilli, and disseminates them in the atmosphere. The coughing act is really an atomization of pulmonary secretion. To the resulting minute particles bacilli are attached and float hours in the air surrounding the coughing patient. This theory contradicts a good deal of clinical experience in the matter of liability to contract the disease on the part of nurses and others who are during long periods in close association with such patients, and has not been published without a good deal of protest. It is admitted that Professor Flüge's experiments have thrown new light on the dissemination of tubercle bacilli in the air, and that his presentation of the subject in so striking a manner cannot but have a good effect in the increase of prophylactic measures. On the whole, however, it is urged that there is an incompleteness in the artificial comminution of tuberculous sputum for experimental purposes which does not hold good in natural processes.

A recent writer has called attention to the fact that a very simple series of experiments will throw a good deal of light on the subject. As guinea-pigs are very susceptible to tuberculosis, he suggests that one of these animals be kept close to the bed of a phthisical patient, but with the most careful precautions to prevent contamination of its food and drink. The resultant mortality and the manner of death will greatly aid in the solution of a very interesting and very practical question.

At the last meeting of the Berlin Society for Internal Medicine, Dr. Bremer's test for diabetic blood was discussed. Dr. Löwy confirmed Dr. Bremer's report to the Moscow Congress as to special reaction of the blood of diabetic patients to the anilin dyes. Professor Goldscheider, who had tried the test a number of times, having had a private communication from Dr. Bremer previous to the Congress, considered that the specificity of this reaction is thoroughly established. The greenish-yellow tint developed in the red blood-corpuscles after staining with eosin from six to ten minutes in a brood-oven, at a temperature of 35° C., is extremely characteristic and easily distinguished from the brownish-color assumed by the red-corpuscles of normal blood when treated in the same manner. Other of the anilin dyes give just as characteristically distinctive reactions.

Dr. Strauss reported that this method had been in use some months in the Third Medical Clinic at the Charité (Professor Senator's clinic), and is there considered of diagnostic value. Opinions seemed unsettled as to whether the significance of the test would add everything to our knowledge of the changes in the constitution of red blood-cells in diabetes, and of glycolytic processes, or ferments. It has not, as yet, been in use long enough to be sure that the reaction occurs in the blood of diabetic patients before the onset of glycosuria, though some claims besides those of the inventor have been made for its diagnostic availability at this stage.

A recent report of some work done at the German University of Prague, on the excretion of pathogenic micro-organisms through the mammary gland, seems interesting. Practically, none of the ordinary pathogenic germs can be found in the milk, even at a time when their presence in the circulation may be easily demonstrated. For instance, in patients suffering from severe puerperal sepsis, when streptococci were frequent in the blood, there were none in the milk. Experiments with the ordinary pus micro-organisms, even when injected directly into the blood, invariably gave negative results, and the milk was sterile to culture tests. There was the same result with virulent anthrax bacilli. Injections of the bacillus pyocyaneus were always followed by positive results, and the bacillus could easily be demonstrated in the milk, but this was discovered to be a result of the local lesions of the mammary gland which were invariably produced. The investigators believe that the same thing holds for all pathogenic micro-organisms, and that tubercle bacilli, for instance, only appear in cow's milk when there are lesions of the udders. These need not be large enough to be easily visible, in fact, they may be so small as to elude any but the most careful observation, and sometimes are only revealed on painstaking microscopic examination of a large number of specimens.

TRANSACTIONS OF FOREIGN SOCIETIES.

Paris.

CHYLOUS ASCITES IN CONNECTION WITH CANCER OF THE STOMACH—RUPTURE OF THE AORTA IN A FIT OF ANGER—SERIES OF ACCIDENTS FOLLOWING THROMBOSIS OF THE PORTAL VEIN—THE GRAVITY OF PROGNOSIS IN THE PRESENCE OF BRADYDIASTOLE—AGGLUTINATING REACTION FOUND TO EXIST IN CASES OF INFANTILE ENTERITIS—MOVEMENT OF THE LIVER DURING RESPIRATION.

AT the session of the Medical Society of the Hospitals, October 8th, HIRTZ reported a case of *chylous ascites in connection with cancer of the stomach*. The patient was a woman aged fifty-seven years. The abdominal fluid obtained by tapping contained 5.5 grams of fatty matter per liter. At the autopsy, which was performed soon afterward, it was found that the cancer of the stomach had invaded both the lymphatic glands and thoracic duct.

TROISIER reported three cases of cancer of the thoracic duct in no one of which was there an accompanying ascites.

LETULLE emphasized the difference between chylous ascites and chyloform ascites. Although the mechanism of the latter is not at all clear, it often occurs in a temporary form, for example, in children attacked with cardiac disease.

At the session of October 15th, THOINOT mentioned the case of a man who *ruptured his aorta in a fit of anger*, and died some hours later. The rupture was found to be in the transverse portion of the vessel and commenced at the edge of an atheromatous plaque. There resulted an enormous subpleural hematoma with infiltration of blood along the abdominal aorta. This, by pressure upon the celiac plexus produced intense pain in the abdomen up to the moment of death.

At the session of October 22d, BARTH described a *series of accidents following thrombosis of the portal vein*. The patient, a man aged forty-seven years, was seized with violent epigastric pain recurring frequently, with vomiting, but without fever. Seventeen days later, without apparent cause, the symptoms of acute peritonitis set in, and the patient died within twenty-four hours. At the autopsy, it was discovered that one intestinal coil was injected, thickened, and blackened, as if it had been strangled. The veins of its mesentery were obliterated. In the portal vein was an old thrombus, apparently the starting-point of all the trouble. It was difficult to say what was the immediate cause of the fatal peritonitis.

GALLIARD was inclined to regard the occlusion of the veins of the mesentery as the primary lesion. In alcoholic subjects, sclerosis, in this locality, is not so very uncommon. He regarded the thrombosis of the portal vein as secondary to it.

HUCHARD read a paper in which he insisted upon *the gravity of prognosis in the presence of bradydiastole* (lengthening of the diastolic interval) in cases of heart disease. An early recognition of this symptom often enables the physician to foresee and sometimes to prevent progressive dilatation of the cavities of the heart. It is in these cases rather than in cases of simple asystole that the heart receives more blood than it can expel. Digitalis, therefore, on account of its effect in prolonged diastole, ought never to be administered if bradydiastole is present.

The two chief therapeutic resources are: (1) Prevent, by one or more venesections, the overfilling of the ventricles; (2) stimulate the myocardium by the administration of large doses of strychnin and spartein as well as by hypodermic injections of caffein and camphorated oil.

At the session of October 29th, FERNET reported the occurrence of very acute pain in the region of the acromioclavicular articulation in the course of a pneumonia. The patient was a man aged fifty-six years. Twelve days after the onset of the pain there existed an abnormal mobility of the joint, with bony crepitus. The diagnosis made was that of pneumococcic arthritis with destruction of the articular extremities. The shoulder was immobilized, and the trouble cured by the establishment of fibrous ankylosis.

LE NOIR related the case of a man aged twenty-seven years, who, in following his trade, breathed the whole day long the vapors of benzine. After some hours he became, as it were, intoxicated, had headache, nausea, and a general ill feeling which persisted for some time after he left the shop. When seen by Le Noir, the patient presented purpuric spots in various parts of his body and a pleuritic effusion which puncture showed to be hemorrhagic in character. He also suffered from epistaxis and bleeding from the gums. Not long afterward he died rather suddenly. At the autopsy hemorrhagic pleurisy was found, as well as myocardial and subendocardial infarcts, numerous ecchymoses and two hemorrhagic foci in the base of the brain.

At the session of the Biological Society, held October 16th, LESAGE announced that the *agglutinating reaction, so well known in connection with typhoid fever, also*

exists in infantile enteritis produced by the coli bacillus provided the test be made in the acute stage of the disease. The period when this reaction may be obtained is a short one, and if the disease becomes chronic agglutination no longer occurs. That is to say, that the agglutinating power is an index of the reaction of the organism against acute intoxication. If the intoxication persists the body loses this property of reaction and the prognosis becomes serious.

At the session of October 23d, LABORDE announced that by means of the Röntgen ray the liver has been shown to sink four or five centimeters (two inches) during inspiration. It is important to remember this fact in attempting to determine the size of this organ. Therefore, patients should be requested to stop breathing while the physician makes percussion over the liver.

At the session held October 30th, JOLLY described the results of experiments made to determine the exact proportion of leucocytes of different varieties in normal human blood. While the relation which exists is not exact, it is sufficient for practical purposes to say that in a normal adult there are, out of every 100 white blood-corpuscles, thirty-eight mononucleated cells, sixty polynucleated cells, and two eosinophilic cells.

BLONDEL called the attention of the Therapeutic Society at the session held October 7th, to the *frequent occurrence of mucomembranous colitis in women suffering from some form of pelvic disease*. It is at present pretty generally admitted that it is not an inflammatory affection, since the excreted membranes are composed exclusively of mucus. Any of the gynecologic affections may exist conjointly with it, but especially those in which retroversion is present, either with or without adhesions of the adnexa.

Treatment consists, first, in remedying the pelvic trouble. Uterine massage has given excellent results. For the affection itself, enteroclysis, with warm water which is slightly alkaline, or to which ichthyol has been added in the proportion of five parts to one thousand, is a successful method of treatment.

Vienna.

RUPTURE OF THE LONG TENDON OF THE BICEPS—
THE TRUE POSITION OF HYDROTHERAPY—ABDOMINAL ACTINOMYCOSIS—SUBLUXATION OF THE CLAVICLE CURED BY A NOVEL OPERATION—CONTAGIOUSNESS AND PROPHYLAXIS OF LEPROSY—MECHANICAL TREATMENT OF TABETIC ATAXIA.

At the session of the Imperial Royal Society of Physicians, October 29th, PORGES presented a patient who, four weeks previously, had *ruptured the long tendons of his biceps muscle*, the rupture being attended by a distinct crack. The symptoms noticed immediately after the injury persisted. The arm was powerless, and at the point of the insertion of the biceps tendon there was a sensitive point. The natural enlargement of the arm, due to the biceps muscle, was lower down on the affected than on the opposite side, this being especially noticeable on bending the elbow. The diagnosis was further confirmed by feeling the end of the ruptured tendon.

EWALD exhibited a case of *micrognathia, in a girl seventeen years old*, of a symmetric type and of extreme

degree. It was without doubt of congenital origin. Such instances among adults are rare, because children born with this malformation usually die early. Cases of micrognathia, due to osteomyelitic affection of the epiphyseal line, are almost always asymmetric. Treatment, according to Bergmann, consists in resection of the joints and the introduction of an inclined plane on the hard palate so that by every closure of the jaws the lower jaw is forced forward.

WINTERNITS spoke of the *advantage of hydrotherapy* in cases formerly supposed to be unsuited to such treatment, for example, in heart disease, anemia, and in wasting conditions. Improvement is observed in an increased metamorphosis, oxidation, and muscular power. In the treatment of nervous diseases hydrotherapy is invaluable. It has been shown by Türck that friction will restore the sensitiveness to anesthetic zones, and reflexes which have been lost may be recovered. He particularly objected to the widespread view that hydrotherapy depends chiefly upon technic. The great difficulty is in determining the dosage of the irritation and the extent of the following reaction, because the latter cannot be exactly measured.

At the session of November 5th, EWALD showed a case of *abdominal actinomycosis* occurring in a woman whose illness began last January with an attack resembling appendicitis. An abscess was opened, and thin pus was discharged during four subsequent weeks. The sinus then closed, but had to be repeatedly opened in the course of the next four months. Then, as the scanty pus contained characteristic actinomycotic grains, and the administration of iodid of potash was without effect, the area was widely incised, and the diseased tissue removed as far as possible. Two lesser operations were necessary at a latter date before the cure was complete. The speaker was of the opinion that actinomycosis is by no means as rare as is generally supposed. When his attention was directed to it, Ewald found a number of patients who had actinomycotic pustules on the face or neck. These lesions usually heal spontaneously, and unless the pus has been carefully examined, they may easily pass for simple suppuration.

STERNBERG mentioned a troublesome *subluxation of the sternal end of the clavicle produced by a fall*. On account of the tendency of the dislocation to recur even after the removal of the meniscus, the clavicular portion of the sternocleidomastoid muscle was transplanted to the periosteum of the first rib, thereby relieving the clavicle of its muscular strain, and affording a covering to assist in keeping the bone in position. The attempt was entirely successful.

KAPOSI spoke of the *contagiousness and prophylaxis of leprosy*. The infectious nature of the disease is agreed to by all observers. Concerning its contagious character there is not such unanimity of opinion. Setting aside the supposition that it is caused by eating fish, the two theories at present held are those of heredity and contagion by contact. The occurrence of the disease in those whose parents were free from it, the discovery of the lepra bacillus, and the sudden increase of leprosy in countries where it had always existed, and its outbreak in places where it

had never before occurred are all facts which incline one to the theory of direct contagion. Nevertheless, we must frankly admit that the means of such direct transference are wholly unknown; and the finding of numerous bacilli upon the persons of the afflicted individuals is not of itself proof that contagion is thereby favored. For instance, favus, whose bacteria are most accessible, is not very contagious, while herpes tonsurans, whose germs are deeply hidden, is contagious in a high degree. The general opinion expressed at the recent Leprosy Conference at Berlin was not so much in favor of a strict segregation of the patients, as it was in favor of removing them from the miserable surroundings in which so many of them are placed. Patients who are comfortably situated can safely be left to the cares of their families.

At the Medical Club, session of October 27th, BUM read a paper on the *mechanical treatment of tabetic ataxia*. The patient's powers of coordination is diminished because his sensibility is diminished; but other organs, especially the eye, can be trained to substitute for the lost sensations, and so enable the performance of many acts which had already become impossible. This is accomplished by having the patient regularly practise such motions as are indicated in the particular case. Thus to train the hand, he is given a board with pegs in various holes, which he attempts to touch quickly, guiding his hand by the sense of sight only, or to follow along a certain line with a pencil, etc. Similar exercises are arranged for the feet, and there are also standing and walking exercises. This method of treatment requires great persistence on the part of both physician and patient, but it is so certain in its results when persistently employed, that Fränkel says, "that if no good results follow its use in uncomplicated cases, the treatment has not been properly carried out." Even in paralytic stages the treatment has been successful, which is proof that the trouble is an ataxic one only. In two-months' time a patient who could not walk has learned to go about even in the dark, and to go down stairs without stumbling. A part of the first rapid improvement is no doubt due to the fact that the patient regains the confidence in himself which has been lost.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.—SECTION ON PEDIATRICS.

Stated Meeting, Held November 11, 1897.

DR. J. HENRY FRUITNIGHT, in the Chair.

DR. W. N. BERKELEY read a paper, describing a case of CONGENITAL TUMOR OF THE HARD PALATE.

On June 15, 1897, an infant, born at or near term, was admitted to the Presbyterian Hospital one-half hour after birth, with a tumor as large as a man's fist projecting from its mouth. The growth was smooth, nodular, glistening, and was attached by a pedicle two centimeters thick to the middle of the hard palate just behind the alveolar process. The growth was at once removed with the *écraseur* by Dr. Andrew J. McCosh, and its base

trimmed with scissors. Slight bleeding was checked by the thermocautery. The patient did well temporarily, but the discharge from the mouth soon caused a septic pneumonia. The father was dissatisfied, and took the baby home on the third day, where it died a day or two after. Autopsy confirmed the diagnosis of pneumonia. No other details were obtainable.

The specimen presented has been kept five months in a four-per-cent. solution of formalin. It now measures 10 cm. in length, 5 cm. in width, and weighs 51.5 grams. It has several hour-glass contractions and polypoid knots. The surface is smooth to the touch. On section the growth is seen to be partly cystic, partly solid. The cysts originally held a clear serum, and probably are dilated lymph-channels. There also are a few nodules of cartilage visible to the naked eye, and one or two small cheesy masses which suggest half-dried gland secretion. Some of the palatal cartilage may still be seen at the point of attachment.

The microscope shows the solid tissue to consist largely of capillaries and very small blood-vessels, lying in a finely reticulated, sometimes granular, embryonal connective tissue. This also contains an immense number of cells which in places lie closely packed around the vessels. The cells are round or oblong with large nuclei. Adipose tissue is present, and what appear to be leucocytes are collected here and there in heaps outside the vessels. There are also many encapsulated groups of fairly typical, closely crowded cartilage cells. The sheath is of thin, striated epithelium, which is sometimes squamous, sometimes columnar. The columnar form shows indefinite traces of ciliation. There are a few altered blood-vessels. No part of the sheath which was examined contained hair. The tumor being a mixture of several elements normal to the palate, is probably a benign growth, or the result of a malposition of tissue-elements in the development of the fetus.

DR. A. JACOBI: This case is a very peculiar one. The majority of large tumors of the mouth are teratomata. This is doubly interesting because it is not of that nature.

A CASE OF LATERAL CURVATURE OF THE SPINE, WITH PHYSICAL SIGNS SIMULATING A NEW GROWTH OF THE PLEURA.

DR. J. S. FERGUSON exhibited a patient, fourteen years of age, who came under observation July 19, 1897, and presented a lateral curvature which had first been observed two months previous to that time. She is the fifth of a family of eleven children, most of whom died young. Her parents are healthy Germans, and there is no family history of cancer, tuberculosis, or syphilis. The personal history is as follows: Height, four feet nine and three-fourths inches; weight, seventy-two pounds, which is somewhat under the average. She had scarlet fever when fifteen months of age, and measles during her third year. She has had no other illness except an occasional attack of tonsillitis. She has never had a cough and complains only of the curvature. The pulse, respiration, and temperature are normal.

Physical examination shows a slight lordosis, marked lateral curvature of the spine to the right, and elevation

of the right shoulder. The point of maximum deviation of the spine is slightly more than one inch to the right of the normal position. Motion of the chest-wall on the right side is limited, and a distinct bulging beneath and just in front of the right scapula is noticeable. In front of this, in the mid-axillary line, is an apparent depression in the chest-wall. The left side of the chest is normal. There is no enlargement of the axillary lymphatic nodes, but those in the anterior cervical region on both sides are slightly enlarged. This, the mother says, dates from the attack of measles. There is slight pallor of the skin and mucous membranes, but the patient appears to be fairly well nourished. Palpation of the chest reveals diminished, almost absent, vocal fremitus over the area of enlargement; it is normal elsewhere. On percussion there is marked dulness with a distinct sense of resistance over the bulging area. This is surrounded by an area of slightly increased resonance, normal or slightly increased resonance being present *below* the area of dulness. Percussion of the opposite lung yields a normal or slightly extra-resonant note. On auscultation, the respiratory murmur is diminished in intensity, distant and harsh in character, over an area of seven and a half inches in the vertical and six inches in the horizontal diameter, which corresponds to the area of dulness. There are no audible râles. Respiration is not bronchial or harsh in character. The voice sounds are diminished in intensity, and there is slight bronchophony. The affected area is surrounded by a zone of puerile respiration, while the respiratory murmur over the left lung, especially at the apex, is slightly exaggerated. She is able to lie equally well upon either side. She also says that she has had an occasional attack of sharp pain beneath the right scapula during the past two months. This pain is intermittent, and continues one or two days.

DR. A. JACOBI: In spite of the elaborate description, I cannot convince myself that there is a tumor in this case. There is dulness over a very small area, but over a large portion of the right side there is good resonance, especially when the spine is straightened out. I believe that the dulness is due to the increased development of the muscles on that side and in part to the turning of the body caused by the scoliosis. This would diminish the area of resonance. There is good resonance everywhere with the exception of over the lower part of the scapula, and there is no such dulness as one would expect if a large and growing tumor were present. The scoliosis is more marked than it usually is in these cases.

DR. L. EMMET HOLT: I am of the same opinion as Dr. Jacobi. I find it difficult to believe that the child has anything but a very rapidly increasing curvature of the spine, and the lung has suffered on account of the compression.

DR. HARRY KOPLIK: I agree with both preceding speakers. The diminished respiratory murmur may be explained by the emphysema which is usually found in such cases. Vocal fremitus is present, and it is only the respiratory murmur which is diminished.

DR. N. E. BRILL: The physical signs would not lead me to make a diagnosis of tumor of the right lung. The

percussion resonance was certainly increased when Dr. Jacobi straightened the child's spine.

DR. FERGUSON: I can only add that the case was not presented with the absolute diagnosis of a new growth of the pleura. This was only suggested on account of the many physical signs which seemed to point to it. I found an area of dulness and diminished respiratory murmur, with a good percussion note not only above, but in front, below, and posteriorly, between it and the spinal column. This I can hardly explain, except by the possible existence of something which is not pulmonary tissue.

DR. JOSEPH COLLINS then read the paper of the evening, entitled

THE CLINICAL AND PATHOLOGIC INTERPRETATIONS OF TIC. (See page 747.)

DR. JACOBI: After hearing this profound and elaborate paper, please listen to a very few words from me. If in tic we have to deal with a degenerative neurasthenic disorder, I think we had better abandon treatment of this symptom so long as we can do so little for the disease. But to my certain knowledge there are tics which can be cured and which are not the result of deep-seated cerebral degenerations. Tic is generally facial, causing grimaces, winking and blinking, sniffing, drawing up one or both sides of the nose, or one or both corners of the mouth, shrugging of the shoulder, or the turning of the head in different directions. The tongue is often thrown about in the mouth, and the patient sometimes makes a peculiar noise. I have seen many cases of torticollis, and I have cured a great many because I pay attention to the etiology. It is possible that I have been fortunate enough to see many cases which were curable. In 1886 I published a paper on chorea due to nasal abnormalities, and have since written another on the same subject. I have seen a great many cases where tic was not dependent upon cerebral degeneration, but upon degeneration of the mucous membrane and submucous tissue of the nose. My attention was drawn to this condition many years ago, and I was glad to find an elaborate paper on the subject by McKenzie, referring to the intimate connection of the outlying branches of the trigeminus with possible reflexes. From this point of view I have studied the cases, and I have had many in which treatment of the nose by simply washing it out twice daily, for years if necessary, touching it with chromic acid or the actual cautery, or by removal of adenoid growths, has cured them. I am also convinced that epileptic attacks may be due to this cause—nasal irritation. Many cases are certainly benefited by treating the nose and nasopharynx. Tic often occurs in healthy children, and it is not always due to degeneration, as modern teaching would have us believe.

DR. B. SACHS: There is every reason to be indebted to Dr. Collins for his fascinating presentation of this subject. I am sorry to be obliged to disagree with him on some points. I am sure that every one will agree with me that no subject has given the writer on nervous disorders so much perplexity as this subject of tics. The first point which the author has raised is the matter of classification. Every one who classifies this subject begins with chorea, and gradually goes on to the tics. Dr. Collins

says that we must call these disorders tic and nothing else. I do not think we ought even to give up the term choreiform. There is not so much difference between these terms as Dr. Collins seems inclined to think. We have just as much right to say choreiform manifestations as we have to use the term epileptiform manifestations, and these, Dr. Jacobi allows, are much more nearly related to chorea than some others which are types of the disease. There is some reason for doubting the wisdom of separating these conditions and putting them in distinct categories. There is every possible difference between an ordinary facial tic, which more often affects old people, and the so-called degenerative neuroses occurring in a child and not necessarily a matter of family degeneracy. I am sorry he attaches so much importance to these newer doctrines which are not under control, although I am glad he grants two kinds of degenerates—the inferior and the superior. All these stigmata are not positive signs. Although there may be a great deal in Lombroso's doctrine as regards degeneracy, I think we are carrying these things too far. The facial tics are found in a large number of individuals who do not present a single one of these degenerative stigmata. If Dr. Collins says that *la maladie tic convulsif* is a degenerative neurosis, I can agree with him. I know of two cases, occurring in a man and a woman, in which there is a tic of this type. But we cannot draw positive inferences from these new doctrines. In regard to the relation of tics to myoclonus, the last case described by Dr. Collins is much more conclusive. I have now under observation in Mt. Sinai Hospital a case very much like the one referred to by Dr. Collins—a man with a distinct tic or spasm of the diaphragm which extends to the intercostal muscles. You can see each single clonus contraction of each muscle involved, and the whole thing would come very properly under the head of myoclonus. While some of the tics may be degenerative neuroses, it is not safe to say that everything which Dr. Collins calls tic come under this head.

In regard to treatment, there is one point of difference between the author and myself. I do not try to poison my patients nor do I think that he does. Drugs should not be given in large quantities; on the contrary, the smallest amount which will check the disease should be employed. I have not seen good results follow the use of the salts of copper and silver. The only remedy which proves beneficial in facial tic is atropin administered by means of hypodermic injections. It will not cure, but it assists in ameliorating an attack and in making the patient a little more comfortable.

DR. COLLINS: I have but little to add, save to reiterate and emphasize some of the statements made in the paper. In reference to Dr. Jacobi's remarks, I would say that I am quite familiar with his paper in which the genetic relationship of nasopharyngeal diseases to certain forms of simple facial tic has been pointed out. No one can deny that that such a relationship exists, but it is relatively uncommon when compared with the whole number of facial tics in the young. At the present time I have two girls with facial tic under treatment, the kind which, if you will still allow, I shall call the degenerative type,

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXI. NEW YORK, SATURDAY, DECEMBER 18, 1897.

No. 25.

ORIGINAL ARTICLES.

RATIONAL GYNECOLOGY.

By JOHN H. KELLOGG, M.D.,
OF BATTLE CREEK, MICH.

IT is not the purpose of this paper to enter upon a detailed consideration of the various pathologic conditions with which the gynecologist has to deal, but briefly to call attention to a few principles which, though not unknown to the masters of this branch of medical science, appear to receive much less practical attention than they deserve. I do not dare to presume that this paper will contain anything particularly novel in principle or unique in method; my aim is simply to show that it is possible to make a practical and successful application of every rational principle which has been developed by the sagacious observations of Sims, Peasley, Emmet, and others of the pioneers of American gynecology.

From a theoretic standpoint, gynecologic methods as presented in our most recent text-books leave little to be desired, but in practice how seldom do we see a thorough-going application of the methods calculated to reach the causes of the pathologic conditions present? For example, every gynecologist knows that uterine retroversion is not a distinct pathologic entity, but merely a symptom, and the same may be said of cervical erosion or granular degeneration, and of the various morbid conditions misnamed chronic metritis, endometritis, etc.; nevertheless, in ninety-nine cases out of a hundred these symptoms, which are Nature's sign-boards to direct attention to disturbing factors, are treated by merely palliative means, such as pessaries, pledgets, cauterization, antiseptic lotions, etc.

It is not usually a difficult thing to cure a cervical erosion, a catarrh, a prolapse, or a retroversion by palliative or more radical measures, and after the lapse of a few weeks or months, often even a few days, the same symptoms or others of allied character return, and the same or similar remedies must be reapplied. It is not uncommon to observe cases in which women have been under the care of gynecologists almost steadily for from one to five years, or even longer, often until both money and patience are wholly exhausted. In the end the unfortunate victim is no better than at the beginning of the treatment, because the underlying causes have not been

reached; the leaves of the pathologic tree have been picked off, but the tree itself has not been plucked up by the roots, and continues to bear fruit. The visible effects of disease are the result of causes which lie beneath and often out of sight. Unless these causes are removed the morbid condition is certain to be reproduced. The principles which I have gradually come to adopt in the practice of gynecology during nearly twenty-five years of active practice are the following:

I. Excluding infectious maladies, the local symptoms or pathologic phenomena do not, as a rule, afford evidence of a purely local disease, but are simply a local expression of morbid conditions more or less generalized in character.

II. Displacement of the pelvic viscera is not, as a

FIG. 1.

FIG. 2.

Fig. 1.—Showing visceral displacement from incorrect standing and corset-wearing.

Fig. 2.—Showing displaced viscera.

rule, an isolated pathologic condition, but is associated with similar displacements of the viscera of the abdominal cavity.

III. The principal causes of uterine and ovarian displacements and congestions are such as affect the static relations and the circulation of the viscera of the abdomen as well as those of the pelvis, and hence, the rational treatment of displacement of pelvic organs requires the removal of all causes of similar displacement of the abdominal organs as well as of the pelvic viscera, and the restoration of the normal supports of these organs.

IV. For permanent results the patient must be made sufficiently well to be able to dispense with special treatment, and so that she can endure with-

out inconvenience the ordinary wear and tear of life and with no resulting injury.

So-called pelvic disease, excluding infections, is seldom a distinctly local affection.—A failure to recognize this principle has led gynecologic surgeons to remove a vast number of hyperesthetic ovaries which were sensitive only because the patient was suffering from a general condition of malnutrition and resulting nervous irritability, and not infrequently to perform unnecessary hysterectomies, dilatations, curettements, and plastic operations upon minute cervical and perineal lacerations; sundry other operations have likewise been performed.

The gynecologist meets with a vast number of cases in which the symptoms relating to the pelvic organs are present simply because the patient's general health is not good. Every function is disordered, every nutritive process disturbed, and it is wholly on account of some predisposing or exciting cause that this expression of a general morbid condition is made by the pelvic viscera. Physical depravity is much more frequent than any other condition in which pelvic symptoms are prominent. Total extirpation of the pelvic viscera will not cure such a condition. I have seen many patients who had had both uterus and ovaries removed by some specialist possessed of a penchant for this sort of surgery, who were not relieved one whit of the various annoying symptoms on account of which the operation was performed, but whose condition was, on the contrary, actually made worse. I may also say the same with reference to such minor operations as trachelorrhaphy and perineorrhaphy. I think it may be safely said that quite a large majority of the patients upon whom these operations are performed, except in the most extreme cases, are greatly disappointed in the results experienced, backache, dragging pains, headache, neuralgia, indigestion, intestinal inactivity, depression, and other annoying and distressing symptoms remaining, or returning as soon as the patient loses the temporary benefit derived from a few weeks' enforced rest in bed. These disappointments are the result of a failure to recognize the *general* character of the patient's malady. It is a fact that the mere existence of a cervical tear, an ovarian or uterine tenderness, or the coexistence of these conditions with symptoms in remote portions of the body cannot be regarded as indications of any causative relation between the pelvic condition and remote local or general symptoms.

A pelvic examination, even the most thorough, is rarely sufficient to furnish the necessary data for instituting a rational plan of treatment. In the great majority of chronic cases, excluding tumors and infections, the whole woman is sick—the whole body—and the condition of every important organ and

every vital function must be investigated, and the possible relation of any general morbid condition to the pelvic symptoms must also be carefully studied.

Displacement of the pelvic viscera is not, as a rule, an isolated pathologic condition, but is associated with similar static disturbances of the viscera of the abdominal cavity.—It should not be forgotten that the pelvic and the abdominal cavities really constitute one cavity, which might be termed the lower cavity of the trunk, since no partition exists between them. From this fact it must be apparent that general causes or conditions operating upon the abdominal viscera must affect in a similar manner the viscera of the pelvis. Prolapse of the organs of the abdominal cavity necessarily tends to produce displacements of the pelvic organs, although it is surprising to note with what obstinacy the viscera of the pelvis not infrequently resist the disturbing influence of extensive displacements of the viscera of

FIG. 3.

FIG. 4.

Fig. 3.—Showing displacement of spleen and other viscera from corset-wearing.

Fig. 4.—Showing visceral displacement in a woman who had worn a "health corset."

the abdomen. During seven or eight years I have made careful observations of the position of the abdominal viscera in all cases of pelvic disease which have come under my observation, and in a recent study of the cases in which complete notes were taken I find some most significant facts which may be briefly summarized as follows:

Total number of cases examined in which pelvic or abdominal displacements existed	2132.
Cases of displacement of pelvic organs.	1089—52 per cent.
Cases of displacement of abdominal viscera without displacement of pelvic viscera.	1023—48 per cent.
Cases of displaced pelvic viscera without displacement of abdominal viscera.	134—6 per cent.
Floating kidney.	357—17 per cent.

Only such cases were included in the list of pelvic displacements as presented some very marked displacement, as retroversion, marked retrocession, or procidentia. Cases of ante flexion and slight prolapse were not counted. It is evidently impossible

to draw from these results any other conclusion than that visceral displacements in the pelvic cavity do not constitute a separate and distinct class of disorders, but that they are etiologically and pathologically linked with static disturbances of the organs of the abdomen. Hence, it is apparent that in the study and the treatment of pelvic disorders, at least those involving visceral displacement, the pelvis must be considered simply as a portion of a common cavity occupying the lower part of the trunk, subject to practically the same disturbances and requiring for the relief of one diseased part attention to the whole.

The rational treatment of pelvic disease requires the removal of the causes of displacement and congestion of the abdominal viscera as well as similar conditions of the pelvic viscera.—The facts previously cited are certainly such as to carry with them the conviction that chronic disease of the pelvic organs, especially

FIG. 5.

Showing position of viscera in corset-deformed woman.

displacement, is associated with similar conditions of the abdominal viscera. They also show that displacements of the abdominal viscera are much more frequent than like conditions of the pelvic viscera, the latter organs being more thoroughly protected by Nature against disturbing influences.

Since Dr. Trestour, the eminent French physician, pointed out a few years ago the important relation of prolapse of the various abdominal viscera to different forms of disease in both men and women, I have made a diligent study of the position of the abdominal viscera in all cases coming under my observation. I have nearly always found serious displacements of the viscera accompanied by extreme irritability of the sympathetic nerve-centers of the abdomen, especially the lumbar or hypogastric plexuses and the solar plexus. The strain upon and the constant irritation of the great sympathetic centers of the abdominal cavity, from displacement of the colon, kidneys, or liver, is a constant source of reflex irritability, which,

acting first upon the great centers of the brain and spinal cord, may be reflected to any or all of the peripheral nerve ramifications. That such an irritation exists is shown by the fact that tenderness of the solar plexus, of one or both of the lumbar ganglia, or of the lumbo-aortic plexus was found in a large proportion of the total number of cases to which the foregoing statistics relate. I have long been convinced that the greater number of symptoms, such as backache, dragging sensation across the lower abdomen, inability to stand long upon the feet, and similar symptoms are not, in the great majority of cases, due to pelvic disorders, but to the general visceral prolapse which not infrequently involves all the organs of the abdominal cavity.

Figures 1 to 6 illustrate some of the characteristic deformities of figure and displacement of internal organs which I have observed in connection with cases of pelvic disease.¹

To effect a permanent cure in these cases usually requires considerably more than the employment of such local palliative measures as pledget-placing, electricity, and vaginal douches, or even plastic operations. Such methods of treatment must be instituted as will reconstruct the constitution, give tone to the nerves, vigor to the muscles, and cause a general increase of vital energy.

Only a brief statement of the methods by which this may be accomplished will be possible within the limits of this paper. First of all, it is my custom to make a thorough examination of every patient who comes under my care. This examination includes, in addition to the ordinary investigation of the patient's early and family history and a careful study of the morbid symptoms and conditions relating to the pelvic organs which the case presents, a thorough study of the position of every abdominal organ, a careful examination of the blood, a test of the strength of each individual group of muscles, and such other special investigation as may be indicated. The examination of the abdomen is begun by careful palpation, all waistbands being loosened and the clothing so adjusted as to facilitate the examination. One's fingers soon become sufficiently trained to enable him to quickly detect any considerable change in the position of the liver, kidneys, stomach, or colon. The condition of the pelvic viscera is then carefully determined by the bimanual method.

Next, careful note is taken of the pose assumed in standing and sitting. The obliquity of the pelvis is determined by the pelvi-oblique-meter. In by far the majority of cases this is found to be greatly diminished through abnormal straightening of the lum-

¹ The cuts used in connection with this article are borrowed from the author's work, "The Art of Massage."

bar spine, a condition unquestionably conducive to prolapse of both the abdominal and pelvic viscera. The patient's clothing is investigated, and peremptory orders are issued that tight bands shall be at once discarded.

The next day, if the condition is such that the patient is able to be about, dynamometer tests of the various groups of muscles are taken, and a physical chart or graphic representation is made, which at once shows the weak spots in the patient's neuromuscular apparatus and also the degree of weakness. The physical coefficients, based upon the mathematic data obtained by the dynamometer, indicate at once whether the patient should gain or lose in flesh, and

FIG. 6.

Showing the effect of heavy skirts and a bad position in a woman aged twenty-four years.

the kind and amount of exercise required. In cases of special interest, outline tracings of the front and side profiles are made, as a record of symmetry and habitual pose. Examinations of the blood and the urine are made; and, if it is necessary to determine the digestive capacity, a test-meal is given. The examination being completed and a careful record made, the treatment is usually outlined as follows:

A week's program of baths, consisting of one or two vaginal douches daily of such a temperature as is adapted to the patient's condition, sitz baths (80° to 90° F.), the ordinary shower-bath, spray, and douche,

the Scotch douche, salt glows, electric-light baths of three- to five-minutes' duration, tonic applications of faradic electricity in the form of general faradization, the sinusoidal electric current with slow alternations applied to specially weak groups of muscles, applications of the galvanic current to the spine and the sympathetic centers of the neck and abdomen, general massage, special massage of the abdomen, pelvic massage, manual Swedish movements daily, mechanical Swedish movements, Swedish gymnastics and light calisthenics in the gymnasium, and, in appropriate cases, swimming, bicycle riding, boating, and other light exercises, and such other specific treatment as individual cases may require. If the patient is thin, careful attention is given to the application of such dietary measures as will be conducive to the most rapid gain in flesh. If the patient is obese, reducing measures are employed. In case the patient habitually sits or stands with the spine abnormally straightened, thus encouraging visceral prolapse by diminishing the obliquity of the pelvis, she is subjected to a special course of training and instruction to correct this injurious attitude. In many cases an abdominal supporter is employed. (Fig. 7.) A more specific description of some of the measures employed may be of interest:

Baths.—In addition to sitz, shower, and other baths, various local applications are made, such as fomentations to the spine, hot sponging, or hot and cold applications to the spine, fomentations, hot bags, and compresses over the abdominal or pelvic regions, foot baths, hot and cold applications to the head, effervescing or carbonic-acid-gas baths, electric, Russian, and Turkish baths, etc. The electric-light bath continued just long enough to produce slight moisture of the skin and followed by a cool shower bath I find a most excellent tonic measure. Showers, and all forms of sprays and douches are employed with apparatus so constructed that absolute accuracy in regard to time, temperature, and pressure may be easily secured. Experience shows that it is only by the employment of accurate measures that definite and reliable results may be obtained.

Electricity.—The era during which electricity was considered a panacea for all human ailments and especially for maladies peculiar to women has passed. The number of over-enthusiastic electrotherapeutists is certainly much smaller than it was a few years ago. It is now, I think, generally conceded that electricity is actually curative when employed by itself alone in but a very small proportion of cases of pelvic disease. Nevertheless, it is an exceedingly useful palliative. For the relief of ovarian and other forms of pelvic pain I find the rapidly alternated sinusoidal current superior to all others. The slowly alternat-

ing sinusoidal current furnished by the apparatus shown in Fig. 8 is a most efficient means of developing weakened muscles. It produces powerful contractions without pain, a contraction occurring at each alternation of the current. Both forms of the current may be used for internal or external application, or in combination.

Massage.—General massage is of great value as a means of improving the patient's general nutrition, but I attach great importance to abdominal and pelvic massage used in connection with general massage. During a good many years I have given attention to the development of these special forms of massage, and have seen most excellent results from their employment. I shall not occupy space in this paper to describe fully the methods of abdominal and pelvic massage, but I have endeavored to consider the subject fully in my work, "The Art of Massage."

Massage of the Abdomen.—The following rules should be carefully observed in abdominal massage:

1. General abdominal massage should not be administered until two hours after eating.
2. The bladder should always be emptied just before abdominal massage.
3. In obstinate cases of fecal accumulation, a colocyser (large enema taken in right Sims' or knee-chest position) of warm water should be administered, the water being allowed to pass off before treatment.
4. The patient should be taught to relax the ab-

FIG. 7.

Showing a natural abdominal supporter.

dominal muscles, and to breathe deeply and regularly during treatment.

5. If the abdomen is very sensitive, apply a hot fomentation before giving the massage.
6. If the skin perspires very freely, render it firm and smooth by sponging with cold water.
7. Very "ticklish" patients require careful education by avoidance at first of superficial movements.
8. Pain and coldness of the extremities or depres-

sion after abdominal massage is due either to bungling or violent treatment or to extreme hyperesthesia of the abdominal sympathetic. In such cases fomentations and the moist abdominal bandage should be employed in connection with massage.

9. It is important in all manipulations of the abdomen to exercise great care not to excite pain. All movements should be executed in such a manner as to avoid sudden thrusts, thereby causing the patient

FIG. 8.

pain or other disagreeable sensations, as such disturbances create rigidity of the abdominal muscles, thus seriously interfering with the effects of the manipulations.

10. In employing massage of the abdomen, the operator should stand over the patient, so as to aid his hands as far as possible by the weight of his body, taking care, of course, to graduate the pressure to the requirements of each individual case.

11. All deep-kneading movements in massage of the abdomen should be slower than for other parts of the body, to allow time for the movement of the fecal mass.

The different procedures to be employed in abdominal massage may be briefly discussed as follows:

Reflex Stroking.—With the ends of the fingers make very light strokes in a circular or semi-circular direction about the umbilicus. Begin very close to this point, gradually extending outward, then return and repeat. Also make vertical strokes along the sides in the mammary line and parallel with the rectus muscle. Strokes may also be made over the fourth, fifth, and sixth ribs at the sides of the chest. In sensitive persons one-sided contraction of the abdominal muscles or a twitching at the epigastrium will be noticed as the result of these so-called abdominal and epigastric reflexes. This procedure is strongly exciting; some patients are not able to endure it. The profound reflex which results in patients who are very sensitive or ticklish is evidence of the

strong influence of this procedure upon reflex nervous activity.

Nerve Compression.—(Fig. 9.) The stomach and the intestines are directly controlled by the solar plexus and the lumbar ganglia of the sympathetic.

make a considerable degree of pressure in order to reach them. The tips of the fingers placed upon the points indicated should be carried directly back toward the spinal column, the patient in the meantime being directed to take first a full breath, and

FIG. 9.

Showing method of compression of lumbar ganglia of the sympathetic.

The solar plexus is at the epigastrium just below the lower end of the sternum. The chief lumbar ganglia are situated on either side of the umbilicus, about two inches from it. Pressure upon these ganglia has a marked stimulating effect, because they send out energetic nerve-impulses into the parts which

then to exhale as completely as possible. This diverts the mind of the patient from the procedure which is being executed and also diminishes the abdominal tension, thus making it less difficult to bring pressure to bear upon the posterior wall of the abdominal cavity. With patients who are extremely

FIG. 10.

they supply, which include not only the stomach and intestines, but all the abdominal viscera. It should be remembered that these nerve-masses lie beneath the abdominal contents, resting upon the bodies of the vertebræ. Hence, it is necessary to

fat or in whom the abdomen is greatly distended with gas this procedure can only be executed in a very imperfect manner.

The position is a matter of great importance. The shoulders should be slightly raised and the knees

well drawn up, the legs being supported so that the anterior abdominal wall will be relaxed as much as possible. The patient's hands should be by her side, and all the muscles of the body in a state of rest. Only gentle pressure should be employed, and the application continued but two or three seconds at each point. In many cases it will be found that extreme sensitiveness exists at the points indicated, which is evidence of an excited or hyperesthetic state of the abdominal sympathetic. Continuous gentle pressure may be beneficial by setting up a series of vital activities which result in the restoration of the nerve to its normal condition.

Vibration.—(a) Strong vibration applied to the abdominal contents has been shown to be one of the most powerful means of stimulating the nervous reflexes, circulation, glandular activity, and peristalsis. Either one or both hands may be used. The flat palm of the hand is applied to the surface, with the arm extended, and fine vibratory movements are executed in such a manner as to throw the whole abdominal contents into vibration. The same movement, may be beneficially applied to the liver. (b) A more vigorous shaking movement is communicated to the abdominal contents by making intermittent pressure either with one hand, or with one hand reinforced by the other, or by both hands in alternation, the movements being made with sufficient rapidity to produce a decided motion of the abdominal contents. The effect of this procedure is very marked in cases in which the abdominal walls are considerably relaxed. (c) A third method of applying shaking is by placing the palm of the hand upon the abdomen, the arm slightly flexed, then making a rapid rotary movement without allowing the hand to slide upon the surface. The direction of the movement is alternated, half a dozen in one direction, and then an equal number in the opposite direction.

Percussion.—This is unquestionably the most powerful of all the stimulating means which can be applied to the viscera through the abdominal wall. All the different modes of percussion, *viz.*, tapping, spitting, clapping, hacking, and beating may be usefully employed.

Digital Kneading.—(Fig. 10.) Standing face to the patient's feet, with the fingers very slightly flexed, place the finger-tips, the hand being reinforced by the other hand placed above it, upon the abdomen low down upon the right side. Crowd the finger-ends backward, pressing with as much force as possible, without giving the patient inconvenience, against the cecum. Carry the hand upward in the direction of the ascending colon as far as permitted by the ribs. Repeat the movement four or five times. Execute similar movements on the left

side, beginning above instead of below, and pressing the fingers upon the abdominal wall at a point close under the ribs on the left side. Then carry the hand downward, turning toward the median line at the conclusion of the movement so as to follow as closely as possible the course of the sigmoid flexure of the colon.

(To be continued.)

THE MANAGEMENT OF HERNIA IN INFANCY AND CHILDHOOD.¹

BY WILLIAM B. COLEY, M.D.,

OF NEW YORK;

ATTENDING SURGEON TO THE NEW YORK CANCER AND POST-GRADUATE HOSPITALS; ASSISTANT SURGEON TO THE HOSPITAL FOR RUPTURED AND CRIPPLED.

THE importance of understanding the best methods of treating hernia in infancy and childhood is evident when we consider the relative frequency of this affection during the earlier years of life. At the Hospital for Ruptured and Crippled, New York, during the six years from October 1, 1890, to October 1, 1896, there were treated 26,388 cases of hernia. Of these, 6586, one-fourth of the entire number, occurred in children under the age of 14 years. Of 22,362 inguinal herniæ, 5554 occurred in children under 14 years of age; almost exactly one-fourth. Of 21,000 cases of hernia observed at the London Truss Society, 3433 were in infants under the age of 1 year.

I believe that many herniæ observed in youth, and even in adults, are due to lack of treatment or to imperfect treatment during infancy.

Some writers advise against the use of a truss during the first year of life, trusting that Nature will effect a cure, or believing that no harm will result from the delay. Such teaching should be strongly condemned. In this I am in most hearty accord with Mr. Macready, who says, "directly the rupture is discovered the truss should be applied. Some have imagined that very young children cannot wear a spring truss, but this is an error." The experience with the light spring truss in infantile hernia at the Hospital for Ruptured and Crippled entirely agrees with Macready's. I have yet to see an infant, save possible three or four suffering from extreme malnutrition, that could not wear a properly constructed and well-fitting steel truss. Such a truss should cause very light pressure, and should be daily removed to permit of careful washing and cleansing of the parts. I regard the steel truss as much superior to the various substitutes, *e.g.*, the "worsted" truss, and this opinion is based upon a careful trial in a large number of cases.

Duration of Treatment.—It is very difficult to lay

¹ Read before the Section on Pediatrics at the last meeting of the American Medical Association.

down any hard and fast rule as to how long a truss should be worn, but it is safe to say its use should seldom be discontinued until two years have elapsed since the hernia was last observed. The younger the patient when the treatment is begun the shorter the time necessary to effect a cure is true in the majority of cases. If the use of a truss is discontinued too soon relapse is likely to occur, and then a much longer time will be required to effect a cure, if, indeed, it be ever attained. Strangulation, though rare during the first year of life, occasionally occurs and furnishes an additional reason for early treatment. I have operated seven times for strangulated hernia in children under two years of age; three of them under one year.

Umbilical Hernia.—This variety is very common during the period in question, 2043 cases in patients under the age of 14 years having been observed at the Hospital for Ruptured and Crippled during the six years previously referred to. The method of treatment which we have employed as a routine measure consists in placing a simple wooden button, about one inch in diameter and first covered with rubber plaster, directly over the umbilical opening, and fixing it in this position by means of a strip of rubber plaster, two inches wide, which completely encircles the abdomen. This is changed about every ten days, and seldom causes excoriation or undue irritation. Nearly all of these patients with umbilical hernia are cured within a short time by some such simple means of support, and it is extremely rare to find a child who has reached the age of puberty with the hernia persisting. Therefore, it follows that it is bad judgment to advise operative treatment in this class of cases.

Epigastric Hernia.—There are occasionally seen herniæ which closely resemble the umbilical variety, but careful examination makes clear the fact that the hernial opening is not at the site of the umbilicus, but slightly above, or more rarely, on either side of this point. Such herniæ are due to congenital defects in the linea alba, or in the lineæ semilunares, and if the opening is very large, *e.g.*, of a size that will admit the thumb, mechanical treatment will seldom effect a cure, and such cases may very properly be subjected to operation. Out of a total of 565 herniæ in this region in children under 14 years of age, but 19 of this variety were observed during the period previously mentioned.

Femoral Hernia.—This is seldom found in infancy and early childhood. Of 1424 cases of femoral hernia treated at the Hospital for Ruptured and Crippled during the six years referred to, only 43 occurred in patients under the age of 21 years, and but 17 under the age of 14. Macready's tables, compiled from

the records of the London Truss Society, show that out of 1658 cases of femoral hernia only 27 occurred in children under the age of 10 years, and only 5 under the age of 5 years. In other words, out of a total of 21,000 cases of inguinal and femoral hernia, only 5 cases of the femoral variety were observed in children under 5 years of age! I have operated upon 8 cases of femoral hernia in children under the age of 10 years, and 15 under the age of 14 years, the youngest having been a male infant just 2 years of age, with a double femoral hernia of large size. An operation was performed upon both sides with an interval of two weeks between the operations. The sac of the right hernia contained the cecum. This is the only case in which I have found this organ in a femoral hernia.

Treatment of Femoral Hernia.—The mechanical treatment of femoral hernia in infancy and childhood can be dismissed with a few words, as the best authorities admit that it is practically incurable by means of a truss. In regard to this point, Macready states that "femoral hernia so seldom recedes in either sex that it must be deemed incurable. It is well known from pathologic observations that these herniæ become obliterated, but the instances are so few that they give no ground for hope of a favorable issue in general." This fact furnishes a sufficient reason for urging early operative treatment, provided, of course, that it may be shown that such treatment is both safe and effective.

Personally, I have had but one relapse subsequent to operation for femoral hernia, either in children or adults. I have operated upon thirty-eight patients presenting this affection, and the oldest is now well upward of six years. The one case which relapsed, that of an adult, was the only one in which primary union was not obtained. The methods I have employed were two, as follows: (1) A very high ligation of the sac and a closure of the canal by means of a "purse-string" suture of kangaroo tendon. The wound is closed with fine catgut suture, and is not drained. Eight patients were operated upon in this manner. (2) Bassini's operation for femoral hernia was employed in the treatment of the remainder, and consists of a closure of the canal by two layers of interrupted sutures. In this operation I likewise used kangaroo tendon for the buried sutures. A truss was not employed after operation in any of these cases and, in all, the wounds healed by primary union.

Treatment of Inguinal Hernia in Children, and the Probability of Cure from Mechanical Treatment.—It will be at once seen that this is a most important point, for upon it depends the whole question of the operative treatment of hernia in children.

Some excellent surgeons have contended that all cases of hernia in infancy and childhood may be cured by means of a truss. Therefore, they argue, operations for the radical cure of hernia, whatever may be said in their favor in regard to adults, have in children no *raison d'être*. This was the burden of the criticism of my first paper upon the "Operative Treatment of Hernia in Children," published in 1893, and in which I reported 51 cases. This criticism, if well founded, would certainly leave the operation without rational support. Hence, it is worth while to most carefully examine the facts in the case.

I had long believed this opinion against operative procedure in children to be the result, rather of preconceived ideas, than of careful or extensive observation. This belief was strengthened when a thorough search through the literature of hernia failed to discover any data upon which to decide such an all-important question. It, indeed, permits of a fairly accurate solution for when simplified it is resolved into the following: How many adults with hernia had it during infancy or childhood? To aid in answering, I have, with the assistance of Drs. Carl Pfister and A. H. Cilley, analyzed all cases treated at the Hospital for Ruptured and Crippled during the six years from October 1, 1890, to October 1, 1896. During this period 26,388 patients with hernia were treated, and of this number 15,197 were over 21 years of age. The object of my analysis was to determine how many of these adults presented a history of hernia in infancy and childhood. Contrary to the opinion of many that few, if any, such cases exist I found 1360 instances of hernia which had been acquired previous to the age of 20 years; of these 306 had been noticed in early infancy; *i.e.*, soon after birth, or during the first two years of life; in 397 the hernia appeared before the age of 14 years. In other words, in 700 cases the hernia appeared before the age of puberty.

It will be seen in calculating the percentage of herniæ in infancy and childhood which persist until adult life is reached that several difficulties at once arise. The number of individuals with hernia, that, having the hernia previous to the fourteenth year of life will survive to reach maturity must be estimated. For the purpose of a concrete example, suppose we take 100 children with rupture who are under the age of 14 years, how many will be alive when the youngest is 20 years of age? From the most reliable mortuary statistics¹ it may be estimated that less than one-half of the number will be alive at the end of this period. Hence, even if there were no instances of cure we should find but 12½ per cent. of all patients with hernia, present-

ing a history of the same affection during infancy and childhood. Undoubtedly many of the adult patients fail to remember the early history of the hernia, and this fact makes our estimate much too small. Making due allowance for errors, the 700 cases found in our analysis represent, approximately, about 25 to 30 per cent. of the cases in individuals who reached adult life; in other words, nearly one-third of all cases of inguinal hernia in children are not cured by mechanical treatment.

Operation should, I think, seldom be advised in children under the age of four years, because there are very few cases in patients under this age which cannot be controlled by a truss, and furthermore, mechanical treatment cannot be given a fair trial in a much shorter period than this. Out of a total of 430 patients operated upon by myself but ten were under the age of four years. This number does not include six cases in which operation was performed for the relief of strangulation. I do not believe that the operative treatment is entirely devoid of danger in infants and very young children, though the chief menace, I think, lies in the anesthetic.

As to selection of cases I cannot perhaps do better than repeat what I recently stated in a recent report on the "Radical Cure of Hernia:"

"I believe it to be a good rule never to advise operation in children until a truss has been satisfactorily tried for a reasonable time, *e.g.*, one or two years without benefit. There are, however, important exceptions to this rule: (1) In femoral hernia operation may be at once advised; for the reason that the chances of cure by means of a truss are too slight to be considered. (2) Irreducible or adherent omentum (rare in children) and reducible hydrocele may furnish sufficient reason for early operative interference. (3) There are, furthermore, a number of cases, especially in dispensary practice, in which the rupture cannot be satisfactorily retained on account of insufficient care on the part of the parents, and such cases may with profit be subjected to immediate operation."

Dangers Attending Operation.—The operation may be regarded as practically free from risk provided the child is in good health and the operation performed under favorable conditions. The fact that most of the few fatal results have been due to ether-pneumonia shows the importance of paying strict attention to the anesthetic as well as the condition of the child's lungs prior to operation.

Adding together the cases of children operated upon for radical cure by Broca of Paris, 477 cases with 2 deaths; by Felitzet of Paris, 105 cases with 1 death, and by myself, 290 cases with 1 death, we

¹ "Eleventh Census, vol. 4, Vital Statistics."

¹ *Annals of Surgery*, March, 1897.

have a total of 877 cases with 4 deaths, or a mortality of less than one-half of one per cent.

This mortality is lower than any that can be computed from a like number of cases in adults, and the percentage of permanent cures is also larger. In other words, operation in childhood is not only attended with less risk, but it also gives the best results.

Choice of Methods.—The results in my hands following Bassini's operation have been so extremely satisfactory that I confess that I may be somewhat prejudiced in its favor, and hence unconsciously do injustice to some of the other methods. When once the principles of Bassini's method are clearly understood and the surgeon has become familiar with the technic the operation becomes a very simple one, and may be easily performed within from fifteen to twenty minutes. In employing this method in children greater care must be exercised than in adults in order to avoid damaging the delicate structures of the cord and sac. As yet, I have never injured the cord either in children or adults.

The necessity of transplanting the cord in operations for the cure of hernia cannot yet be regarded as definitely settled, though no surgeon has been able to show as brilliant results by any other method. Dr. Bull and myself have operated upon a small number of cases using exactly the same technic as in the Bassini operation, except that the cord was not transplanted. These cases have remained well with few exceptions; some of them upwards of four years. The number of cases is hardly sufficient to justify a comparison with the results following Bassini's operation. The only advantage which might be urged in behalf of this method is the fact that it is more simple and that less time is required in its performance. These are somewhat doubtful advantages since the difference in time would probably not be more than one or two minutes. The sac cannot be properly isolated without at the same time freeing the cord sufficiently to perform Bassini's operation, so that it makes little difference as regards time whether the sac be placed above or below the deep layer of sutures. Personally, I am inclined to regard the transplantation of the cord an important element in the success of the operation. There are a few practical points in Bassini's method which I think of great value: One is to at once stop all bleeding, so that the field of the operation may be perfectly clear; all of the layers of muscle and fascia should be as easily demonstrable as in a dissection on the cadaver. If the tissues become stained with blood the sac is separated with difficulty, and the bruising resulting from prolonged manipulation greatly diminishes the chances of securing primary

union. Another point upon which I lay much stress is never to cut any of the muscular fibers (external or internal oblique) in opening the canal. In this operation the aponeurosis of the external oblique is slit up above the internal ring, but I exercise great care not to cut any of the underlying muscles. Many surgeons freely cut these structures. The cut edges retract, and they can never become accurately adjusted or thoroughly united. The cutting is entirely unnecessary, as gentle stretching with the fingers is sufficient to open the canal to the desired extent. The substitution of the kangaroo tendon for silk in the buried sutures (Bassini himself uses silk), I believe, has been a distinct gain, and to this I attribute the very large percentage of primary union in my cases, as well as the improvement in ultimate results.

Final Results.—With the assistance of Drs. Jaegen, Thompson, and Ledlie I have been able to trace all but ten of the 285 patients operated upon.

Of my 290 patients under 14 years of age who were operated upon, Bassini's method was employed in 257; of these all but 8 have been traced with the following results:

2 were sound after.....	5 years
15 " " "	4 to 5 "
23 " " "	3 to 4 "
50 " " "	2 to 3 "
76 " " "	1 to 2 "
35 " " "	$\frac{1}{2}$ to 1 "
41 " " "	1 to 6 months
2 relapsed	
1 died six days after operation of pneumonia.	
4 died of various diseases within from a few months to a year after operation; perfectly sound as regards the rupture at the time of death	
8 were not traced.....	

Total, 257 cases; 166 continued well more than a year.

Of the two relapses one was following the first Bassini operation I had performed in children. The hernia was very large, and the operation imperfectly done, and moreover, this was the only case in which silk was used for buried sutures. Extensive suppuration followed, and relapse occurred within four months. In the other case the relapse occurred nearly one year after operation, and was due to the tearing apart of Poupart's ligament.

Of the 33 patients remaining, 13 had *inguinal hernia*, and were operated upon without transplanting the cord, the technic otherwise being practically the same as in Bassini's method. Of these 13 patients, 11 were traced; 4 relapsed, 2 were well after 5 years, 3 remained well after 4 years, and 2 after 2 years.

Fifteen patients had *femoral hernia*, of which 14

have been traced with the following results: No relapses:

1 well after.....	5½ years
2 " "	4 "
3 " "	2 "
4 " "	1-2 "
4 " "	less than 1 year

Umbilical and Ventral; 5 cases.

Of these 2 were not traced, 2 relapsed after operation, and 1 was reported well after 2 years.

Summary of Results:

Bassini's method: 257 cases; 249 traced; 1 death (pneumonia).....	2 relapses
Cord not transplanted 13 cases; 11 traced; 4 "	
Femoral 15 " 14 " no "	
Umbilical and ventral 5 " 3 " 2 "	

In compiling these statistics 20 cases have been added in which operation was performed between June 1st and October 1, 1897. It has been stated by some writers, especially by Kocher, that operations upon children do not afford a good test of the value of Bassini's method. I will simply say that in my cases in patients over fourteen years of age, 150 in number, this method was most frequently employed, and the results were almost if not quite as good as in children; there was no mortality and but two relapses.

CLINICAL MEMORANDA.

CASES OF PARALYSIS OF SOME OF THE OCULAR MUSCLES.

By CLARENCE A. VEASEY, M.D.,
OF PHILADELPHIA;

ADJUNCT PROFESSOR OF DISEASES OF THE EYE, PHILADELPHIA
POLYCLINIC; DEMONSTRATOR OF OPHTHALMOLOGY IN THE
JEFFERSON MEDICAL COLLEGE.

THE following cases of paralysis of some of the ocular muscles, taken from my private records and from those of the Ophthalmic Department of the Jefferson Medical College Hospital (service of Dr. Geo. E. de Schweinitz), are reported, not because of any unique features in their symptomatology but because they are fairly illustrative of some of the causes which occasionally give rise to this condition and of the means adopted for its relief.

CASE I. *Oculomotor Paralysis Associated with the Appearance of the Menstrual Function.*—H. S., female, aged fifteen years, was referred to me by Dr. A. F. Allman, under whose care she had been during a short time only, for partial left oculomotor paralysis, which had existed fourteen months. At the time of my examination, the eyeball was turned outward and downward and the greatest exertion failed to move it in the slightest degree upward or inward. The lids had been entirely closed during the first few weeks after the appearance of the paralysis. The upper lid could be elevated about one-third of the usual distance. There had also been moderate dilatation of the pupil and paralysis of accommodation, but both had regained their normal

condition. Diplopia and the altered carriage of the head was still present. A high compound hypermetropic astigmatism existed, for which she was wearing proper correcting lenses.

The paralysis came on very gradually, about five days elapsing between the first appearance of diplopia and the complete loss of accommodation and drooping of the upper lid. Two weeks after the beginning of the ocular symptoms, menstruation appeared for the first time and was exceedingly scant in quantity, the patient having been in ill health (presumably on this account) for four weeks. Rapidly increasing doses of potassium iodid, and later, galvanism, strychnin, and pilocarpin were administered. Under this treatment the lid regained most of its power and some of the strength of the ocular muscles returned, but not enough to do away with the diplopia and the disfiguring squint. Orthoptic exercises were faithfully employed and during several weeks the patient wore a shield over the unaffected eye, thus compelling the use of the paralyzed eye, but no improvement was observed from either of these measures.

It was then thought best to attempt some operative procedure, one and one-half years having elapsed since the beginning of the paralysis, and the chances of improvement being fairly stated, the advice was accepted. A 20° prism, with the base toward the nose, over the right eye, and a 33° prism, with the base upward, before the left eye were required to produce single vision. The external rectus muscle of the affected eye was first divided, and this correcting only a small amount of the deviation, tenotomy of the external rectus of the right or unaffected eye was next performed. After healing, there were required, to fuse the images, a 2° prism, with the base inward, over the right eye, and a 20° prism, with the base upward, over the left eye. The inferior rectus of the left eye and the superior rectus of the right eye were next divided at different sittings. The result is even better than had been anticipated as the eyes are now straight and the diplopia entirely relieved for the central portion of the field, though the poretic muscles are, to be sure, somewhat deficient in power.

CASE II. *Paralysis of the External Rectus Produced by Exposure to the Weather.*—A. C., female, aged forty-two years, presented herself at the Jefferson Medical College Hospital complaining of double vision which had been present eight weeks. A previous attack of diplopia had occurred two years before and after a few weeks had disappeared without treatment. On this account she had failed to seek advice for the present condition until it had existed eight weeks.

There was marked diplopia, with altered carriage of the head, false projection of images and a slight convergent strabismus which increased somewhat when the patient became excited. Specific history was denied, but formerly there had been excessive use of alcohol and of snuff. Two days before the present attack she had been exposed for a long time to the weather, the day being cold and rainy. This exposure seems to have been the undoubted exciting cause of the paralysis, probably giving rise to an exudate which pressed upon the sixth nerve

somewhere in its course between its exit from the base of the brain and entrance into the muscle.

The paralysis entirely disappeared under the administration of rapidly increasing doses of potassium iodid.

CASE III. Congenital Paralysis of the External Rectus.—C. T., male, aged forty-six years, complained of inability to turn his left eye outward beyond the median line, a condition which had existed since birth. Diplopia had never been observed and there was no altered carriage of the head or false projection of images. There was, however, a marked deficiency in the converging power, the eye rotating not more than 15° inward. The inward movement of the right eye was also somewhat impaired. The visual acuity was normal and there were no lesions of the fundus.

It is impossible to determine by examination during life the exact cause of the trouble in these cases. In the present instance there may have been some affection of the nucleus of the nerve during intra-uterine life, or an anomalous insertion of the muscle into the sclera, or even the absence of the muscle itself.

CASE IV. Traumatic Paralysis of the Superior Rectus.—M. B., a widow, aged twenty-one years, fell against the corner of a mantel, striking the left eye through the closed lids. There was considerable pain, but this wearing off after a short time she thought no more of the accident. A few hours later, however, she noticed that she saw double. The diplopia continued to grow worse and she was annoyed very much by the false projection of the images and continued dizziness during attempted employment of the eyes. This condition continuing for a week she presented herself for advice.

Examination showed a slight discoloration of the upper lid where it had been bruised. The upward movement of the left eye extended but a short distance above the normal level of the eyes when looking directly in front. Diplopia began as the test object was brought near this level, was crossed, the image seen with the left eye being somewhat higher than that seen with the right, and the lower end of the false image was slightly inclined toward the real image.

The same treatment as described in the other cases was employed, but after several months there remained a slight vertical diplopia, for which the patient is now wearing with absolute comfort a 5° prism divided between the two eyes.

The patient evidently had had a small hemorrhage somewhere along the orbital portion of that filament of the third nerve supplying the superior rectus muscle which was not entirely absorbed, or which being absorbed, left its impress, as it were, upon the nerve fibers so that they could not regain their original power of transmission.

CASE V. Oculomotor Paralysis Appearing During an Attack of Influenza.—A. H., female, aged sixty-five years. The patient first noticed diplopia and drooping of the upper lid of the right eye on the third day after the beginning of an attack of influenza. Three days later the ptosis was complete, and the external ocular muscles supplied by the third nerve were completely paralyzed. The accommodation of the eye was unaffected. Upon ele-

vating the upper lid of this eye, marked divergent strabismus was observed. The same treatment employed in the other cases was used. As the patient was brought to the hospital for consultation only, remaining under the care of the family physician, no subsequent history was obtained.

A CASE OF DOUBLE HARE-LIP.

By JOHN A. WYETH, M.D.,
OF NEW YORK.

THE child whose pictures accompany this article was brought to me when three months of age. He presented an extremely bad form of double hare-lip with complete cleft of the bony and soft palate. The vomer was unnaturally long, and the premaxillary bone, which pro-

FIG. 1.

Showing appearance of child previous to operation.

jected from the end of the vomer was covered by a little peninsular of integument which was continuous with the end of the nose, to which it was attached by a small pedicle.

FIG. 2.

Showing appearance of child just after the operation, as well as silk-worm-gut anchor.

As it was impossible to save the premaxillary bone and carry it into a position to complete or perfect the anterior

arch of the alveolus, I removed this bony process, taking great care to dissect up and preserve the little particle of integument covering it, which I used in making the septum of the nose.

It was also necessary to cut away about one-half inch of the vomer, which being done, I was enabled to so fashion the lip on either side of the fissure that by free dissection of the tissues from the maxillæ the denuded edges were brought together, as shown in Figs. 3. Silkworm-gut sutures were used, as well as the silkworm-gut anchor,

FIG. 3.

Showing appearance of child two weeks after the operation.

Fig. 2, which I employ in all these operations. This feature of the method is, in my opinion, essential to success.

The sutures were removed on the tenth day and the child recovered without any interruption. The interval between the pictures Nos. 1 and 3 was two weeks.

HOSPITAL REPORT.

TREATMENT OF TYPHOID FEVER IN ROOSEVELT HOSPITAL,

By W. H. THOMSON, M.D.,
OF NEW YORK:

VISITING PHYSICIAN TO NEW YORK, BELLEVUE, AND ROOSEVELT HOSPITALS.

FOR a number of years my autumn service at the Roosevelt Hospital has included the months of September and October, the time during which typhoid fever is most prevalent in New York City. An exception, however, must be recorded for this year, 1897, as the patients with typhoid fever admitted during the months mentioned were but half the usual number.

In discussing the various modes of treatment recommended for this affection, it is too often the custom to rely upon the mortality percentage as affording the chief indication of the success of the method employed. In hospitals, however, this may be quite misleading; because, if the course of this prolonged fever can be advantageously modified by any particular line of treatment, then the earlier it can be resorted to in each individual case the better will be the result. In hospitals a large

proportion of the patients are not admitted until after they have been ill for a considerable time, and are then brought to the institution as a last resort. Under such circumstances it is plain that the rate of mortality would scarcely afford a fair criterion of the efficacy, or the reverse, of any form of treatment.

A much more trustworthy indication as regards the effects of treatment in a hospital is the actual percentage, in the non-fatal cases in a given series, of the occurrence of certain prominent symptoms which are characteristic of the course of typhoid fever, either when left to itself or when treated more or less according to what may be termed the expectant method. In the following observations I have, therefore, selected for comparison the percentage, among 69 patients who recovered from typhoid fever, of the occurrence of diarrhea, tympanites, delirium, and hemorrhage: The total number of patients with this disease admitted to my wards during September and October of 1895, 1896, and 1897 was 75, of whom 6 died, or 8 per cent. An analysis, however, of the histories of these fatal cases shows how little they can be considered as regards the question of treatment.

Of the total number, 50 cases occurred in males and 21 in females. Of the males, the youngest was 7 years old, the oldest 57; 4 patients were under 10 years of age, 15 between 10 and 20, 33 between 20 and 30, 21 between 30 and 40, and but 2 were over 40 years of age.

Diarrhea.—Among the 69 cases in which recovery occurred diarrhea was present on admission to a marked degree in 13, and moderately so in 2. In all of these cases it ceased within a week, except in one, that of a woman, in whom it continued until the fortieth day. Subsequent to admission diarrhea occurred in 5, but was moderate in each, and ceased within from three to five days. Hence, in a total of 69 cases, only 5, or 7 per cent., had any looseness of the bowels after beginning treatment, and none required special medication for it.

Tympanites.—This was present on admission in 11. In each it disappeared within five days after beginning treatment, except in one case, in which it continued nine days. In one case, admitted on the sixth day of the disease, it developed moderately two days later, coincident with a high temperature, and then ceased within five days. Thus, out of 69 patients, there was only 1 who developed this symptom after admission.

Delirium.—This symptom was noted in 11 patients, but of these, 9 were delirious on admission. The remaining 2 had delirium after beginning treatment, and it is significant that in each of these it was present only while the use of the cold bath had to be omitted, owing to the occurrence of intestinal hemorrhage. In each it was very moderate, and did not last a week. Of the 9 patients who were delirious on admission, in only 1 case did this symptom continue ten days after treatment was begun. Therefore, out of the total of 69 patients, only 2 became delirious in the hospital, and 58 did not have delirium at all.

Hemorrhage occurred in 4 cases, and in 1 was fairly severe. One of these patients was admitted on the four-

teenth, and 1 on the twenty-first day of the fever. In the first it occurred on the nineteenth and twentieth days, and in the second on the twenty-third and twenty-fourth days of the fever.

Relapses occurred in 5 out of the total of 69 cases.

I think that this showing indicates that the course of this disease was materially altered by the manner in which its common functional derangements were either prevented, or else soon controlled when already present when the treatment was begun; for as just stated, after treatment was started, there were only 5 cases of diarrhea, in each of which it was very temporary, 1 case of moderate tympanitis, and 2 of transient delirium. Similar statistics of the course of typhoid fever under treatment might be collated from the Roosevelt Hospital records for a number of years past, so that the occurrence of such symptoms as sordes, dark, dry tongue, meteorism, diarrhea, delirium, or subsultus tendinum, were but rarely seen, except when already present at the time the patients were admitted to the hospital.

The clinical histories of the 6 patients who died are briefly as follows:

CASE I.—Male, aged seventeen years, admitted on the eighth day of the disease; temperature, 104° F.; pulse, 108; respiration, 36; persistent vomiting. The continued frequency of respirations and the early hyperpyrexia present in this case led to suspicions of pneumonia, but no physical signs of this affection were discoverable until eight days after admission, when consolidation suddenly developed at the base of both lungs, and he died on the following day; no autopsy. This clearly seemed a case of mixed infection from the first.

CASE II.—Male, aged thirty-two years, admitted on the tenth day of the disease; very delirious; temperature, 105.4° F.; pulse, 116; respiration, 28. He became rational nine days after admission, and seemed to be convalescing, when, according to the rule to administer the cold bath on the temperature reaching 103° F. he was having his single daily bath, he suddenly died on being transferred to his bed. Death occurred on the eleventh day after admission. Autopsy showed the intestinal ulcers to be nearly healed, and no other lesion was discovered to account for the fatal issue, which, therefore, may have been due to syncope.

CASE III.—Male, admitted on the eleventh day of the disease, with a very weak pulse, great tympanites, and continuous diarrhea until death which occurred on the sixth day after admission. The peculiarity in this case was that at the autopsy extensive ulcers were found in the large intestine, but none whatever above the ileocecal valve.

CASE IV.—Male, aged thirty-five years, admitted on the sixteenth day, with high temperature, rapid pulse, and noisy delirium. He died on the eighth day after admission.

CASE V.—Male, admitted on the twenty-first day; very delirious, and lived but two days.

CASE VI.—Male, aged thirty-three years, presented a history of having been a hard drinker. His urine was albuminous, with numerous granular casts, and he was threatened with gangrene of the left leg from thrombosis. He finally succumbed with pneumonia and car-

diac symptoms. At the autopsy, besides the intestinal ulcers, evidences of recent endocarditis, bronchopneumonia, and chronic nephritis were found.

Treatment.—The treatment adopted at the Roosevelt Hospital is as follows:

If a patient be admitted before the end of the second week of the disease, 5 grains of calomel and 35 grains of compound jalap powder are administered on three successive nights. The effect of this measure in securing intestinal antiseptics is almost invariable. The temperature drops from one to three degrees on the day following the first dose, and if diarrhea be present, this seems to be the quickest and most effectual means of arresting it. After the eighteenth day of the disease the calomel treatment is omitted on account of the liability, after this time, of intestinal hemorrhage.

The next therapeutic measure is directed to the prevention of tympanitis and pea-soup diarrhea. It seems to me that typhoid fever is too exclusively regarded as an intestinal affection, when in reality the stomach is almost as much affected, with the result that its peptogenic power is more reduced, as Fenwick has shown, in this disease than in any other affection, acute or chronic. In fermentation of the gastric contents begins a disorder which soon results in meteorism and diarrhea. I have therefore, during many years, prescribed 10 grains of saccharated pepsin with 10 grains of carbonate of bismuth to be taken every three hours, making 80 grains of each in the twenty-four hours. The result has been that tympanitis rarely supervenes. Bismuth is the most effective and least irritating of the intestinal antiseptics. If the diarrhea persists it is my custom to double the dose of bismuth. Whenever the tongue begins to be dry at the tip, 15 minims of the oil of turpentine is given in emulsion every six hours. Moderate doses of strychnin and caffeine are sometimes administered for symptoms of cardiac debility, but never digitalis. The compound spirit of sulphuric ether (3i in camphor water) seems the best remedy for restlessness with prostration. Alcoholic stimulants are also employed according to the usual rules.

Owing to the extremely reduced condition of the digestive power, milk, the only diet allowed, is always diluted one-half with lime water, the latter being an antiseptic as well as a diluent.

The cold bath is resorted to as soon as the temperature is above 103° F. The patient is actively rubbed while in the bath, and taken out when the temperature falls to 101° F. It should be emphasized that the cold bath is beneficial in this fever, not simply as an antipyretic, but as an eliminative through the kidneys. The symptoms of this fever are those of toxemia, and the powerful effects of the Brand method in increasing the toxic coefficient of the urine have been amply demonstrated.

MEDICAL PROGRESS.

Present Status of Infant-feeding.—HOLT (*Archives of Pediatrics*, November, 1897) finds that all authorities are agreed upon the following points: (1) Good breast-milk is the best infant food. (2) No substitute for breast-milk

can be trusted which does not furnish essentially the same elements, fat, sugar, proteids, etc. (3) These elements are found only in the milk of other animals, cow's milk being the only one available for general use. (4) Cow's milk requires some modification before it is fed to infants; first, because the proportions of the different elements (fat, sugar, etc.) are not the same as in breast-milk; and second, because some of these elements, notably the proteids, are not identical with those of breast-milk.

Other important questions in connection with infant-feeding are still in dispute. Thus the question of milk sterilization is not agreed upon by all. Holt thinks that milk which is sterilized thirty, sixty, or even ninety minutes at a temperature of 212° F. is not unfitted for infantile digestion. As the keeping qualities are greatly increased thereby, no doubt sterilization and Pasteurization will continue to be used, although the aim ought to be to produce perfectly clean milk, thus rendering sterilization unnecessary. Of infant foods and condensed milk he has little good to say.¹ Within the past few years he has seen nearly twenty cases of scurvy in children who were fed exclusively upon some one of the various patented infant's foods. Those which require the addition of fresh cow's milk are naturally better than those which are not to be mixed with milk. If a food contains a large amount of unchanged starch it is successful in inverse proportion to the amount used. It may serve a useful purpose as a diluent of the milk, and not affect the nutrition of the child one way or the other. Great gain has been made by the establishment of milk laboratories, and by the prevailing accurate knowledge in respect to milk modification. It remains to be seen whether the minute fractions of percentage of the different elements upon which some writers have insisted are really necessary, and whether equally good results may not be obtained with approximate proportions of fats, proteids, etc. The field of infant-feeding is by no means exhausted and will repay anyone who will devote time to its study.

Tuberculosis from Butter.—GRONIG (*Centralbl. für Gynäk.*, September 30, 1897) examined 17 vessels of butter and injected portions of the butter into 51 guinea-pigs. The result was that 11 of the guinea-pigs were found, *post-mortem*, to present the pathologic appearances of tuberculosis. Of these 17 specimens of butter 8 produced tuberculosis. Unfortunately the diagnosis was not confirmed by culture, inoculation experiment, nor was a histologic examination made to determine the character of the lesions.

OBERMULLER examined 14 specimens of butter, injecting 5 or 6 animals with them, and found tubercle bacilli in every case. Here again, neither culture nor inoculation experiments were made to control the diagnosis. It is only fair to state that in this case all the specimens of butter were obtained from the same source, and one which had previously been determined by the milk supply to be tuberculous.

RABINOWITSCH examined eighty specimens of butter from various sources, and in no instance were tubercle bacilli found.

PETRI says he has tested one hundred samples of butter, and found tubercle bacilli in thirty per cent. of them. In sixty per cent. of all the samples he found bacilli which might easily be confounded with tubercle bacilli. The question evidently requires further investigation.

The Use of the Phonendoscope in Surgery.—VAN ARSDALE (*N. Y. Polyclinic*, August 15, 1897) praises the use of the phonendoscope in surgical diagnosis. In the case of a broken bone, over which a scratching noise is made, the instrument will detect the difference of such a noise from one made over a bone which is uninjured; as, when a fracture is present, the break in the bone obstructs the passage of sound, and again, the presence of soft tissue between the ends of a broken bone may be detected in the same manner. He has found this instrument to be of great value in the study of aneurism, in the diagnosis of the extent of tumors the density of which is different from that of surrounding tissues, in the detection of the presence of small quantities of fluids in the joints, and especially in the diagnosis of abdominal tumors. He employs a phonendoscope which is fitted with a pin so that the sound is received upon a very small point. The ease with which the colon and intestines may be located and traced appears to be one of the great advantages of the use of this instrument. By means of different notes transmitted through it the author was enabled to locate a growth of the colon which could not be detected by the ordinary methods.

THERAPEUTIC NOTES.

Palpitation of the Heart.—HUCHARD (*Wien. Med. Blät.*, July 15, 1897) for purposes of treatment divides cases of palpitation of the heart into those varieties which are, and those which are not, benefited by cardiac stimulants. Those cases arising from the ingestion of poisons, coffee, tobacco, and drugs, such as sulphate of quinin, are usually relieved by a removal of the cause. Palpitation due to gastro-intestinal disturbance, usually occurs at night, and is associated with dyspepsia and hyperacidity. For the most part these attacks may be cured by large doses of alkalies, and regulation of the diet. Iron, if taken in too large quantities, may also produce palpitation.

There is no necessary connection between cardiac palpitation and cardiac disease. The diseases usually accompanied by palpitation, and which are improved by digitalis and similar remedies are beginning aortitis, acute endocarditis and pericarditis, adhesions of the pericardium, and mitral insufficiency. In such cases the following prescription will often be found useful:

R	Quiniae hydrobrom.	.	.	.	gr. lx
	Digitalis	.	.	.	gr. xxx
	Ext. convallariæ	.	.	.	gr. xxx.
	M. Ft. pil. No. xl.				

Sig. Two to four pills daily.

For Infantile Constipation.—CARRIERE (*Bull. Gen. de Therapeut.*, August 20, 1897), in speaking of infantile constipation, says that the alimentation should first be attended to. If the child is on the breast, the number of nursings is probably at fault; or, it may be necessary to prescribe

exercise for the mother. At the period of weaning arrow-root and other preparations of a somewhat laxative character will be of service. A little soup, preferably that of chicken, with tapioca, or bits of bread, may also be given. In other cases, massage, laxatives, or suppositories may be employed. Massage is practised as follows: Every morning the palm of the hand is oiled with vaselin, and with it circular motions are made around the umbilicus, beginning in the right iliac fossa. The pressure should be light, and the whole treatment should not exceed ten minutes. After the first year the massage should follow the course of the large intestine. As laxatives, the author recommends castor oil and magnesia. In order to secure an immediate evacuation injections or suppositories may be used. Injections should not be larger than 2 ounces during the first six months, and 4 ounces after the first year. Boiled water, a weak solution of camomile, or water with a spoonful of oil of sweet almonds may be used.

The Treatment of Burns.—WERNER (*Phila. Polyclinic*, October 30, 1897) advises the following simple and at the same time rational rules for the treatment of burns of the third degree: (1) Place the burned member or surface in a carbolized bath of from two to five per cent., depending upon the age of the patient and the extent of the injured surface. A threefold effect is gained by this, *viz.*, antiseptis, aseptis, anesthesia. (2) Remove all the carbolie solution by a second bath in a physiologic saline solution. (3) Dust the entire surface with a powder containing acetanilid (1 part) and compound stearate of zinc (5 parts). (4) Cover the surface with narrow strips of Lister's green protective, or, if economy must be studied, with thin gutta-percha tissue. (5) Place ten to twenty thicknesses of wet sublimated gauze over and around the surface, and bandage.

The dressings should be changed as often as necessary. The advantages of this treatment over that by lotions, oils, and salves, are freedom from any accumulation of fats or dead epithelium, encouragement and protection of the new epithelium, and finally, almost the entire absence of fibrous tissue in the cicatrix, and avoidance, therefore, of resulting deformities.

A Treatment of Uterine Colic.—AUDERBERT (*Bull. Gen. de Therapeut.*, August 23, 1897) objects to the customary treatment of uterine colic by means of ergot or intra-uterine injections. Both methods are ineffectual and may be dangerous. As a curative treatment tincture of opium in 15-drop doses per rectum is most to be recommended. This usually succeeds in relieving the colic, but of course it is a little constipating, to avoid which chloral, bromid of potassium, or antipyrin may be substituted. The extract of viburnum prunifolium, either alone or in combination, possesses a marked sedative action. Twenty drops of the following mixture may be given every two hours in a warm drink:

℞ Ext. viburn. prun. fl. }
Ext. hydrast. canad. fl. } aa . 3 iv — m.

If the colic is due to fecal or urinary retention the

bladder and rectum should first be evacuated, and then, between the pains pressure should be made upon the uterus to facilitate the expulsion of clots. Vaginal injections at a temperature of 115°–120° F. act in the same manner. If these measures are not successful in emptying the uterus intra-uterine injections may be employed with care and a low pressure. On account of their danger they should only be used when other remedies have failed.

Nervous Vomiting.—MEISL (*Ther. Woch.*, September 19, 1897) says that nervous vomiting produced by disturbances of the nervous system, both central and peripheral, without external irritation or anatomic lesion, is a purely functional disorder; it occurs without any over-exertion and is independent of the quality and quantity of the ingested food. It varies in relation to the different kinds of diet, and is often absent when particles difficult of digestion have been eaten, and may be present when only suitable food has been taken. For treatment he recommends the following:

℞ Menthol gr. i
Sodii bicarb. gr. c.

M. Ft. in caps. No. xii. Sig. One capsule three times a day.

In severe cases it may be necessary to give suppositories, each containing $\frac{1}{2}$ grain of belladonna and $\frac{1}{2}$ grain of codein. Oxalate of cerium, preparations of bismuth, and alkalies in large doses are also recommended. In the painful form papayotin renders good service. It is given in combination with soda. With some patients the painting of the pharynx with a ten-per-cent. solution of cocain results in a cure. Treatment directed to the strengthening of the body will be of help in all instances.

The Treatment of Whooping-cough.—WERTHEIMER (*Ther. Monatshefte*, September, 1897) lays great stress on the dietetic and hygienic treatment of this disease. He objects to the use of morphin, because if given in doses sufficient to have any effect it leads to a retention of secretion in the lungs which may result disastrously. Bromoform has proved valueless in his hands. He has seldom used quinin. He advises, however, a mixture of belladonna and ammonia bromid, as follows:

℞ Ammonii bromidi gr. xviii
Ext. belladonnæ gr. ⅔

Div. in chart. No. xii. Sig. One to three powders daily.

He especially recommends the use of antipyrin in doses of $\frac{1}{2}$ grain for children under one year of age. It should be ascertained that the kidneys are sound before this drug is administered. In order to enable the child to get rid of the thick mucus, alkaline mineral waters should be given during the course of the disease. There is no such thing as reliable local treatment. This writer finds that children under one year of age have whooping-cough as frequently as older children, and that in them it is more dangerous.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, DECEMBER 18, 1897.

THE PRESIDENT'S MESSAGE TO CONGRESS AND NATIONAL QUARANTINE.

THE President in his Message, and the Secretary of the Treasury in his annual report, show a lively appreciation of the defects of our quarantine laws. Both recognize that their inefficiency is due to lack of uniformity and cooperation.

The Secretary recommends that the law of 1893 be amended so that National quarantine regulations shall everywhere prevail, and that local interference with them shall be impossible. This law should also be so amended that the Secretary of the Treasury may promptly establish a quarantine station whenever or wherever public safety demands it, without regard to State or local establishments or authorities.

The President sees in the Marine Hospital Service the proper agent for putting these ideas into effect, and recommends that its powers be sufficiently enlarged to accomplish these ends, *viz.*: that the functions of National quarantine and the supervision of the Public Health be delegated to the Marine Hospital Service.

Insecure tenure of office is a serious, if not fatal, weakness of State or local quarantine. Subject to political changes, or even hasty popular whims,

how can any one expect that officials, under such circumstances, will be thoroughly efficient.

The defects of this system have just been glaringly demonstrated in Louisiana, where the officers of the State Board of Health, probably as efficient as any, have been compelled to resign by an outburst of popular clamor.

Quibble as they may over invasions of State rights, it is about time for the people to perceive that, in some matters, Federal authority must be supreme, and one of these is the protection of the country from alien disease and the management of epidemics when such occur. If to these powers could be added authority to compel municipalities to adopt modern sanitation, the situation would be quite ideal.

SIX-DAY BICYCLE RACES.

"THE six men whose brains have given away to this terrible strain are among the leaders in the van, and it is the efforts that they have put forth to hold their coveted positions which have cost them their sanity. These men are fit for little else than a ward in a lunatic asylum."

This is quoted from an evening newspaper's description of the closing scenes of a six-day bicycle race that has just been held in the most civilized center of the Western Hemisphere. It furnishes food for serious reflection. That a people who decry cock fighting, dog fighting, and even "ratting" for amusement, and who are horrified beyond expression and tolerance at the thought of an encounter between a toreador, a few banderilleros and a bull, should permit one of the most harrowing spectacles than can be imagined to continue without protest, or indeed refrain from taking matters into their own hands and stopping it *tour de force* is cause for wonderment.

The physiologic and psychic incidents of the race have a lively interest for the alienist who sees in it the corroboration of an experiment in the artificial production of insanity made some time ago by Mendel of Berlin. This savant showed that if animals, rabbits let us say, were placed on a flat surface, and the surface caused to rotate continuously a number of times per minute during a few days, the animals would develop all the physical manifestations of general paresis. The experiment as performed

by Mendel had serious limitations which heretofore have seemed impossible to overcome, but now the winners in a six-day bicycle race have lent themselves to a repetition of the experiment, and the results may be utilized to corroborate Mendel's statements. In reality, going around the short circular track in the Madison Square Garden is practically the same as being whirled on a revolving table, save that there is added thereto the element of physical effort and consequent physical exhaustion. It is interesting, therefore, to note the symptoms of disordered mind which have been engendered in the six men who have been adjudged insane by the secular press. These symptoms seem to be irascibility, unamenability to suggestion and control of "keepers and trainers," visual and auditory hallucinations, delusions of persecution, and of being poisoned, fighting mania and dementia. One man's mind is "a complete blank." It is difficult "to restrain another from getting over into the boxes and attacking the spectators." Aside from the fact that the latter richly deserve the most summary punishment which could possibly be inflicted upon them for being present at such a disgraceful exhibition, it is to be noted that it was not this laudable object that prompted the rider to belligerency, but a conviction that those in the boxes were persecuting and conspiring against him.

We have not been sufficiently apprised of the physical signs which the participants showed to guide us in making a differential diagnosis, or even a diagnosis at all of the riders' insanity, although tremor, incoordination, and a degree of motor paresis seem to have been among them. Acute confusional insanity caused by exhaustion and rotation seems to approach nearest the mark.

Fully realizing the futility of words to prevent a repetition of one of the most disgusting, demoralizing, and pernicious contests parading in the guise of "sport" known to humanity, we are inclined to propose a plan which, if put in operation, will quickly terminate it. When the time for the next yearly exhibition comes around, let it be made known that a certain number of contestants are to be entered with a view of determining, by a commission appointed for that purpose, how quickly the sanity of the riders can be overthrown, and the form that the alienation which it produces assumes. In other words, let us have a vivisection experiment

on a colossal scale, without anesthetics, and with human beings for subjects. In order to insure the realization of the success of the experiment, we would suggest that the track be shortened, to make a greater number of laps to the mile, not with dishonest intent, as it is alleged was the case this time, so that new records might be established, and the necessary impetus given to promoters to get up a new "contest," but that the experiment may parallel more closely that of the Berlin professor. It might be advisable, moreover, to utilize the center space enclosed by the track by setting up a number of tables, revolved by machinery, on which the same number of men as there are bicyclists may be strapped and revolved as many hours per day as their fellow-victims are kept on their wheels. Then the two sets of mentally dethroned beings may be contrasted and compared, and thereafter the most fatal form of "sport" enjoyed more fully.

We feel convinced that one trial of this will so eradicate six-day bicycle races from the program of sports that they cannot be resuscitated as long as the memory of the present generation continues.

THE NEW YORK BOARD OF HEALTH AND PULMONARY TUBERCULOSIS.

THE history of the movement which led the New York Board of Health to classify pulmonary tuberculosis among the communicable diseases, and to render compulsory the report of instances of this affection occurring in private and public practice, was reviewed in *THE MEDICAL NEWS* of February 20, 1897. A few weeks later, *THE NEWS* took occasion to defend the action of the Health Board in its effort to limit the spread of this most ravaging of all human diseases, and to urge upon the profession the desirability and the necessity of sustaining the Board in its work against the common enemy. At this time, when a committee of the Medical Society of the County of New York is considering the legality of much of the work in which the Board of Health is engaged, and when the Board of Estimate has allowed the Health Board \$60,000 for its care of consumptives for the year 1898, the special report to the Mayor, reviewing the history of its action in relation to tuberculosis of the lungs, is interesting and instructive.

Sanitary authorities and bacteriologists, as well as clinicians, have held during some years that the

transmission of pulmonary tuberculosis is by means of the sputum, which, becoming dried after expectoration, circulates as dust. Though there are a few dissenters from this view, we will assume, *causa loquendi*, that this is a scientific truth. It must be further agreed that the danger of close association with consumptives lies mainly in the improper disposal of the expectorated matter, by allowing it to become circulated in the atmosphere rather than destroyed by means of incineration, the use of antiseptics, or by boiling it or the material in which it is contained. In its report the Board of Health announces that it is on the premises above deduced that its action in relation to tuberculosis is based. It substantiates this position by the authority of its pathologists, consulting pathologists, and by numerous citations from French, American, and German writers of eminence. It proves beyond cavil that the position it has assumed as to the manner of the extension of phthisis is scientifically correct, and in doing this it has overcome possible prejudice by deducing incontrovertible evidence from several sources outside of its own bureau. The next logical step in the process consists in proving that, with proper assistance on the part of practising physicians, pulmonary tuberculosis can be stamped out or exceedingly limited. We learn from the report that since the Board of Health has investigated the reported cases of consumption (1893 to 1896), the death-rate from tuberculous diseases has decreased 12.8 per cent., and that from phthisis alone 11.3 per cent. That this is not mere coincidence is proven by a perusal of the other vital statistics contained in the report, which show that the number of deaths annually occurring from tuberculous diseases increased or remained at about the same figure for many years previous to the beginning of the official inspection. It must be remembered that this represents but the very beginning of the crusade against consumption, and the report gives evidence of what may be accomplished in the prophylaxis of this disease by citing Flick ("The Prevention of Tuberculosis"), who shows that through legislative enactment tuberculosis of the lungs has practically been banished from the Kingdom of Naples.

The report further contains interesting tables of the distribution of tuberculous diseases in the two

most crowded tenement districts of New York City, the Fourth and Sixth Wards. From these tables the inference is made that even where tuberculosis occurs most frequently it is not uniformly distributed, but appears to be confined within narrow boundaries in certain streets and in certain houses; that prolonged exposure to the atmosphere of the infected rooms is a source of danger, and that proper sanitary measures rigidly enforced will lessen this danger. These measures are of course, inspection, disinfection of rooms, clothing, and bedding, the destruction of the bacilli in the sputum, and the isolation of cases when the necessary hygienic directions cannot or will not be enforced.

The educational work accomplished by the Department cannot be doubted by any one who comes into frequent contact with the tuberculous poor of the city. Although many of the more ignorant of them believe consumption to be directly contagious, this kind of ignorance does no harm, for it makes the patient more careful than he might otherwise be. The more intelligent, on the other hand, seem to be fully alive to the dangers lurking in their sputa, and use every means suggested to prevent the contamination of their neighbors. It may be said that such instruction should issue from the attending physicians, hospitals, dispensaries, etc.; but, as a matter of fact, it is well established that this information was never given to phthisical patients by hospital and dispensary physicians until the initiative was taken by the Board of Health, which has educated the physician in this respect as well as the patient.

The relations which the Department desires to hold toward the profession is tersely but emphatically stated on page seven of the report. The Board has no desire to interfere with the treatment of cases already attended by a physician, whether in a private or tenement-house; it will send no inspector if the attending physician so desires; it will send no circulars of information if the physician in charge will agree to deliver them, or, we are willing to assume, if he will orally deliver the hygienic information and prophylactic data contained in the circulars. Upon the following the Board of Health insists: That all cases of tuberculosis of the lungs shall be reported to its Sanitary Bureau. It is scarcely asking too much of the physicians in this

city to direct a postal-card to the Health Department announcing the discovery of a case of phthisis and stating that all essential hygienic directions and measures are being carried out. Reliance upon the integrity of the Department not to interfere with the treatment or direction of the case need hardly be doubted; for its honest intentions have been demonstrated too frequently in the conduct of contagious diseases to require further comment. Moreover, such reports as those mentioned can be of assistance to the Board in increasing its information in regard to the extent and distribution of the disease in question. A certain amount of arbitrary power must, finally, be conceded to a body possessing such inherent responsibilities as the Board of Health.

So far as the appropriation of \$60,000 for the care of indigent consumptives is concerned, there can be no moral or political objection to it. The greatest authorities, some of whom are cited in this report, are agreed that the most efficient treatment of pulmonary tuberculosis is to be obtained in sanatoria. The well-to-do can afford the luxury of such resorts; but the pauper who is afflicted with consumption has no such place to which he can go. The general public and private hospitals will not receive him, and he must, perforce, remain in his miserable dwelling, a constant source of danger to his companions and even to himself. The Board of Health, we assume, has no intention of assigning its own physicians to the treatment of these cases; indeed, by the action of the Board of Estimate, it is stipulated that the money granted be expended in hospitals already existing which have, of course, their attending staffs. The very poor who will avail themselves of this appropriation would never come under the professional care of a physician in private practice, and therefore, no one, as far as we can perceive, can be injured by this measure. The patient only will be the gainer. Since the city has established special hospitals for the treatment of scarlatina and diphtheria, it is to be hoped that in time it will awaken to the fact that tuberculosis is more fatal than these, more widespread, more ravaging, and demands a hospital devoted solely to its treatment.

Space forbids our going into further details. We would like to speak of the benefits accruing from the official examination of cows and of milk as having

lowered, or having a tendency to lower, tuberculous infection. We would like to go into detail concerning the regulation of expectoration in public places and in public conveyances, a regulation altogether too laxly enforced by the employees of the railroad companies, and a neglect which should be promptly corrected. But these and kindred subjects are a little foreign to our purpose, which has been to show that the position of the Board of Health in its action concerning pulmonary tuberculosis is an honest one toward the community and the medical profession, and that it deserves the cordial support of both.

ECHOES AND NEWS.

Bubonic Plague in India.—Telegraphic news from Bombay reports the bubonic plague still raging at Poona.

Maidstone Typhoid Epidemic.—Up to the first of December the cases of typhoid fever reported at Maidstone, England, numbered 1871.

A Medical Diplomat.—Dr. G. H. Bridgman of Elizabeth, N. J., has been appointed Ambassador and Minister Plenipotentiary to Bolivia.

Tennessee Medical College.—The building of the Tennessee Medical College, at Knoxville, Tenn., was destroyed by fire on the third inst.

Dartmouth Medical College.—The one hundredth annual graduation exercises of Dartmouth Medical College, Hanover, N. H., occurred on November 24th.

University of Chicago and Rush Medical College.—Negotiations are said to be under way looking toward the affiliation of the University of Chicago and the Rush Medical College.

Tuberculosis Hospital for Hamburg.—An unknown benefactor of Hamburg, Germany, has donated 250,000 marks for the purpose of erecting a hospital to accommodate one hundred patients suffering with tuberculosis.

A Doctor as Mayor-Elect of Buffalo.—Dr. Conrad Diehl, recently elected Mayor of Buffalo by a large majority, takes office on January 1, 1898. Dr. Diehl has practised medicine in Buffalo for thirty years, and is well known to the profession and general public.

Dr. Roswell Park.—According to the *Buffalo Medical Journal*, Dr. Roswell Park, who went abroad in search of health, is reported by a friend, who met him recently in Italy, to be in a very much improved condition and expecting to return to his professional duties in the near future.

Sanitarians and the Palace of Versailles.—According to the *Scientific American*, a sanitarian who visits the palace

of Versailles should never inquire about the arrangements pertaining to hygiene and sanitation. In its palmy days it possessed only a single bathroom, which was never used, and its present facilities are no better.

The Late Dr. Harrison Allen.—At a meeting of the Philadelphia Neurological Society, held November 22, 1897, resolutions were passed offering sympathy to the family of the late Dr. Harrison Allen, and expressing a sense of the great loss to science and the medical profession sustained by his death.

Medical Signers of the Declaration of Independence.—According to the *Charlotte Medical Journal* five practitioners of medicine signed the Declaration of Independence: Benjamin Rush of Philadelphia, Lyman Hall of Georgia, Oliver Wolcott of Connecticut, Josiah Bartlett and Matthew Thornton of New Hampshire.

Four Babies at a Birth.—A young woman, twenty-eight years of age, recently gave birth in New York City to three healthy boys, whose combined weight was nineteen pounds. Thirty-six hours later a fourth child was born. The last died shortly after birth, but the three boys are thriving. The mother is doing well.

City Aid to New York Charities.—In accordance with an opinion rendered by the Corporation Counsel the Comptroller is sending out letters to all charitable organizations which have received public aid through mandatory legislation, to the effect that their claims for support will hereafter be considered on their merits only.

A Correction.—In the article on the "Thyroid-gland Treatment of Cretinism," by Samuel H. Friend, M.D., of Milwaukee (issue of December 4th), the weight of the brain should have been given as 50 ounces (1548 grams, not grains), and the weight of the thymus gland should have been $2\frac{1}{8}$ ounces (64 grams, not grains).

Measles in Springfield, Ohio.—An epidemic of measles is prevailing at Springfield, Ohio. Owing to the negligence of parents and of physicians in not reporting cases, the spread of the disease is now beyond control, and about twenty-five new cases are reported each day. Over 1182 cases have been recorded to date. But one death has occurred.

Illinois Board of Health and the Bone-setter.—The State Board of Health has notified Atkinson, the "bone-setter," that he will not be permitted to treat patients publicly or privately in that State. In this respect Illinois has shown more energy than was manifested by the authorities when this same man was giving public demonstrations in New York City.

Medical Victims of Yellow Fever.—During the recent epidemic of yellow fever in New Orleans, twelve physicians were stricken with the disease, and two of them died. The same number of trained nurses were also attacked, but all recovered. The two physicians who succumbed to the disease were young men who had not lived long in New Orleans and were unacclimated.

Belladonna and Strychnia Pills Cause Death.—A woman recently died in Brooklyn, N. Y., after taking a number of pills containing belladonna and strychnia. The woman, who was suffering from indigestion, received the pills from a young woman employed in a wholesale drug-house in New York City, and was told by her to take one after each meal. Death was due to an overdose.

Vaccination War at Atlanta.—The large negro population of Atlanta, Ga., is fighting vaccination, and armed policemen are detailed to protect the physicians who are attempting to carry out the law in regard to compulsory inoculation. In several instances it has been necessary to resort to force, and in many cases the negroes disappear and remain away from home for weeks in order to evade the law.

Anthrax among Tanners.—An outbreak of anthrax has occurred among the tanners employed by the Elk Tanning Company at Williamsport, Pa. The disease has been contracted by handling hides, and the men have refused to continue work, in consequence of which the tannery has been compelled to shut down. Two deaths had occurred up to the 9th inst., and the condition of a third patient has been pronounced hopeless.

Pedlers and Eye-glasses.—The Mayor of Buffalo, N. Y., will not permit the sale of spectacles in the street by vendors, and every license granted to a pedler bears the clause: "No eye-glasses are to be sold under this license." The Mayor very properly holds that he has the power to forbid the sale of spectacles on the ground that the eyes not being scientifically tested before purchase, great injury might result to the purchaser.

Paterson's Epidemic of Typhoid.—Up to the 10th inst., ninety-nine cases of typhoid have been recorded in Paterson, N. J., and numerous cases have been reported in Jersey City, Newark, and the surrounding country. The wide dissemination of the disease, which originated in the family of the owner of a large dairy, shows that some amendments to the health laws of the State are required. The New Jersey State Board of Health is in favor of a law which will compel physicians to report all cases of infectious or contagious disease in city and country.

Report of Bubonic Plague in Cuba.—A recent despatch from Cuba to the secular press announces the presence there of the bubonic plague, saying that children and the aged are both attacked. Sanitary Inspector W. F. Bruner, United States Marine Hospital Service, announces that the disease reported as bubonic plague is beri-beri, which he states was until recently confined to the Chinese population, but is said to exist to some extent among the natives of the lower classes. He has not observed the disease except among Chinamen.

Typhoid-fever Epidemic at Lynn, England.—The present epidemic of typhoid fever at King's Lynn and the investigation of its water-supply recall the fact that in 1423 the lack of drinking-water caused such distress that Henry VI. gave powers to cut a canal to Gaywood River, the water

of which was considered to be very pure. Under Cromwell the water-canal was carefully cleaned out and a larger supply provided for. Strange to say, the keepers of ale-houses alone were made to pay for this improved water-supply, thus making the consumption of alcohol promote the cause of temperance.

Abdominal Hysterectomy.—In its report of a recent meeting of the Obstetrical Society of London, *The Lancet* says that Dr. Heywood Smith, in discussing the treatment of myoma of the uterus, referred to a paper which he had read in 1892 on subperitoneal treatment of the stump after hysterectomy, which he contended described the operation better than the term "intraperitoneal," and in which he mentions cases done by Goffe of New York and Milton of Cairo, as well as some by himself. He expressed his gratification that the most advanced operators were pursuing that method to the exclusion of the *serre-nœud*, oöphorectomy, and so-called panhysterectomy.

The Responsibility and Annoyances of Surgery.—Dr. Nicholas Senn of Chicago has been served with a writ compelling him to testify in a suit which is being brought in Galena, Ill., by a young woman against two physicians living in that vicinity. Some time ago the two physicians performed an operation for appendicitis on the young woman, and it is alleged she was told that the appendix was removed. Her condition became worse, however, and she went to Chicago, where Dr. Senn performed another operation, whereby the appendix was removed. When Dr. Senn was first summoned he telegraphed that he was unable to leave his practice, but said he would send a deposition. This did not satisfy the Court, and therefore the writ was issued.

An Abuse of Medical Charity.—Last winter a man presented himself at the New York Ophthalmic Hospital and asked that an operation for cataract be performed, stating that he was very poor. The hospital is partly supported by charity. In view of the man's statement, that he was unable to pay much, the physician in charge reduced the usual \$15 per week to \$5 per week for board and attendance. The man was admitted and stayed several weeks. It was then learned that he was senior member of a large wholesale grocery firm, and was worth about \$150,000. The hospital, therefore, presented a bill for \$200, the full rates; the man refused to pay; the hospital sued and received a verdict for the amount. Such vigorous treatment applied to a few of the many similar cases constantly occurring would have a beneficial influence upon the community.

Louisiana Board of Health Resigns.—The commercial community of New Orleans, La., blames the Board of Health of that State for permitting the entrance of yellow fever into the city, for failing to stamp it out sooner, and for all the consequent ills; hence, the Board of Trade issued a call to the various Exchanges to send committees to an indignation meeting which was held December 6th, for the purpose of making a united attack upon the Health Board. Governor Foster, however, forestalled the mer-

chants, and announced through the secretary of the Cotton Exchange that Dr. Olliphant, the President, and other members of the Board of Health who were appointed by the Governor, had placed their resignations in his hands. Those members of the Board who were appointed by the City Council will be asked by the Mayor to resign. It is expected that as soon as the Board can close up its business the members will give way to their successors without protest. Governor Foster will reorganize the Board on different lines. Hitherto, it has been made up principally of New Orleans physicians and citizens, and it is now proposed to appoint men from different parts of the State, as it is thought that a body so constituted will have more influence in regulating quarantine and health matters outside of the city.

Obituary.—Dr. Joseph F. Edwards, editor of the *Journal of Health and Hygiene*, died at Atlantic City, N. J., December 6th, in the forty-fifth year of his age.—The death is announced of Professor Tarnier, the eminent obstetrician, of Paris. Dr. Tarnier graduated in 1857 and succeeded Professor Depaul in the Chair of Midwifery and Diseases of Women and Children in the Paris Medical Faculty in 1884. A special Chair of Clinical Obstetrics was founded for him in 1889. His great work on obstetric medicine, written with the collaboration of MM. Chantreuil and Budin, appeared between the years 1878 and 1886. He was also the author of important works on the hygiene of infancy. He was very active in introducing antiseptic principles into midwifery, and was the recognized leader in his special department of medicine in France.—Dr. Campbell Morfit, the "American chemist," died in London, England, on the 8th inst., in his seventy-eighth year. Dr. Morfit was born in Herculaneum, Mo., and was educated at the Columbian University, Washington, D. C. He organized the Chemical Department of the Maryland Institute, and in 1854 became Professor of Applied Chemistry in the University of Maryland. In 1861 he went to London, where he has since resided.

The Hospital for Scarlet Fever and Diphtheria Patients in New York.—This hospital will be opened on or about December 29th, 1897. It is intended for pay patients, and is situated at the foot of East Sixteenth street, facing the East River. The hospital is a private corporation, controlled by its own Board of Governors, and is not connected with any other institution. The President of the Board of Health and one of the Health Commissioners are *ex-officio* members of the Board. The charges for rooms will be from thirty to fifty dollars a week, nursing and services of resident physician being included. Patients may be attended by their own physicians, if it is so desired. Patients intended for the hospital must not be removed from their apartments until the hospital authorities have been notified (telephone call, 2880 Eighteenth street), and the requirements of the Board of Health complied with. The hospital has its own ambulance and coupé service. The visiting physicians are: Drs. L. E. Holt, W. H. Katzenbach, George M. Swift, F. M. Crandall, W. K. Draper, and R. J. Carlisle. The con-

sulting physicians are: Drs. E. G. Janeway, A. Jacobi, W. H. Draper, R. H. Derby, F. P. Kinnicutt, A. A. Smith, and J. W. Brannan. Consulting laryngologist: Dr. H. H. Curtis. Resident physician: Dr. E. L. Dow.

CORRESPONDENCE.

THE EXISTENCE OF RABIES.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: I was very much interested in reading in your valuable journal, issue of November 20th, the report of a discussion on rabies, which occurred at a meeting of the Harvard Medical Society of New York, held October 23d.

I was much surprised to find that still there are members of the medical profession who do not believe that such a disease as rabies exists. As I happen to have seen two cases of this disease, one of which was in a patient who was under my care in the Massachusetts General Hospital, you may find space for a memorandum in regard to them in your journal.

In my early professional days, years before the discoveries of Pasteur, there was a general disbelief here as well as elsewhere among the most enlightened members of our profession in the existence of hydrophobia. I suppose this was owing to the fact that not one of them had ever seen a case. The admission to the Massachusetts General Hospital, at a time when I held a subordinate position there, of a beautiful little girl who had been bitten by a mad dog, accomplished much in overthrowing skepticism in regard to the existence of the disease in question. The patient was about seven years of age, and lived in the suburbs of Boston. While playing in the street she was bitten by a large, strange dog, which then passed on, biting a man a few moments afterward. Certain nervous symptoms which the child developed led her parents to send her to the hospital, where I saw her, and well remember the impression the little thing produced on my mind as she sat on the lap of a nurse in the female surgical ward.

I need not give the symptoms in detail; suffice it to say that the poor child died. This case convinced Drs. John Ware and Jacob Bigelow, both professors in the Harvard Medical School and visiting physicians to the hospital, who had before been skeptical of the existence of such a disease as hydrophobia.

In later years, when I was a visiting physician to the same hospital, I had a case myself, in the person of a youth some sixteen years old, who developed all the usual symptoms and died of the disease, the diagnosis being fully confirmed by Dr. Fitz, at that time pathologist of the institution, who made the autopsy. I am prompted here to make a remark which I think has been made before: The word hydrophobia, as indicating a fear of water, is entirely a misnomer. The young fellow of whom I speak longed for water, as he had an intense thirst; but the least attempt to drink brought on a spasm of the throat which completely prevented swallowing. At my first visit, however, I succeeded in persuading him to make an attempt to swallow a little milk. By making a strong ef-

fort he swallowed a teaspoonful or two, and then the spasm prevented for a few moments any further attempt. After a short delay, however, he renewed the effort, and so by frequent energetic attempts succeeded in getting down the whole tumblerful. As the disease advanced the effort to swallow brought on such tetanic spasms that he was obliged to desist.

In addition to these cases I am well-informed in regard to another, which occurred in my neighborhood in the person of a boy, about twelve years old. The boy was perhaps a mile from home, when a large dog approached, and, without provocation, jumped up and bit him on the eyebrow. As soon as the family physician could be brought to the patient, he washed the wound and then applied his lips to it, sucking it an hour, and hoping to thus extract any venom that might be present. Of course he frequently expectorated, not caring to swallow any poison should such be present. The wound was then cauterized with a red-hot knitting-needle. I ought to add that the courageous physician who tried this experiment was a homeopathist, who later distinguished himself as a soldier during the late Civil War.

It has sometimes been said that the disease known as hydrophobia is an affection of the nervous system, perhaps a delusion of the imagination, and has no real existence. I do not think the cases I have reported can be fairly explained away on any such theory. The little girl was too young to be the victim of a morbid imagination. The second patient had no suspicion of the nature of his disease, the word hydrophobia not being mentioned in his presence. The only history of a bite in this case was that an enraged female flying-squirrel, which he had taken from her nest and little ones a year before, bit him furiously when he reached home and was removing the animal from his pocket.

The last case was also that of so young a patient that it does not seem reasonable to suppose that apprehension had anything to do with the development of the symptoms, especially as the sucking of the wound would have quieted his fears by making him feel, even though the wound were poisoned, that all of the venom had been removed. In the case of the second patient, I could not learn that he had ever been bitten by a dog, though his character indicated that had such been the case he probably would not have mentioned the accident at home, especially if the bite had been apparently trifling. He had been sent to the hospital by a physician who told the family that it was a case of "lockjaw," and they did not know its true nature until after death had occurred.

S. L. ABBOT, M.D.,

Member of the Board of Consultation of the Massachusetts General Hospital.

BOSTON, December 6, 1897.

ANESTHESIA BY THE SCHLEICH MIXTURE.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: In reply to inquiries in regard to the nature of petroleum-ether, I desire to state that it is identical to benzinum benzin, only of higher rectification—*i. e.*, higher boiling-point. Benzin, as usually found at

pharmacies, has a boiling-point of 55° C., and is, therefore, not applicable for use in the Schleich mixture, which requires benzin of a boiling-point of 60° to 65° C. I have used the Schleich mixture now in ten cases, substituting rhigolene (which is benzin at 70° C. boiling-point). This mixture has worked as well as the original, and I consequently recommend it for present use. This highly rectified benzin, or rhigolene, is not obtainable at an ordinary pharmacy. I have asked Squibb & Son to provide a supply of benzin of the proper degree of rectification, and to place it on the market for use in the Schleich mixture.

Yours truly,

M. L. MADURO, M.D.

NEW YORK, December 11th, 1897.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

NEW PROVISIONS FOR THE CARE OF THE CHRONIC INSANE—COLLEGE OF PHYSICIANS OF PHILADELPHIA—PHILADELPHIA OBSTETRICAL SOCIETY—JEWISH HOSPITAL—EXAMINATION OF STUDENTS' EYES AT THE UNIVERSITY OF PENNSYLVANIA.

PHILADELPHIA, December 13, 1897.

IN order to relieve the overcrowded condition which exists in the large State insane asylums, it is proposed by the State Board of Public Charities to remove all chronic cases from these central institutions and to distribute them among the various smaller county hospitals and almshouses. For a number of years past the congested condition of our general State insane asylums has hampered their work in many ways, and this plan for the removal of the great mass of the indigent chronic insane will no doubt solve the difficulty which has existed so long, and will result in many improvements from both socialistic and economic points of view. Under the new system, for which, by the way, provision was made some six months ago by an act of legislature, the State institutions will contain only the acute, recent, and curable class of cases such as could not be treated to the best advantage in the county hospitals, and will also continue to care for the criminal insane, until further provision is made for such patients. It is stated that there is ample room in the several county hospitals for all the transferred patients, so that additional institutions will not be necessitated.

A stated meeting of the College of Physicians of Philadelphia was held on December 1st. Dr. John B. Deaver read a paper on "The X-Ray Pathology of Fractures about the Elbow," the leading feature of which was the demonstration of the value of fluoroscopic examinations in this class of cases, by which it was shown that not infrequently a chipping off of the radius, not revealed by the ordinary means of examination, could be seen by the Röntgen-ray. A number of skiagraphs illustrating the speaker's topic were shown on a screen by stereoscopic projection. Dr. F. Savary Pearce read a paper, entitled "A Study of the Blind," in which 180 blind pupils at the Pennsylvania Institution for the Blind were analyzed as to their mental and physical status for comparison with those individuals possessing normal sight. Dr. Pearce's investigations showed that the blind are not "but seeing people in the dark," as the French school teach, but that they

are a distinct class of human beings with individual mental characteristics due to loss of the important function of sight, and that their vital capacity and physique is below that of seeing people of the same social standing; it was also shown that, as a rule, the blind are prone to anemia, due in most instances to lack of exercise. The advantages of institutions for the blind were pointed out as being threefold, as follows: (1) Segregation, producing concentration of efforts in like thoughts. (2) Similarity of physical work, as in the gymnastics of a school, or in labor production in a home, and (3) the application of restraints and self-restraints by capable instructors.

At the last stated meeting of the Philadelphia Obstetrical Society, December 2d, Dr. Joseph Eastman of Indianapolis, read by invitation a paper dealing with the question of operative treatment of pelvic support, in which he advocated supporting the uterus from above, as by the procedure of drawing down and stitching the broad ligaments to the vaginal wounds in order to prevent rectocele after the operation of vaginal hysterectomy, and he also recommended ventral fixation of the uterus for the same class of cases; the speaker strongly deprecated the French clamp operations, and held that support was never obtained in this way.

Dr. Joseph Taber Johnson of Washington, D. C., read by invitation a paper on the abdominal and the vaginal operations for the treatment of pus collections in the pelvis, and advocated the latter method as the one to be generally preferred, particularly in collections of pus low down in this cavity, in which evacuation can be secured by a free vaginal incision, without the higher mortality which attends abdominal section. The speaker believed that by the vaginal operation he had reduced the mortality from twenty-five per cent. to *nil* in patients whose weakened condition before operation made them liable to succumb to the shock of celiotomy. At the close of the evening's meeting a reception was tendered the visitors of the Society by Dr. E. E. Montgomery at his residence.

The Jewish Hospital is preparing plans for the erection on their grounds of a convalescent hospital and home for incurables. The sum of \$50,000 is now available for building purposes, and a legacy exists which will give the hospital authorities a handsome endowment for this department. Work on the new structure will be commenced during the spring of next year.

The authorities of the College Department of the University of Pennsylvania have recently announced that all students in that department of the University must have their eyes examined by an ophthalmologist, the expenses of this examination to be borne by the college authorities. This new step, which is being made to care for the physical condition of the students at this institution, is to go into effect at the same time that the regular physical examinations begin.

Dr. Richard C. Norris, who has recently recovered from a serious illness, has obtained a two-months' leave of absence from his duties as physician-in-chief of the Preston Retreat, and intends to leave during the latter part of this month for an extended trip to the Mediterranean and the Continent.

The total number of deaths in this city for the week ending December 4th was 391, a decrease of 3 from the preceding week, and an increase of 50 over the corresponding period of last year. Of the total deaths there were 139 in children under five years old. There were 324 new cases of contagious diseases reported, or 85 more than last week. Deaths from diphtheria numbered 41, with 152 new cases; from scarlet fever, 1, with 55 new cases; and from enteric fever, 10, with 117 new cases.

The number deaths in this city during the week ending December 11th was 401, an increase of 10 over those of the preceding week, and an increase of 26 over those of the corresponding period last year. New cases of diphtheria numbered 128, with 32 deaths; of scarlet fever, 47, with 3 deaths; and of enteric fever, 125, with 12 deaths. The rather alarming outbreak of diphtheria which occurred in two of the uptown wards last week and the week before has been somewhat suppressed by the strenuous efforts of the health authorities, although the disease can be scarcely said to be under full control as yet, for 28 new cases were reported from this district during the past week.

OUR BERLIN LETTER.

[From our Special Correspondent.]

PROFESSOR EDINGER AND THE TENDENCY TO SPECIALIZATION IN MEDICAL CONGRESSES—A NEW SUGGESTION IN THE APPLICATION OF THE X-RAYS—MODIFICATIONS OF THE CHEMISM OF THE BLOOD IN LEUCOCYTOSIS AND THEIR SIGNIFICANCE—THE USE OF GLOVES DURING SURGICAL OPERATIONS—PROFESSOR LEYDEN ON THE DIAGNOSIS OF ADHERENT PERICARDIUM.

BERLIN, December 11, 1897.

AFTER two recent experiences with large medical congresses—the one at Moscow and the other the meeting of the German Naturalists and Physicians at Brunswick—some of the medical men here have asked the very pertinent question *cui bono?* What is it all worth? It seems that there was a time, within the memory of men now living, when even the meeting of a National medical society was an occasion for the general practitioner to gather together the scattered threads of advancement in theoretic medicine, and the specialist to realize their application to the problems of general practice, and each would return to his clientele with broader views, newer methods, and with a sense of satisfaction at the information gained, which amply repaid the expenditure of time, money, and labor.

But all this has been changed. Whatever the specialist may hope for from the discussions, the general practitioners has little to gain. Medical congresses are afflicted, like everything else in our profession, with the furor for specialism, until now they are hardly more than a series of special society meetings, the only bond of union being the fact that they are held at the same time and place as their sister societies. No gynecologist thinks of attending a section on internal medicine; he scarcely has time in which to attend all the sessions of his own specialty. The laryngologist, the neurologist, each has the same reason

for confining himself to the comparatively narrow circle of his brother specialists, and their communications are the only ones for which he has an ear.

It is true that all specialists insist with unabating emphasis that real success in specialism lies in not allowing oneself to be limited by the narrow confines of a specialty, and that the broadening influence of general practice, even as regards success in a particular department of medicine, is likely to be seriously undervalued. Such expressions seem to be merely the result of habit, *vox et præterea nihil*. The theoretic branches of scientific medicine, which truly are the foundation of all real advance, receive the least attention. None but teachers and investigators have any interest in them. The sections on anatomy, physiology, even the one on pathologic anatomy, at a large congress, may be accommodated in small rooms with no fear of overcrowding. As Professors Edinger and Waldeyer say, for it is their opinions I have been quoting, "the only remaining chance for the theorists and practitioners to meet on common ground seems to be rapidly slipping away. Yet each class has urgent need of the experiences of the other. The practitioner will be aided in the application of new therapeutic measures, and the theorist and experimenter will be assisted in determining the direction his efforts should take, according to the success or non-success of existing methods.

National and International medical gatherings are becoming more and more unsatisfactory to the attendants. Except as pleasant opportunities for friendly greeting they almost cease to have an excuse for existence. The remedy is not easy to find, though Professors Waldeyer and Edinger each have a suggestion to make. Professor Waldeyer would have a National meeting in Germany but once in two years instead of once a year. Even then the number of papers would have to be limited, and precautions taken to see that only the most important ones and their discussions occupy the time of the meeting.

Professor Edinger thinks that the specialists should hold congresses by themselves, and that instead of the usual announcement of the committee of arrangements, "We take pleasure in announcing that at this year's congress our military-veterinary brethren will hold sessions of their own," there should be a limitation of the number of special sessions to be held to five or six, and that there should be a clearing-house committee to whom all papers should be sent, and who should select the ones of sufficient general interest to be read before the sections. The others being printed in a volume of preliminary transactions to be distributed before the meeting opens. As this is about the time of year that committees of arrangements are preparing for next summer's meetings, he commends this scheme or a modification of it to their consideration.

The Röntgen-rays are every day finding new applications, but not the least surprising is the very recent matter-of-fact suggestion of a stolid, prosaic, German doctor, as to their availability in the selection of a bride. The end of marriage being the reproduction of the species, any hindrances to this end which exist, and which may be discovered without subjecting the persons concerned to any

indignity, he argues, should be found out before marriage. Any insuperable pelvic contraction may thus be easily detected, and he suggests that *fiancés* should exchange not only ordinary, but X-ray photographs, when the preliminary steps to matrimony are being taken. This method, he considers, will be of invaluable services to members of royal and aristocratic families to whom the birth of an heir is all important, and the skiagraph of his beloved will be one of the things that a princeling will be supposed to possess before seriously commencing negotiations for her hand.

Some very suggestive work on modifications of the chemic constitution of the blood and certain of its metabolic processes after destruction of white blood-corpuscles, as seems to occur during both hypo- and hyperleucocytosis, has just been reported from Professor Senator's clinic at the Charité. Drs. Lœwy and Richter pointed out some time ago in the *Berliner Klinische Wochenschrift* that artificial changes in the number of leucocytes present in the blood produced by the injection of such substances as nuclein, spermin, or pilocarpin, were followed by changes in the alkalescence of the blood. The well known connection of variations in luxuriance and rapidity of micro-organismal growth with the varying degree of alkalinity of the culture medium led them to suggest that these variations of alkalescence are of great biologic importance in the practical questions of infection and immunity. The fact was at first disputed, but has now been confirmed by a number of experimentors, though the conclusions suggested by the original observers have not all been accepted. They now announce that the presence of albumoses in the blood may also be demonstrated in these hypo- and hyperleucocytic states. These albumoses are not the result of chemic processes caused by the substances injected to produce leucocytosis, but are the result of vital changes in the blood, especially in the white corpuscles. Their observations, if confirmed, will add another link to the chain of information as to the chemism of the blood in infectious diseases, which Klemperer and Von Jaksch so strikingly illustrated by their discovery of the increase of uric acid present during the leucocytosis of pneumonia. Such discoveries now constitute one of the most hopeful sources of information with regard to the real significance of symptoms in the infectious fevers.

Besides, Drs. Lœwy and Richter have shown, by adding sugar to freshly drawn blood which has been kept some hours in a brood-oven, that the glycolytic faculty of the blood, its power to dissolve and carry sugar, is considerably lessened if the blood be drawn from an animal after the production of artificial leucocytosis. This fact would seem to account for the observation made by Von Noorden and others that during pneumonia in which a typical leucocytosis is always present, the faculty of the individual for sugar metabolism, *i.e.*, for the storage and use of sugar products is greatly lessened.

Since Professor Mikulicz introduced the use of cotton gloves in operations at his clinic the custom has been gradually spreading here in Germany until now many of the younger surgeons are using them. In the larger

clinics, as a rule, not the operator himself, but the chief assistant nurses wear them. That they are a distinct advance in asepsis is admitted on all sides. This advance too, comes just with reference to that part of surgical asepsis which the bacteriologists have been some time insisting is likely to be most incomplete—the disinfection of the hands. The older surgeons still object to them, because of the unusual sensations their use involves, but it is evidently only a question of time when some such mechanical addition to the asepsis of the hands of nurses and operators will be generally adopted.

Professor Leyden recently reviewed the question of diagnosis of adherent pericardium during life in connection with the specimens from a case in which it had been found *post-mortem* without having been diagnosed previous to death. It constitutes the *pièce de résistance* of the young, ambitious diagnostician, and the veteran's opinion may be of interest. The general symptoms it causes he considers as those which may occur in almost any condition, endomyo- or pericardial, which hampers heart action. As to the one symptom which sometimes is pathognomonic, the systolic retraction at the apex, or even over a considerable area of the precordia, it is not always present and when it is, is not always significant. It depends for the latter upon the arrangement of the fascia. Fascia is notably liable to anomalies, and this special fascia has been shown by recent investigation to be subject to a great many variations. The diagnosis concretio pericardii is never more than a probable one, and this important pathologic change remains as one of the interesting diagnostic problems for the future to solve.

MYCOSIS OF THE HUMAN SKIN AND DISEASES IN GENERAL PRODUCED BY PATHOGENIC YEAST FUNGI—BOTTINI'S OPERATION FOR HYPERTROPHY OF THE PROSTATE.

AT a session of the Medical Society, October 20th, BUSCHKE read a paper on *Mycosis of the Human Skin and Diseases in General Produced by Pathogenic Yeast Fungi*. This is an old subject, and during more than twenty years the question has been disputed whether or not yeast fungi are pathogenic for men and animals. Raum, in 1891, obtained some positive results from experiments upon animals. Busse and Buschke, some time since, reported the death of a woman, aged thirty-one years, from ulcers of the face and a tumor of the left tibia. During life they demonstrated, both microscopically and by the culture method, the presence of yeast fungi in the lesions. Some months later, at autopsy, similar lesions were found in the lungs, kidneys, spleen, and in some of the ribs. Microscopic examination of the ulcer in the skin showed increased growth of the epithelium, inflammatory infiltration, loss of the line of demarcation between the cutis and the subcutaneous tissue, and the presence of numerous giant-cells. The epithelium was finally destroyed, the fungi pressing into the epithelial tissue, and by their growth contributing to the destruction of the lat-

ter. In general, the process greatly resembles the infectious tumors of actinomyosis, glanders, tuberculosis, and syphilis. Isolated instances of the occurrence of this disease in human beings have been reported of late years. Several observers have attempted to show that yeast fungi are responsible for the lesions of carcinoma, sarcoma, and variola, but such opinions are not as yet well-founded. Undoubtedly there have been many cases of disease produced by fungi which have been overlooked, and now that attention is turned in this direction, it is to be hoped that this obscure subject will soon be elucidated.

At the session of October 20th, HERZFELD described *two cases of mycosis*, the lesions of which greatly resembled those of thrush, although the microscope showed them to be produced by yeast fungi. One patient was an old man convalescing from influenza-pneumonia. The other was a girl twenty years old, who sought medical relief for difficulty in swallowing. The whole pharynx, mouth, and tongue were covered with thick, loosely interwoven masses of a grayer color than is usually seen in thrush. Cleansing of the mouth with a solution of borax speedily produced a cure in both instances.

FREUDENBERG spoke of his experience with *Bottini's operation for hypertrophy of the prostate*. This procedure is not entirely without danger. He lost one patient on the day following operation from pulmonary embolism. Another, a man aged seventy-seven, died the day after from a long-standing pyelitis; but it should be remembered that any operation in these cases is attended with a certain amount of risk, even the use of the catheter having its dangers. Hemorrhage occurred in three cases, but was not alarming. It may be avoided by making the incision slowly and keeping the cautery point at the right temperature. The success of operation depends upon the number of incisions, their length and their direction; and also to no small degree upon the after-treatment. In a few cases of Freudenberg's the operation was followed by incontinence of urine, but this was only temporary. Bottini has had the same experience. This complication is probably due to the extension of the incision into the membranous portion of the urethra.

London.

RECENT EXPERIENCE WITH LARGE DOSES OF CREOSOTE IN CONSUMPTION—TREATMENT OF LATERAL CURVATURE OF THE SPINE—EMPHYEMA OF THE ANTRUM IN A CHILD EIGHT WEEKS OLD—PARTIAL CRETINISM—SUCCESS OF COLEY'S FLUID—MESENTERIC CYSTS—ABDOMINAL HYSTERECTOMY FOR MYOMATA OF THE UTERUS—MEDICAL HEMORRHAGE.

At a meeting of the Harveian Society, October 21st, BEALE read a paper, entitled *Recent Experience with Large Doses of Creosote in Consumption*. The patients were treated with beechwood creosote dissolved in cod-liver oil, the dose being slowly increased from 5 minims daily to 160 or even 180 minims. The results achieved were highly satisfactory and in some cases most striking. The fall in temperature, gain in weight, and the subsidence of symptoms seemed to be more definite and lasting than the degree of improvement commonly observed as a

result of hygienic treatment alone. The creosote was well tolerated. In many instances the patients passed blackened or greenish urine; but it could not be ascertained that either the quantity or chemic composition was seriously altered. The speaker doubted if the more specialized products, such as guaiacol and its carbonate can give equally good results. However, the drug should be regarded not as a specific remedy but rather as a valuable adjunct to the many existing methods of hygienic treatment of phthisis.

THOMSON stated that at Dettweiler's sanatorium for consumptive patients at Falkenstein in the Taunus Mountains, creosote was given a long trial and finally abandoned, along with tuberculin and all other specific remedies. Treatment is now entirely symptomatic, and general dietetic and hygienic influences are the only therapeutic measures relied upon. FELCE said that commercial creosote is a somewhat variable product, and for this reason he prefers the carbonate of guaiacol.

At the session of November 4th, SMITH read a paper on the *Treatment of Lateral Curvature of the Spine*, pointing out the advantages which may be derived from mechanical, in addition to other methods of treatment. He said that it is claimed by advocates of the treatment by exercise alone that deformities in the bones cannot be remedied, and further stated that rotation is a test of such deformities. Smith has found that it is quite possible, by means of the hands alone, to hold the patient in a straight position, even though slight rotation has commenced; and it is also possible, by means of apparatus, to maintain the position until the bones readjust themselves.

CLARKE said there is much misunderstanding as to the various methods of treating lateral curvature. In rickety infants instrumental treatment is absolutely necessary. Some surgeons are mistaken in supposing that they use exercise alone in their treatment. Thus Roth's plan consists in placing the patient, during three-quarters of an hour, upon a hard table, as well as the use of a series of exercises. The weight of the patient pressing against the table makes the latter an instrument. Other similar instances were mentioned. Thus, there is less difference between the methods employed by various surgeons than at first sight appears to be the case.

At a meeting of the Pathological Society, November 2d, POWER showed a specimen of *empyema of the antrum in a child eight weeks old*. The face of the child was bruised in a forceps delivery, but the abscess was not noticed until one month later. At the time of operation the facial bones were extensively necrosed, and the child died thirteen days after the abscess cavity had been freely opened and curetted.

CALVERT and PIGG showed a specimen of *calcification of the pericardium*, the result of a chronic suppurative process which apparently had continued five years. The heart was almost entirely encased in calcareous material, and there were several ounces of inspissated pus in the pericardial cavity.

At a meeting of the Medical Society, November 8th, COLMAN showed a *child nine and one-half years old*

who was a partial cretin. A stunted growth, absence of any demonstrable thyroid gland, fat masses in the anterior triangles of the neck, thick lips, puffy eyelids, lordosis, and prominence of the abdomen were the signs of cretinism which she presented. There was, however, an entire absence of the usual nervous symptoms. The child was given daily 3 grains of the dry thyroid extract, and, within four months, grew two and one-half inches. Colman explained the absence of nervous symptoms by the assumption of an accessory thyroid whose secretion was sufficient to maintain the nutrition of the brain.

MOULLIN showed two cases in which *inoperable tumors had almost disappeared after the repeated injection of Coley's fluid*. One patient was a man, aged twenty-eight years, with a deep tumor in the groin. Gradually increasing amounts of the fluid were injected every three or four days. The tumor increased rapidly until three months after the beginning of the treatment, when it gave evidence of acute inflammation. From this time it rapidly grew smaller until only a trace of it remained, in which condition it still continues. The second patient was also a man, aged forty-eight years, with an irregular, hard swelling in the left flank, which was not connected with the skin or abdominal muscles. In this case the injections were given for some time without much apparent effect. Then the tumor became acutely inflamed as in the other case, and afterward rapidly subsided. Both tumors were considered to be sarcomatous, although there was no definite proof of this fact.

At a meeting of the Royal Medical and Chirurgical Society, November 9th, EVE read a paper on *Mesenteric Cysts*. The first case described was that of a male infant, aged eleven weeks, with a freely movable fluctuating tumor in the right side of the abdomen which was diagnosed as a mesenteric cyst. There was almost constant diarrhea and vomiting. Celiotomy was performed and a cyst of the mesentery of the small intestine was found attached to the abdominal wall. A few days later it was opened and drained. The child appeared to have recovered, but six weeks after had convulsions and died. The cause of death was not demonstrated at the autopsy. The second case was that of a male child, aged three and one-half years, in whom a cyst of the mesentery of the small intestine containing thirty-two ounces of serous fluid caused an acute intestinal obstruction. This cyst was excised, but death occurred nine hours after operation. These two cases illustrate the typical symptoms of mesenteric cyst in the earlier and later stages. The first had symptoms resembling gastro-enteritis with accompanying emaciation, the second, typical intestinal obstruction without definite premonitory symptoms. In the first case the cyst was easily recognizable by physical examination; in the second, it was obscured by coils of intestine.

At a meeting of the Obstetrical Society, November 3d, SUTTON read a paper on *Abdominal Hysterectomy for Myoma of the Uterus*, in which he took a position that provoked rather sharp criticism. He said that on account of the favorable results from the newer methods of hysterectomy, it is the duty of physicians to point out to patients the desirability of having myomata removed before

they grow too large to permit of a vaginal operation. As is the case with ovarian tumors, an early operation is less dangerous than one performed at a later stage. Whenever possible, if operating upon women who have not reached the menopause, he leaves the tubes and ovaries, on the principle that the best surgery does not needlessly sacrifice any organ, least of all such important ones. His results were admirable. Of twenty-eight patients he lost but two, and the period of convalescence was far shorter than if there had been a pedicle requiring extraperitoneal treatment.

DORAN insisted that the comparison between an ovarian tumor and a fibromyoma was an unfair one, for the reason that the former, if let alone, will almost always cause the death of the patient; whereas the latter will, in many instances, not even become troublesome. He objected to leaving the Fallopian tubes behind, because they often contain pathologic fluid. PLAYFAIR said that he could not subscribe to the doctrine that the mere existence of a myoma, whether it gives symptoms or not, is sufficient ground for a hysterectomy. This theory is dangerous and untenable. In many cases an oophorectomy should be preferred to a hysterectomy, on account of the lower mortality which attends the latter operation. He felt sure, however, that the extraperitoneal method is doomed. MEREDITH is not so dissatisfied with the extraperitoneal method as some of the other speakers. With this method of operating he obtained eighty-three recoveries out of ninety abdominal hysterectomies.

At a meeting of the Hunterian Society, November 10th, SMITH read a paper on *Medical Hemorrhage*. He divides the long list of medical hemorrhages into (1) those accompanied by some severe or fatal general dyscrasia or diathesis, and (2) those without such concomitant. As far as the immediate treatment of hemorrhage is concerned, he thought it wrong to administer ergot for arterial bleeding, as it increases the blood pressure, has no tendency to induce coagulation, and its power to stimulate contraction of involuntary muscle cannot stop arterial bleeding, except in case of hemorrhage from the uterus. In venous and capillary hemorrhage the contraction of the arterioles is beneficial by reducing the flow of blood through these vessels, and hence, ergot may be rationally administered in such cases. The most reliable treatment includes rest obtained by a horizontal position, and the administration of cannabis indica, or, better, opium. For pulmonary hemorrhage he recommends the administration of iodid of potash, and also inhalations of the vapor of turpentine. If the hemorrhage is gastric or intestinal, astringents are indicated. Colman spoke of the value of a large dose of sulphate of magnesium given at the beginning of a case of hemoptysis. Several of the members disagreed with Smith's opinion in regard to the injury which may follow the use of ergot in arterial hemorrhage.

Preparation of Aristol Ointment.—The formation of lumps which is apt to occur when aristol is directly incorporated with vaselin will be avoided if the aristol first be triturated with the neutral oil of vaselin.

SOCIETY PROCEEDINGS.

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY OF NEW YORK.

Stated Meeting, Held October 20, 1897.

THE President, DR. CHARLES L. DANA, in the Chair.

DR. L. D. BULKLEY read the paper of the evening, entitled

THE NON-SURGICAL TREATMENT OF BOILS, CARBUNCLES, AND FELONS.

The paper gave in detail the treatment which the author has employed during more than ten years in curing these conditions without the use of poultices or the knife. Referring to the causes of the formation of pus, he said that the essential features of suppuration, the staphylococci aureus and albus, are spoken of by one writer as being normally present on the skin, and that opinions are becoming divided as to the true pathogenesis of many conditions which were supposed to have been fully understood years ago. The author recognizes the pyogenous qualities of micro-organisms, but asserts that their powers are temporary and limited by their own nature and the condition of the tissues in which they are found, as shown by the different results attending superficial wounds in different individuals and also in the same individual at different times. Pus bacilli are everywhere present, and ready at all times to lodge and do their work if the soil be suitable, yet suppuration is set up in comparatively few instances. The occurrence of suppurative processes should always be regarded as a result of faulty metabolism, and a careful search should be made to find out and remedy that which is wrong.

Persons with boils, carbuncles, or felons are not in perfect health, and patient investigation will generally reveal the line upon which successful treatment should be instituted. Iron is most commonly needed, and the preparation used by the author is known as Startin's mixture, *viz.*: Ferri sulphatis, 3 i; magnesiæ sulphatis, 3 vi; acidi sulphurici diluti, 3 iv; syrupi zinziberis, 3 iv; aquæ, q. s. ad., $\frac{3}{4}$ iii. M. Sig. One teaspoonful, in water, through a tube, after meals. Unless contraindicated, treatment should be begun with a mercurial purge: Mass. hydrargyri, ext. colocynth. co., aa gr. x; pulv. ipecac., gr. ij. Divide into four pills. M. Sig. Two at night and the remaining two on the second night after. Repeat at the end of a week, or oftener if considered necessary. Sulphid of calcium should be administered because it has a decided effect on the process of suppuration, and it should be given in free doses— $\frac{1}{4}$ grain every two hours until eight or ten doses have been taken. Careful attention should be paid to the diet and mode of life.

The local treatment of furunculosis is as follows: To soothe and protect the inflamed area, to exclude the air, and to exert a slight antiseptic action, the surface is covered with a moderately thick layer of absorbent cotton, in the center of which is placed a mass of the following ointment: Acidi carbolici, gr. v-x; ext. ergotæ fld., 3 iii; pulv. amyli, 3 ij; zinci oxidî, 3 ij; ung. aq. rosæ, $\frac{3}{4}$ j. M. Sig. This is placed over the boil and held in place by

adhesive straps, which, however, should not pass over the boil. The dressing should be changed every twelve hours. Combined with internal medication this application will often absorb the boil.

The local treatment for carbuncle is the same as that for boils, the author adding that he has not found it necessary to incise a carbuncle since November, 1882. He admits that from neglect or other cause a very large suppurating carbunculous area may exist, which may demand active surgical treatment. This will not occur if the above treatment is carried out.

For inflammatory conditions about the ends of the fingers, commonly known as paronychia, whitlow, and felon, the same treatment is advocated, with the exception that diachylon or litharge ointment is employed. This is prepared according to Hebra's method, as follows. Olei olivarum optimi, 3 xv; plumbi oxidî, 3 iij-vj; olei lavandulæ, 3 ij. M. Add the oil to two pints of water, with constant stirring; the litharge is to be slowly sifted in while it is well stirred, fresh water being added as required. It should be stirred until cold and the lavender added. The finger is to be plunged into the jar and the first joint entirely enveloped in the ointment to the thickness of a quarter of an inch; over this absorbent cotton is placed and loosely bound. The author said that in cases seen reasonably early this treatment will relieve the pain and cause resolution, but that he places the greatest value on the internal and general treatment.

DISCUSSION.

DR. J. H. FRUITNIGHT said that all were agreed that in many of these cases constitutional treatment is as essential as local treatment. In general furunculosis he has always been in the habit of administering the sulphid of calcium, and with beneficial results. In this disease constitutional disturbance seems to be present, while carbuncle is more local, and not so much dependent upon constitutional causes. When a carbuncle is seen early, he makes a crucial incision and cauterizes it thoroughly. Ichthyol ointment sometimes aborts the process of suppuration.

DR. COLE said he could not agree with the author, although in many respects he coincided with him in regard to the constitutional treatment. There can be no doubt that in diabetes there is a tendency to these conditions, but they also occur when there is no constitutional disturbance. In these days of modern aseptic surgery, the patient can be more quickly and thoroughly relieved by incision than by any other method of treatment. The relief is instantaneous and recovery takes place in a remarkably short time. When there is constitutional disturbance he employs the sulphid of calcium in large doses— $\frac{1}{4}$ grain every hour, until the system is thoroughly saturated with it. Incision he considers the only treatment for carbuncle, and, if it be large, all diseased tissue should be removed. He cited the case of a man, seventy years of age, from whose back he removed a carbuncle as large as a dinner-plate. The indurated mass removed was two and one-half inches thick. The man recovered. Regarding the treatment of deep-seated

felons, he thought the tension should be relieved by an incision reaching to the bone. He referred to a case of felon of the thumb occurring in a young woman, who absolutely refused to submit to incision, and in which the thumb was lost. He expressed the opinion that it is simply tampering with a very serious trouble to treat these cases with ointments and constitutional remedies. By the use of the knife, relief is immediate and the patient is saved weeks of suffering. Ointments are useless when suppuration has set in. Building up of the system is well enough, but the knife is indicated in hundreds of cases. If pus is present, it will not escape unless an incision is made, and if it is not evacuated the bone will become affected and a joint or two will be lost.

DR. S. H. DESSAU said that, while he agreed with the previous speaker regarding the treatment of felons and carbuncles, his experience with furunculosis in children led him to think that there must be some constitutional factor which occupies an important place in the occurrence of this affection. It is common during the summer months to see an eruption of boils in children which is not often seen at any other season, and it would seem that the heated term acts as a depressor upon the nervous system, and thus favors the development of boils. In these cases excision of the furuncles when they reach the stage of suppuration does not seem to prevent the appearance of a second crop. Internal treatment is indicated, and is successful. For this purpose he prefers the syrup of the hypophosphite of lime, which seems to act almost like a specific in clearing up the skin. Carbuncles and felons are apt to occur in neurotic subjects, and felons are much more common in the female sex; and this would lead to the belief that they are the result of some nervous condition. He is in favor of incision down to the bone in the treatment of felons.

DR. ROBERT H. GREENE called attention to the value of carbolized oil as an application for boils and carbuncles. He has used it of a strength of half a dram to the ounce, or stronger, according to the susceptibility of the patient, during a number of years with excellent results.

DR. ROBERT MILBANK expressed the opinion that furuncles, boils, and carbuncles are due to one and the same microbe, differing only in the number of foci. He incises them early, freezing the part with ethyl chlorid, swabs them out with carbolic acid, washes them out every day, and keeps them covered with a light dressing. He cited a case in which a man, aged twenty-six, powerful and in splendid health, a rubber in a Turkish-bath establishment, had a series of carbuncles. Incision was advised, but the patient refused to submit to it, and the carbuncles followed one another until he allowed the speaker to open one, with the result that he has never had another. The patient probably contracted the disease by rubbing a man who was suffering from boils. Constitutional treatment should be employed to build up those who have become worn out and exhausted as a result of this painful disease, and not because the constitutional disturbance is the cause of the trouble.

DR. ROBERT A. MURRAY said that it is a distinct retrogression instead of an advance to treat these cases in

the way described by the author. The disease is due to infection, and applications to the skin will have no effect upon its progress. Constitutional disturbance may act as a causative factor in that it is accompanied by a depraved condition of the system. Furunculosis occurs in children because they are not cleanly, and during the warm weather because the skin is tender and easily infected. Boys who frequent the free swimming-baths are peculiarly liable to develop boils, obviously as a result of infection, even though a certain amount of anemia may exist. The administration of sulphid of calcium is all very well, but its effect is slow. Early incision under ethyl chlorid freezing or under nitrous oxid anesthesia is much better treatment.

The speaker stated as his belief that a felon is a periostitis; that the firm attachment of the periosteum to the bone at the tip of the finger prevents the escape of pus, and that necrosis will be the result if the case is not treated surgically. Mechanics and washerwomen often have felons because they are constantly stubbing and bruising the ends of their fingers, the mechanic with his tools and the washerwoman on her wash-board. The proper treatment is to incise and split the periosteum, evacuate the pus, and thus save the bone. If done early and properly there will be no deformity, whereas, if it be allowed to go on to rupture an ugly scar and often a distorted finger is the result. As the latter may prevent the patient earning his or her living, it is especially important that it be avoided.

He is in favor of incision and wide excision in cases of carbuncle, and cited a case in which he had successfully removed one as large as his hand from a woman ninety-five years of age. As a dressing he employs a 1 to 4 mixture of ichthylol and glycerin, and never iodoform in any shape, because poisoning is liable to occur as a result of rapid absorption. He referred to another case, that of a man who worked among horses, in which a series of carbuncles seemed to be due to infection by the anthrax bacillus.

DR. A. M. JACOBUS said that he had had no experience with the line of treatment laid down by the author. His custom is to promptly excise all carbuncles and felons, dividing the periosteum in the latter in order to let out the pus and save the bone. In regard to the constitutional treatment, there is no doubt that it should be thorough. Iron is generally indicated. He has used sulphid of calcium with practically no benefit.

DR. JOHN F. ERDMANN remarked that an experience such as that of the author, which covers twelve or fifteen years, deserves some consideration, but thought that Dr. Bulkley had not seen severe cases. Boils and carbuncles do not call for the same treatment as that indicated for felons. In the form of felon known as paronychia it is unwise to delay incision and run the risk of necrosis of the bone, destruction of the sheath of the tendon and of the tendon itself, and, possibly, palmar abscess. When pus is forming the knife should be used at once. Tension and pain are thus relieved, and the danger of infection traveling through the lymph-channels is averted. In carbuncle the question is not one of the formation of

pus, but one of the formation of slough. The pus is of low grade. The only thing is to make a free incision, several if necessary, in order to secure discharge of the slough itself. With regard to Dr. Murray's case, carbuncle is not caused by the anthrax bacillus unless there is true malignant pustule.

DR. JOSEPH COLLINS said he had not had much experience in the treatment of these three conditions, but that his knowledge of surgical pathology would seem to indicate that the views of the author of the paper are not in keeping with the rules of pathologic teaching. If it is taken for granted that felons, boils, furuncles, and carbuncles are caused by certain cocci, and that these cocci get into the system through abrasions of the skin or through the hair-follicles, it does not seem as though external applications would be beneficial. In his opinion, these conditions are due to the presence of cocci, and whatever constitutional symptoms there may be, are secondary or their presence is a coincidence. Depraved vitality predisposes to the disease. In such a condition iron and sulphid of calcium may be given with benefit.

DR. WILLIAM STEVENS also advocated early incision in the treatment of felons and carbuncles. In boils incision may sometimes be avoided by injecting carbolic acid deep into the substance of the boil.

DR. ROBERT NEWTON agreed fully with the author, and said he had seen many of these cases in a large dispensary practice, and that formerly he had used the knife, but now he employs the methods laid down in the paper, with very good results. Diachylon ointment, when freshly made, gives excellent results. Sulphid of calcium internally is one of the most valuable of remedies, and will sometimes prevent suppuration. In felons, when there is necrosis, the knife should be used. He was surprised that no one had mentioned the hypodermic injection of carbolic acid in the treatment of carbuncle. Dissolved in glycerin and injected well into the base of a carbuncle it often prevents suppuration. Furuncles and boils are a constitutional disease, and in many cases simple bicarbonate of soda will cure the dyspepsia which causes them. The worst type of felons he has ever seen occurred in a young woman with anemia associated with malaria. Proper treatment of these conditions cured her of the felons.

THE PRESIDENT said he felt that the members had attacked the author's position rather unsympathetically. It is certainly true that there are felons which get well without surgical treatment. There were points in the paper which ought to be considered more fully.

DR. BULKLEY, in closing, said that he was prepared for the criticism which his paper had called forth, but he had hoped that some of the members would agree with him. That many do agree with him is proved by the fact that after he published a series of papers on the subject he received letters from physicians all over the country in reference to the treatment. It should be remembered that this treatment is not a new thing. During the twelve years in which he has practised it he has seen many cases recover. The prevalence of carbuncles in diabetes is an argument in favor of the constitutional

origin of these disorders. The final parasitic cause is not denied, but he insists that constitutional disease makes the system ready to receive and nourish the parasitic element.

REVIEWS.

CLINICAL METHODS, a Guide to the Practical Study of Medicine. By ROBERT HUTCHISON, M.D., M.R.C.P., Demonstrator of Physiology, London Hospital Medical College, and HARRY RAINY, M.A., F.R.C.P. (Edin.), F.R.S.E., University Tutor in Clinical Medicine, Royal Infirmary, Edinburgh. Philadelphia and New York: Lea Brothers & Co., 1897.

THIS work fulfils its purpose admirably. It is intended as a guide to the student and to the physician as to the manner of proceeding in the investigation of a case. It includes, therefore, case-taking, the examination of the various anatomic systems and organs, the examination of pathologic fluids, and also clinical bacteriology. As its title well indicates, it is a treatise on clinical methods without purporting to be a complete work on medical diagnosis.

The work begins with a description of methods of securing anamnestic data from the patient, and this is amplified by a "scheme" for taking a thorough physical examination. Chapter II. deals with the general condition and appearance of the patient; it brings forth points of vital importance in the examination and is very complete. The ten succeeding chapters take up in detail the examination of the systems of the body, in the following order: The alimentary system and abdomen, the circulatory system, clinical examination of the blood, the respiratory system, the urine, the skin, the nervous system, the eye, ear, throat, and nose, and the locomotor system. Our only criticism of these chapters would be that they are too diffuse; the authors have tried to cover too much ground. The spectra of hemoglobin and its derivatives and the table of origin of the spinal nerves belong rather to works on physiology and anatomy than to a book on *clinical* methods. On the other hand, the visual representation of auscultatory phenomena and of the direction of sound of the various cardiac murmurs are in the right direction and will prove distinctly helpful to the reader, be he student or practitioner. The nomenclature and terminology are decidedly modern, and this is especially true of the nervous system, although we prefer the word "convulsion" to "fits."

In Chapter XII. are given the usual methods of examining children, and many useful hints not ordinarily found in books of this class are to be noted. The succeeding chapter deals with the examination of pathologic fluids, including the fluid obtained from cysts and that secured by lumbar puncture. The concluding chapter of the book treats of the clinical bacteria with methods of preparing them for microscopic examination. Widal's test appears here and the Schottelins-Koch method of differentiating cholera bacilli is described, although not mentioned by name. The animal parasites are described in the chapters devoted to the organs which they inhabit.

We have cited enough to show how complete and up-to-date is this handbook of medical diagnosis and its methods. If the authors have included too much, it is a sin which is easily forgiven. We do not know of any book of its kind, in the English language, at least, which so thoroughly covers the ground. It contains much more than the average text-book of medicine, with as much as most books devoted solely to microscopic diagnostic methods. Moreover, the size of the book is convenient for carrying in the pocket. It contains 8 colored plates and 137 illustrations, all of them useful in elucidating the text. The illustrations exemplifying physical signs and conditions are particularly instructive.

TRAUMATIC INJURIES OF THE BRAIN AND ITS MEMBRANES, WITH A SPECIAL STUDY OF PISTOL-SHOT WOUNDS OF THE HEAD, IN THEIR MEDICO-LEGAL AND SURGICAL RELATIONS. By CHARLES PHELPS, M.D., Surgeon to Bellevue and St. Vincent's Hospitals. Forty-nine illustrations. Pp. 532. New York: D. Appleton and Company, 1897.

THE author very justly regards traumatism of the brain as "a division of brain surgery which has the greatest practical importance and has received the least careful attention." This is due to the fact, as he remarks, that "the intrinsic difficulty which has been encountered in the interpretation of symptoms resides in the usual complexity of lesions, and has been increased by their apparent identity in cases in which dissimilar pathetic conditions have been found to exist." Many useful papers have appeared, from time to time, on various branches of this subject, but until the present there has been no complete treatise which in any proper manner answered the demands of the surgeon. The want is now supplied by this work, a most interesting feature of which is that it is an original study. The basis of that study was five hundred consecutive cases of recent injury of the brain, occurring in hospital practice where the opportunities for accurate observation were favorable. The subject-matter is incomplete only in the illustration of secondary pyogenic infection, involving the brain substance, but this deficiency has been supplemented by a quotation from Macewen's "History of the Pyogenic Inflammations of the Brain and Spinal Cord."

The work is divided into two parts, *viz.*, Part I., General Traumatic Lesions, and Part II., Pistol-shot Wounds of the Head; to which is added the condensed histories of three hundred intracranial traumatisms. A preliminary section is devoted to the consideration of cranial fractures in which the lesions are classified and the general features of each class given, with the principles of treatment. In the subsequent chapters of this part the author discusses at length each variety of cranial lesion with that accuracy of detail and that precision of opinion which his great clinical experience abundantly warrants. This is especially noticeable in the chapters on symptomatology and diagnosis. In the treatment of cranial injuries the author makes a well-deserved distinction, too frequently overlooked, between epidural and subdural collections of blood. The line of treatment which he draws throughout

this chapter is decidedly conservative, and the rules of procedure which are given for the various forms of injury cannot be too carefully heeded by the young surgeon.

Part II. comprises the results of the most careful and painstaking study of pistol-shot wounds of the head on record. As these injuries necessarily receive slight consideration from military surgeons, they must be studied in civil practice, and some features must be determined by experiment on the cadaver. The author has had unusual opportunities for the clinical study of pistol-shot wounds of the head in the two great hospitals of this city with which he is connected, and he has evidently improved these advantages by a close and careful analysis of the facts in each case. His experiments on the cadaver were very extensive, and are illustrated by a large number of admirably executed plates. The medico-legal questions which these experiments elucidate are judicially considered and determined.

Our space does not permit of that critical examination of this work which would set forth in proper method its peculiar claims as an authority in this hitherto neglected and quite abandoned field of practical surgery. We can only state in closing this brief sketch that the author has produced a work which will be an imperishable monument to his long and patient labors and an honor to American surgery.

The publishers have done ample justice to the work, the paper, type, and illustrations being in the most approved form.

THERAPEUTIC HINTS.

For the Glossitis of Alcoholic.—

℞ Ac. chromici gr. x
Aq. dest. ℥ i.
M. Sig. Apply lightly to points of inflammation.

For Intertrigo.—Gently bathe the affected parts once daily with a watery solution of picric acid (1-120). When the irritation has subsided and the epidermis reformed, keep approximated surfaces separated with thin layers of absorbent cotton upon which the following powder is spread:

℞ Pulv. amyli } aa 5 parts
Pulv. lycopodii }
Cretæ præparatæ } aa 10 parts.
Bismuth subnit. }

ORIGINAL ARTICLES.

AN ACCOUNT OF A RECENT EPIDEMIC OF MEASLES IN THE NEW YORK FOUNDLING HOSPITAL; ITS RELATION TO IMMUNIZATION WITH DIPHTHERIA ANTITOXIN.

By W. P. NORTHRUP, M.D.,
OF NEW YORK;

PROFESSOR OF PEDIATRICS IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE; VISITING PHYSICIAN TO THE NEW YORK FOUNDLING, WILLARD PARKER, AND PRESBYTERIAN HOSPITALS.

MEASLES in private practice, compared with measles epidemic in a public institution, seems to bear much the same relation in respect to gravity that varioloid bears to modified smallpox. Soldiers in barracks, prisoners in penitentiaries, and children in institutions seem to suffer from the grouping of cases of this infectious disease. This is especially true of epidemics occurring during the late winter months, after a long period of housing. There is certainly no epidemic disease which has ever visited the New York Foundling Hospital that has inspired such dread as has measles; its contagiousness is greatest, its complications most constant, its sequelæ gravest, and its mortality highest. Two years ago the Medical Board of the Foundling Hospital set itself the task of keeping measles out of the institution. Its methods were so far successful that no case occurred within doors or was brought in by children returning from the out-door department during a period of sixteen months. At the end of this time, by accident, an infant in the earliest stage of the disease, sojourning in the house one night, started the epidemic which forms the subject of this paper. In its results, this epidemic was by far the most favorable of all ever experienced in the institution; it was widely distributed, least serious in its complications, and least grave in its fatalities; it appeared in every nursery, penetrated every quarantine, attacked children already suffering from whooping-cough, bronchitis, diphtheria, and tuberculosis, infecting all susceptible infants. Though the figures may not impress the practitioner, whose experience is confined to measles occurring in well-nourished children living at home, the hospital physician will appreciate them, and also the steps taken to modify the course of the disease.

Season.—This epidemic occurred during October and November. The temperature during these two

months was unusually uniform and mild, allowing efficient ventilation. The children had had, during the previous summer, abundant recreation in the open air, and were in a good state of physical health.

Distribution.—Every precaution was taken to avoid grouping, so far as possible, of children in the active stage of the disease.

Precautions.—The children's eyes, noses, and mouths were cleansed with boric-acid solution. The rooms were not kept dark, but the beds were so arranged that the eyes were turned away from the bright light and reflecting surfaces.

It was a rule to keep all children in bed, under watchful care, during at least six days from the time the temperature became normal. Special stress was laid upon this regulation, at the same time that mouth cleanliness and ventilation were carefully supervised. Under this routine practice but two patients developed pneumonia. In both the temperature had previously been normal twenty-four hours. The complicating pneumonias developed during the first stage of the disease—the first week.

Statistics.—In all, there were 258 cases and 36 deaths (13.9 per cent.). Of the 258 cases 53 were complicated with bronchopneumonia (20.5 per cent.); of these 31 terminated fatally (5.8 per cent.). Autopsy showed the presence of complicating bronchopneumonia in 31 of the 36 fatal cases.

It should be remembered that the mortality is from complicated measles occurring in susceptible children, in age from nurslings to "runabouts" 4½ years old, regardless of previous illness or general condition of nutrition.

Complicating Diphtheria — Immunization.—In many measles epidemics diphtheria, pharyngeal and laryngeal, with subsequent bronchopneumonia, has been a most pronounced feature. In the one under consideration systematic immunization was practised upon all children not believed to be, by reason of age or location in the hospital, reasonably safe from complicating diphtheria. No nursing babies were immunized—one developed diphtheria. Of those believed to be in danger of contracting this disease (in age from 2½ to 4½ years, or from location in or near nurseries in which diphtheria had been observed in the memory of Dr. N. R. Norton, the present house physician) 129 were immunized. Some of this number had probably had measles

previously; for though fully exposed they did not contract the disease. However, 77 of the number immunized against diphtheria successfully passed through measles without developing this dread complication. In one nursery, considered safe, no cases of diphtheria developed, and yet none of the patients contained in it (13 susceptible) were immunized. This nursery was at the top of the largest building—the administration building—and widely separated from others. In a second nursery, where diphtheria had been occasionally observed, nine children with measles were not immunized, and the third day after the appearance of the rash, four out of the nine had a bloody nasal discharge. Cultures made from this showed the presence of the diphtheria bacillus. It was considered that this nursery would afford a fair control upon the observations in the remainder of the hospital. When the diagnosis of diphtheria was confirmed the four patients mentioned were immediately injected with 2000 units of antitoxin; the five remaining patients were immunized. No further cases appeared in this nursery, and the four children already having nasal diphtheria recovered.

The immunizing dose of antitoxin employed was 250 units (antitoxin of the New York Board of Health). No antitoxic rash appeared after the employment of this dose. On two occasions a dose of 400 units was employed for purposes of immunization, with the subsequent appearance of urticaria. No local disturbance or constitutional reaction was observed in the cases immunized with 250 antitoxic units. As regards the accepted period of immunity following the injection of the diphtheria serum, it was interesting to note that in two cases, after respectively 31 and 33 days, pharyngeal diphtheria developed. In these, curative doses of the serum were at once administered, and the patients promptly recovered.

A CONTRIBUTION TO THE SURGERY OF EMPYEMA, WITH THE HISTORY OF AN ILLUSTRATIVE CASE.¹

BY CHARLES E. LOCKWOOD, M.D.,
OF NEW YORK.

A CASE of empyema having recently come under my observation, and having found myself much involved in doubt as to proper methods of treatment to be pursued during the long course of the affection, I have thought it might be profitable to record my experience, and thus, perhaps, elicit that of others.

Pleurisy has been divided into three varieties dependent upon the character of the exudate, whether fibrinous, serofibrinous, or purulent, the last being

the one which at present especially claims our attention. The subject of empyema and its rational treatment has, during many years, been involved in much obscurity, owing to a lack of knowledge of the etilogic factors which determine the various manifestations of the disease. The consensus of modern opinion seems to be "that every empyema is due to microbic invasion of the pleural cavity."¹ The relative frequency of the different varieties of this disease has been stated to be as follows: "In adults, 50 per cent. of all cases are streptococcic, 25 per cent. pneumococcic, and the remaining 25 per cent. may be divided among several forms, of which the tuberculous is relatively most common. In children the pneumococcus causes at least 60 per cent., possibly 75 per cent. of all cases; most of the remainder are streptococcic or staphylococcic, both tuberculosis and putridity being rare."²

The rational treatment of purulent pleurisy demands the immediate evacuation of the pus by means of one of the methods now employed, *viz.*, aspiration, simple incision, thoracotomy with resection, and siphon drainage. It is now believed by many competent observers that each of these methods is useful when applied to properly selected cases.

The following is the history of the case observed by me:

C. B., a student, aged 16 years. His father died as the result of an accident. His mother is living and well. The paternal grandmother died of cancer of the stomach, and three brothers, one sister, and one uncle of the mother died of phthisis pulmonalis.

With the exception of chicken-pox, which he had two years before, the patient had always enjoyed good health up to the date of the illness under consideration. Just previous to this he had been training for a football match, and living upon a restricted diet. On December 10, 1896, while on the cars going from New York to Sing Sing, he had a chill, followed by high fever, the temperature under the tongue being 104.8° F.; pulse, 108; respiration, 28. A careful examination showed acute pneumonia of the lower lobe of the right lung, and also friction-sounds, indicating involvement of the pleura. The disease continued six days, with a morning temperature of about 102° F. and an afternoon rise to about 103° F., respirations averaging 36 to the minute, and pulse 112. At this period his daily diet consisted of about four pints of milk. On the seventh day the temperature dropped to 100.6° F. at midnight, and on the eighth day to 99.2° F. at 3 P.M., pulse and respiration remaining the same as before. On the tenth day the temperature dropped to normal at 3 A.M., and remained so until 9 A.M., rising to 100° F. at 3 P.M. Thereafter, from the eleventh to the 15th day, the temperature was normal or be-

¹ Read at a meeting of the Medical Society of the County of New York, October 25, 1897.

¹ Whitney, "Twentieth Century Practice of Medicine," vol. vii, Section on Diseases of the Pleura.

² *Ibid.*

low normal at 9 A.M., and then gradually rose to 100° F. by 9 P.M. Physical examination now showed pleurisy with effusion. On the sixteenth day the temperature was normal at noon and 102.4° F. at midnight. On the seventeenth day at 6 A.M. the temperature was 99° F., and at 9 P.M., 103° F., and the patient suffered considerably from dyspnea and pain in the right side, respiration rising to 32 and pulse to 120 at 6 P.M.

On the eighteenth day, December 28, 1896, I saw him with Dr. Madden of Sing Sing, who had been in daily attendance, and it was decided to aspirate the chest to relieve the patient and ascertain the nature of the effusion. From the character of the symptoms the latter was suspected to be purulent. Accordingly, I aspirated the chest under proper antiseptic precautions between the fourth and fifth ribs on the right side, and drew away twenty ounces of so-called laudable pus, much to the patient's relief.

On the nineteenth day the temperature was normal at 9 A.M., and rose to 101° F. at 6 P.M. An examination of the sputum by Dr. Harlow Brooks on December 29th showed the presence of the diplococcus of pneumonia, a few pus-cells, but no tubercle bacilli. From the twentieth to the twenty-second day the morning temperature was about 98.8° F.; evening temperature, 101° F.; pulse, 100; respiration 20. On the twenty-third day, with a morning temperature of 98.8° F., there was a rise at midnight to 100° F. On the twenty-fourth day the chest was again aspirated between the fifth and sixth ribs, and twenty ounces of pus removed.

January 4, 1897, the patient was brought from Sing Sing to New York, and bore the journey well. On January 5, 1897, it having been decided that an opening should be made to secure proper drainage and the skin surface of the chest having been properly cleansed and treated with applications of corrosive sublimate 1-1000, an incision was made by Dr. W. T. Bull on the right side in the axillary line through and parallel to the fibers of the latissimus dorsi muscle over the eighth and ninth ribs, and portions of these ribs, about one and one-half inches in length, were removed by first lifting up the periosteum and sliding it off, and then with a chisel and hammer cuts were made in the ninth rib, which was then cut through with the bone-forceps. The portion of the eighth rib was also cut through in the same manner. The pleural cavity was opened, and a large quantity of pus and fibrinous material removed. The cavity was irrigated with sterilized water and two rubber tubes (with perforations) three and one-half inches in length and about one-third inch in diameter were introduced, with a silk ligature tied through them from end to end as a precautionary measure in case of breakage. A large safety-pin was placed at the external end of the tubes, and a dressing of sterilized gauze and cotton applied and held in place by a folded towel over which were fastened strips of adhesive plaster by means of tape connected with the pieces of plaster.

On January 6th, the day after the operation, the temperature at 4 A.M. was 98.4° F., and at 4 P.M.

99.8° F.; respiration, 24; pulse, 108. Dr. J. B. Walker dressed the wound, removing the soiled gauze as often as it became saturated with discharge, and substituting fresh sterilized gauze, the change of dressing being made three times in each twenty-four hours. On account of sleeplessness the patient was given trional in 10-grain doses, and for the relief of pain $\frac{1}{4}$ grain of codein was administered. Action of the bowels was secured by means of two cascara tablets given each night. On January 7th, 8th, and 9th the wound was dressed as before, the average morning temperature being normal or subnormal, and at 4 P.M., 99.2° F., respiration 20, pulse 96. January 10th the tubes were removed, cleaned, and the usual dressing applied, the temperature being 98° F. at 4 P.M. and 100° F. at 12 P.M. January 11th the dressing was changed twice; there was considerable discharge, and the temperature at noon was 98.4° F. and at 8 P.M., 100.8° F.

From January 12th to the 15th the dressing was reapplied as usual, the morning temperature being 98.4° F., evening temperature about 100.8° F. On January 16th the tubes were removed and the wound irrigated, for the first time since the operation, with sterilized normal salt solution; tubes cleaned and reinserted; temperature at 8 A.M., 98.9° F., 8 P.M., 102.8° F.; pulse, 115; respiration, 20. From January 17th to the 24th irrigation of the cavity with sterilized normal salt solution was continued once daily, and the morning temperature averaged on each day about 102° F., and on one of these days I remarked that the evening temperature seemed to have gone persistently higher since the irrigations of the chest-cavity had been employed, although the patient had freely taken a most nourishing diet. From January 25th to February 1st the same treatment was continued, the temperature retaining the same characteristics, and the patient now complained of night-sweats; the spleen was found to be somewhat enlarged. There was an anemic murmur audible over the base of the heart. There was also slight edema of the lower portion of the legs, and I feared amyloid degeneration. I will here state that on January 17th Dr. Harlow Brooks of the Carnegie Laboratory wrote me as follows: "I did an autopsy to-day upon the guinea-pig which I inoculated with the pus from your case of empyema, and I find no evidence of tuberculosis. I find the cultures made from the pus to be a mixed growth, largely composed of pneumococci." It may also be stated that the Wolff bottles for promoting expansion of the lung had daily been used by the patient, and that a careful examination of the urine revealed nothing abnormal.

Realizing that some measure must be taken to prevent further absorption of septic matter, I asked Dr. Janeway to see the case with Dr. W. T. Bull and myself, and after a careful examination he expressed the opinion that he was unable to find any evidence of tuberculous consolidation or chronic pneumonia; that there was considerable thickening of the walls of the pleural sac, and an anemic murmur at the base of the heart, and also that the spleen was somewhat enlarged. His diagnosis was that the fever

was septic, and he recommended irrigation of the chest-cavity with a solution of carbolic acid in warm water (1 to 1000) and careful observation of the effects, being sure to measure the quantity introduced and compare the same with the amount returned, so as to leave no residue in the chest-cavity. He remarked that he had seen septic fever of this character abate under such treatment. The chest-cavity was irrigated with the above-mentioned solution of carbolic acid at 6 P.M. on February 2d, with no bad effect. On February 3d the chest-cavity was irrigated with a solution of carbolic acid, and in order to improve the general nutrition it was recommended that the patient take three milk punches daily, each containing $\frac{1}{2}$ ounce of whiskey, and also a teacupful of beef juice three times a day and as much nourishing food as possible. One or two teaspoonfuls of Gudes' solution of pepto-manganate of iron after meals was added to the medication. His temperature on the evening of February 3d was 103° F.; pulse, 112; respiration, 24.

On February 4th the temperature remained normal all day, the same treatment being continued, and we had an illustration of Sir Joseph Lister's principle "that the untoward consequences of operations are frequently due not to the operation itself, but to the poisoning of the wound by the products of decomposing discharges and poisoning of the system generally by absorption of these products. The decomposition is due to low organisms introduced from without, and may be eliminated by the use of such substances as will prevent their development or destroy them when present." The only question is whether it is safe to use such agents in a suppurating pleural sac immediately after an operation or during the following few weeks. In this case, during the first ten days following the operation, thorough drainage was secured by means of proper tubes and sterilized dressings frequently changed, with the effect that septic fever still continued. Irrigation with sterilized normal salt solution was then used, with the result that the fever was increased and did not abate until the carbolized water was used. I may add that owing to the fact that air was drawn into the cavity through the external opening, as was shown by the patient breathing and whistling through it, decomposition was produced by the introduction of low organisms with the air.

On February 5th the tubes were removed, cleaned, and the cavity irrigated with carbolized water, the temperature remaining normal, but the patient had a profuse perspiration during the night. On February 6th and 7th the same treatment was continued.

On February 8th the two tubes were removed and the cavity irrigated with carbolized water and a single perforated tube, one-half inch in diameter and three inches in length was introduced in the opening. There has been no rise of temperature above normal since February 2d. On February 9th the opening in the chest was observed to be growing smaller. There was some difficulty in inserting the large tube; patient daily takes three milk punches with one-half ounce of whiskey in each, three tum-

blers of beef juice, one ounce and a half of Gudes' pepto-mangan, and three pills containing 1 grain of powdered iron, $\frac{1}{100}$ -grain of strychnin, $\frac{1}{100}$ -grain of arsenious acid, and $\frac{1}{100}$ -grain of phosphorus, and also a most nourishing diet. February 11th to 13th, temperature normal; same treatment continued. On February 14th the large one-half inch tube was removed, and a smaller tube, one-quarter inch in diameter and three inches in length inserted; irrigation continued; temperature normal; drainage perfect; treatment continued. February 18th, the patient took an hours' ride in a carriage. On February 22d, he went home.

February 26th: Temperature normal during the twenty-four hours; no pain; patient walked around the block in the open air. He is using the Wolff bottles and an elastic exerciser to promote lung expansion, as he shows a tendency to stoop over and lean toward the right side, due to contraction of the pleural cavity.

I will add that during all this period particular attention was paid to the diet, the patient taking daily one pint of beef juice, a bottle of beer with his dinner, and three milk punches each containing one-half ounce of whiskey.

March 1st: Dr. Walker dressed the wound, irrigating the sinus with carbolized water and removing the one-quarter-inch tube. On coughing only about twenty drops of pus was expelled. A new perforated rubber tube one-eighth of an inch in diameter and two inches in length was now inserted, and the wound dressed with sterilized gauze.

March 8th: The same method of irrigation and dressing have been continued. The tube was found in the dressing when the latter was removed, and it was not reinserted. The sinus was now one and one-quarter inches in depth, and it was wiped out with cotton saturated with carbolized water, and a piece of gauze put in the opening. March 9th: A piece of gauze saturated with balsam Peru was inserted. March 13th: Sinus one and one-eighth inches in depth. A solution of nitrate of silver sixty grains to the ounce was applied to its walls and it was dressed with a piece of gauze dipped in thioform.

From March 14th to March 30th the sinus was daily dressed by cleansing with carbolized water, and a small piece of gauze saturated with balsam of Peru was inserted and then covered with a pad of gauze which was held in place by strips of adhesive plaster.

April 2d: The patient went to the country, and was instructed to apply daily the same dressing.

April 26th: The patient was seen by Dr. W. T. Bull and myself. Sinus has been daily dressed as previously described, and as there was no evidence of necrosis, it was decided to discontinue previous method of dressing and apply an ointment consisting of ten grains of boric acid in one ounce of white vaselin, under which application the sinus closed in about three days, healing soundly, and patient has remained well until the date of writing.

May 15th: I made careful measurements of pa-

tient's chest with the following results: On the right side a line drawn from the spinous processes of the dorsal vertebræ, on a line with the nipple, to a marked point on the middle of the sternum measured, on inspiration, $15\frac{3}{4}$ inches, on expiration, $14\frac{3}{4}$ inches. The same measurement on the left side, on inspiration was $16\frac{3}{8}$ inches, on expiration, 15 inches. Measurement of the whole chest over the same line: Inspiration, $31\frac{1}{2}$ inches; expiration, $29\frac{1}{2}$ inches. This shows a difference between the two sides on inspiration of $\frac{5}{8}$ of an inch, and on expiration of $\frac{1}{4}$ of an inch—a good showing, it seems to me, in consideration of the circumstances.

Summary.—The points of interest in connection with this subject and the history of the case observed by me are as follows:

1. The necessity of securing the highest point of nutrition in cases of pneumonia to sustain the vital activity and power of the body-cells to enable them to limit the ravages of the pneumococcus.

2. The importance of an early operation in empyema as affecting the prognosis, owing to the results of delay in allowing the increase of fibrinous effusion into the pleural cavity and thickening of the walls of the pleural sac, thus hindering healthy repair and lung expansion after evacuation of the pus.

3. The marked effect of irrigation of the suppurating pleural cavity with a solution of carbolic acid (1-1000), and thorough drainage in arresting the septicemia after its duration of four weeks following the operation, thus demonstrating the principle of the importance of preventing the entrance of low organisms into a suppurating cavity, or of destroying them after entrance in order to prevent or arrest septic poisoning.

4. The evidence given in this case by a characteristic temperature on the sixteenth and seventeenth days of the illness and on following days which pointed to purulent infection, although it has been shown that pus accumulation may occur in the chest with no sign of fever.

5. That in the case described there was evidently a perforation of the lung, thus allowing communication between the bronchi and the pleural sac which favored putrefaction, and that in such cases, characterized by putrid pus, carbolic irrigations are necessary.

To sum up my ideas after a limited experience and a careful review of the literature of the subject, aspiration is found to give twenty per cent. of cures, as shown by Holt's cases, and is sometimes efficient in children, tuberculosis, and in other cases which in the present state of our knowledge it is difficult to differentiate, and is, therefore, an uncertain method of treatment.

Simple incision with drainage and without resec-

tion, according to some statistics, gives equally good results as thoracotomy with resection, and reliable testimony seems to recommend it as particularly adapted for the disease in infants and in the debilitated, as the operation can be done without a general anesthetic, local anesthesia being sufficient, though further facts are needed, as Dr. Morrison says, before its position can be established. Thoracotomy with resection, when performed early, so as to secure thorough and efficient drainage, and combined with proper after treatment of the wound thus preventing the entrance of germs and the avoidance of irrigation, if possible, would seem by the now accumulated experience of many observers to offer the best prospect of a successful issue in the majority of cases. Still, that antiseptic irrigation may prove useful in certain instances, is, I think, proved by the course of events related by me. Siphon drainage would seem, according to the results obtained, to be a justifiable procedure under certain conditions.

RATIONAL GYNECOLOGY.

BY JOHN H. KELLOGG, M.D.,
OF BATTLE CREEK, MICH.

(Continued from page 791.)

Kneading with the Closed Fist.—(Fig. 11.) With the closed fists used in alternation work along the whole course of the colon, beginning at the upper end of the cecum and directing the movements upward to the lower border of the ribs to a point midway between the umbilicus and the sternum, at which the median line is crossed, then down on the opposite side, ending at a point close to the pubic bone, and just to the left of the median line.

The rate of movement should not be more than thirty per minute or two seconds for each hand. Care should be taken not to release the pressure upon the bowels with one hand until the other hand has been placed in position just in advance and close to it. Care must be also taken to follow the curves of the colon.

Kneading with the Thumbs.—(Fig. 12.) With the fingers behind and the thumbs in front, grasp the loin on each side between the thumb and the fingers. The right hand should thus grasp the lower end of the cecum, while the left hand grasps the upper part of the descending colon just beneath the ribs. Movements are then executed in an upward direction with the right hand, and in a downward direction with the left, the operator facing the patient's feet.

Mass Kneading.—(Fig. 13.) Still another procedure of value in abdominal massage is what may be termed "mass kneading," in which the operator endeavors to seize the abdominal contents with both

hands, manipulating them precisely as a baker does a mass of dough, the fingers of one hand being used in opposition to the heel of the other hand, and the abdominal contents kneaded and manipulated between the two hands.

upon the recti muscles, the operator facing the patient, the muscles are rapidly manipulated by the thumbs, working from below upward.

Replacement of the Abdominal Viscera.—(Fig 15.) This is necessary in many cases of abdominal mas-

FIG. 11.

Showing fist kneading of colon.

Rolling.—When the abdominal walls are considerably relaxed, they may be gathered between the hands placed parallel with the body, one on each side, and thus compressed, rolled, and shaken, together with the intestinal contents. Care must be taken to include the abdominal contents, and not

sage as a preliminary procedure. It is especially required in women, since in the majority of invalid women some of the viscera are almost certain to be misplaced. The stomach is displaced from two to five inches below its normal position in nineteen out of twenty of all adult civilized women who have

FIG. 12.

Showing thumb kneading of colon.

merely the skin and subcutaneous tissue or a mass of subcutaneous fat. A very effective mode of masseing the recti muscles is to cause the patient to raise the head (Fig. 14), then, with both hands placed upon the abdomen in such a manner that the thumbs rest

worn the conventional dress. A movable or floating right kidney is to be found in at least twenty-five per cent. of women who are likely to require abdominal massage. The liver is also not infrequently found displaced. The patient lies upon the couch

with the head, not the shoulders, elevated, and with the knees well drawn up so that the abdominal walls shall be as thoroughly relaxed as possible. First of all, the patient is made to take several deep breaths, care being taken to see that the abdomen is

Shaking and rolling movements are valuable as a preliminary measure, or used in alternation with the lifting movements, as a means of loosening up, so to speak, the abdominal contents, to prepare them for gliding easily into their normal positions. The lift-

FIG. 13.

Showing mass kneading.

expanded well with each inspiration.

The next procedure is to lift the entire intestinal mass. To do this the masseur stands with his right side to the patient, facing the patient's feet, and places one hand in either groin, the hand resting upon the ulnar borders (little fingers), and having

ing movements should be executed from three to six times in alternation with rolling or shaking movements.

Inspiratory Lifting.—I was led to adopt this means of lifting the abdominal contents by a series of studies for the purpose of noting the influence of

FIG. 14.

Showing method of kneading abdominal muscles.

the direction of Poupart's ligament. The hands are made to move slowly upward, the ulnar borders being at the same time crowded as deep as may be into the pelvis so as to grasp as much as possible of the abdominal contents, which are then drawn forcibly upward. (Fig. 16.)

respiration upon intrapelvic pressure. I observed that the ascent and descent of the uterus in respiration may be greatly increased by modifying the inspiratory and expiratory movements. For example, by directing the patient to take a deep breath and then asking her to force the breath downward, it

was noticed that the pelvic contents were forced downward to a notable extent; while by causing the patient to completely empty the lungs, and then, with the glottis closed, to make a forcible effort, the pelvic and abdominal contents were made to ascend

tory force is used in lifting the abdominal contents. In this movement the patient should be made to expand the chest, both the upper and the lower parts, as much as possible, as it is desired to suppress the action of the diaphragm so far as may be done vol-

in a very remarkable manner. In one instance it was noted that the uterus which lay quite low in the pelvis was drawn up more than an inch with each respiratory effort executed in the manner described. The patient, lying upon the back, with the hands at the side, so as to relax the abdominal muscles as

untarily, while bringing into most active play those muscles of inspiration which act upon the ribs. This not only produces a powerful upward draft upon the abdominal contents but at the same time enlarges the waist, and makes room for the viscera, so that their ascent is facilitated. At the same time that

FIG. 16.

Showing method of lifting the viscera.

much as possible, is directed to first take a full breath, breathing as deeply as possible, and then to completely empty the lungs. Then instead of drawing in the breath as usual, the glottis is closed, and a strong inspiratory effort is made without the admission of air. By this method the whole inspira-

the patient executes inspiratory lifting the abdominal contents should be lifted from below with the hands as previously directed. The patient should not be allowed to refrain from breathing more than ten or fifteen seconds. During this time, however, from three to five vigorous inspiratory liftings may be

made. Then the patient may be allowed to take a few ordinary respirations, and finally a deep breath, followed by a complete expiration and a renewal of the inspiratory lifting. This procedure is of special value in connection with pelvic massage.

slightly elevated, arms by the side, and the head (not the shoulders) supported by a thin pillow. The following brief descriptions of each of the manipulations will be useful to those who may be desirous of making practical use of massage as a

FIG. 17.

Showing apparatus for kneading the abdomen.

Pelvic Massage.—Pelvic massage should never be undertaken by any person who is not a qualified and experienced physician. The success of this procedure depends, first, upon a correct diagnosis and secondly, upon special aptitude on the part of the masseur. It is scarcely possible for a person to be-

curative measure:

Preliminary Procedures.—The manipulations practised in pelvic massage are rendered very much more efficient by the application of a few preliminary movements for the purpose of placing the abdominal and pelvic contents in the most favorable condition

FIG. 18.

Showing apparatus for pelvis tilting.

come proficient in this special application of massage without personal instruction from some one who has by long experience become skilled in its employment and in the selection of cases to which it is adapted. The patient lies upon the back, with the heels well drawn up, the knees separated, the hips

possible. It should be remembered that in pelvic displacement there will also be found displacement of the abdominal contents. When the uterus falls backward the folds of intestines which have formerly been behind it, aiding and supporting it, change their position, overlying it above and in front.

Replacement of the uterus requires, first of all, replacement of the intestines; in other words, room must be made for it in its old position before it can be restored to its normal place.

The preliminary movements which I have found most effective are: (a) deep breathing; (b) lifting

placed in perfect position, then lifted upward and forward as far as possible without giving too much pain. The extended fingers of the right hand are at the same time pressed upon the abdominal wall just above the pubes, so as to impinge upon the fundus, covering as large an area of the uterus as possible.

FIG. 19.

Showing head and leg raising forward.

abdominal contents; (c) inspiratory lifting, all of which have already been described. Essentially the same movement as lifting the viscera may be executed with the patient in the knee-chest position. The masseur stands with his back to the patient's head, and reaching around the patient with one arm,

Firm, intermittent pressure is then made, continuing two or three seconds, with intervals of one or two seconds, this being repeated six to twelve times. In this procedure the pressure of the external hand will fall chiefly upon the top of the fundus.

Digital Kneading of the Uterus.—The fingers of

FIG. 20.

Showing head and leg raising backward.

drags the bowels upward during inspiration.

Intermittent Compression of the Uterus.—The preliminary movements being completed, one, or when possible, two fingers (index and middle fingers) of the left hand are introduced into the vagina and crowded upward behind the cervix, the uterus being first

the left hand being returned to the first position behind the cervix, thus supporting the organ, the fingers of the right hand execute a circular digital kneading movement, beginning at the top of the fundus, and enlarging the circle until the fingers are made to press down the sides of the uterus and all about it.

Lifting Movements.—The preceding manipulations will have completely freed the uterus from the overlying intestines so that the top of the fundus will be in immediate contact with the peritoneal surface of the anterior wall of the abdomen. By the combined action of the internal and external hands the uterus can now be freely lifted forward so that its form may be easily outlined by the fingers of the right hand. The action should be intermittent. After lifting it forward as far as possible without inconveniencing the patient the uterus is released, and allowed to drop down, then again lifted, the action being repeated six to twelve times, at intervals of two to three seconds the uterus being held forward for a like period.

Vibration of the Uterus.—While supporting the organ with the fingers of the left hand behind the cervix the thumb or one or more fingers of the right hand is applied to the top of the uterus, and fine vibratory movements are communicated to it. This is a powerful means of stimulating the uterine circulation.

Digital Kneading of the Appendages.—In pelvic massage the manipulations should not be confined to the uterus alone. The ovaries, tubes, and the broad and round ligaments may be massaged thus: After lifting the uterus well forward, freeing it from the overlying intestines, the fingers of the left hand are directed toward an ovary. Starting as low down as possible, firm pressure is made in an upward direction, while the fingers of the external hand are made to cooperate in an effort to grasp beneath the ovary and tube and lift them forward. At the same time, gentle digital kneading movements are executed, the pressure of the external (right) hand being directed toward the fingers placed internally.

Digital Kneading of the Round Ligaments.—The fingers in the vagina should be directed toward the inguinal canal while digital massage is executed by the fingers of the right hand, traveling in a curved line from the external ring along the side of Poupert's ligament and toward the fundus. The internal fingers will to some extent follow the movements of the right hand so as to compress the tissues between the fingers of the two hands.

Stretching of Adhesions and Kneading of Exudates.—When adhesions and exudates are present, firm pressure should be made directly upon the bands of adhesion or the masses of exudate with the tips of the fingers opening internally, counter-pressure being made externally, and, so far as possible, the morbid parts should be grasped between the fingers of the two hands and thus subjected to digital massage. Adhesions are also stretched by the lifting movements of the uterus previously described.

Nerve Compression.—The sacral plexus of the spinal nerves and several of the lowermost pairs of ganglia of the sympathetic are accessible to digital pressure through the vagina, and in appropriate cases these, as well as other nerve structures, may be stimulated by gentle compression in connection with other procedures. One of the largest nerve masses accessible to compression through the vagina is the hypogastric plexus, which is located on the anterior surface of the sacrum just below the promontory. A row of four or five sympathetic ganglia lie on either side of the median line just over the junction of the sacrum and the ilium, the anterior aspect of the sacro-iliac synchondrosis. A single ganglion (coccygeal) lies in front of the coccyx. Pressure made upon these points stimulates the ganglia and their branches, and by this means excites the circulation in the pelvic vessels. Nerve compression in this region as in other parts of the body must be applied with very great discretion. This procedure should never be employed in cases in which inflammation, active congestion, or excessive hyperesthesia exist. It is only appropriate in cases of passive congestion, atony, subinvolution, and general relaxation of the parts.

It is generally well to alternate some of the foregoing procedures, especially the lifting and kneading movements, instead of adhering closely to the order in which they have been given for the purpose of precise description. Upward deep kneading movements executed with the closed fist may be advantageously alternated with the other movements mentioned.

Massage of the Abdominal Muscles.—After the internal manipulations, the muscles of the lower abdomen and inner thighs should be gently massaged. The procedures most useful are the following, employed in the order named: Tapping, hacking, spitting, centripetal friction, and finally stroking.

Finishing Movements.—(a) Knee separating; breathing. The patient should inspire while separating the knees, and expire while closing them. The vigor of the exercise may be increased by making a slight resistance to the movements of both adduction and abduction. The movements should be made at the rate of ten to twelve per minute. (b) Hip raising, breathing in as the hips rise and breathing out as they sink. This movement should be repeated from four to eight times. The movements of the knee separating, hip raising, and breathing may be executed simultaneously.

The treatment should be concluded by having the patient turn upon the face, and then administer percussion, tapping, hacking, spitting, beating, and clapping over the sacrum and fleshy portions of the hips.

The following points should be carefully observed in the administration of pelvic massage:

1. Never administer pelvic massage to erotic patients, nor in cases of vaginismus, acute pyosalpinx, pelvic abscess, growing tumors of the uterus or ovaries, rectal ulcer, acute vaginitis, irritable urethra, or inflammation of Skene's glands, until these conditions have been removed. The best results are obtained in cases of subinvolution of the uterus, relaxed ligaments, recent exudates, and passive congestion with little sensitiveness. Kesch recommends that uterine massage be applied especially during menstruation, but does not give valid reasons for the recommendation. My opinion is very positive that massage should be discontinued during this period.

2. Before treatment have the patient thoroughly empty the bladder and bowels, employing an enema if necessary, or a colocylyster. A hot vaginal douche should also be administered.

3. No movements should be made with the hands used internally except with the ends of the fingers.

4. The force employed should generally be sufficient to produce slight pain.

5. In cases of flexion the flexion should, if possible, be straightened during the manipulation. In all cases of displacement the uterus must be restored to the proper position.

6. Care must be taken to have the patient breathe deeply and regularly during treatment.

I have devised an apparatus for kneading the abdomen (Fig. 17) and a tilting-table (Fig. 18) which elevates the pelvis as in the knee-chest position. I find the tilting-table especially valuable as a means of vasomotor gymnastics and draining the pelvis. This apparatus is of great service in all forms of pelvic congestion and in ovarian disease, uterine catarrh, displacement of the pelvic viscera, and in rectal disease of various forms. After spending a few minutes upon the tilting-table, rising and falling with its oscillations at the rate of about eight times a minute, patients suffering from the maladies named and similar ones almost invariably express themselves as experiencing a marked sense of relief. The effects of this mode of passive exercise of the blood-vessels are so agreeable that patients are inclined to continue the application as long as they are allowed to do so. This apparatus also aids in the restoration of the displaced viscera. This is accomplished by adding to the tilting-table a device by means of which the pelvis is lifted free from the table while the patient lies upon the face, thus causing the abdominal wall to sag downward. As the table is tilted, the patient is lifted into such a position as to cause gravity to make an upward (in relation to the normal position) pull upon the viscera of the trunk.

I find Swedish gymnastics of various forms especially serviceable in correcting those abnormal bodily shapes which favor the development of pelvic disease, and in shortening and strengthening weak abdominal muscles—two things which I consider most important in the curative treatment of pelvic displacements. Those movements are especially useful which act upon the muscles of the trunk. The accompanying cuts show a few of those which I have found most serviceable. (Figs. 19, 20.) Some fourteen years ago I visited Stockholm, Sweden, for the purpose of becoming acquainted with this system of gymnastics which is universally acknowledged to be the most thoroughly scientific of all. Since that time I have made constant use of it on an extensive scale, and I am fully persuaded that it is one of the most essential and important factors in the radical treatment of curable pelvic disorders.

Light calisthenics, especially such as bring into play the muscles of respiration, are of the highest value as a measure for building up the patient's general health.

Swimming I regard as especially helpful in this class of cases provided, of course, that the exercise can be practised under favorable conditions. The enforced and vigorous action of the adductor muscles of the leg and of the muscles of the back during swimming is highly conducive to the correction of one of the fundamental causes of visceral prolapse. I might dwell at considerable length upon the details of the methods of treatment referred to, but space forbids. I will only add that the results obtained during the last twenty years in the treatment of many thousands of women suffering from chronic pelvic disorders have been in the highest degree gratifying and encouraging. Scores of women previously sentenced to submit to surgical procedure of various sorts have by the measures outlined been enabled to escape from unnecessary and mutilating operations, and are now in the enjoyment of good health.

In conclusion, I wish to enter the earnest plea that the gynecologist in the practice of his specialty shall cease to fix his eye so exclusively upon the organs which occupy the pelvis, but that he shall extend the domain of his investigations and therapeutic endeavors to the organs of the adjacent cavity, the abdominal viscera, giving particular attention to the sympathetic nervous system. Indeed, must it not be conceded that the gynecologist is only prepared to deal intelligently with the morbid conditions which may manifest themselves in the pelvis, when he has thoroughly investigated every region and function of his patient, and that his supreme effort should then be, not simply to cure some pelvic disorder compre-

hended under some specific name, but to restore to health and physical soundness the whole system; in other words, that he shall undertake to cure his patient rather than her malady?

CLINICAL MEMORANDUM.

A FATAL CASE OF DIFFUSE RECURRENT LEPTOMENINGITIS CAUSED BY OTITIS MEDIA.

By GEORGE H. POWERS, M.D.,
OF SAN FRANCISCO.

THE patient, a man aged thirty-five years, and in splendid physical condition, called me early on the morning of July 30, 1897, having been suffering with excruciating pain in the right ear during several hours of the night. He had been swimming—a form of exercise in which he frequently indulged—on the 28th, and began to have moderate trouble with his ear on the 29th, attributing it to the effect of the water which he had taken into his mouth and nose, as he had had a previous experience of the same kind. On the former occasion he had otorrhea during three weeks, from which he recovered with no sequelæ except a slight deafness in the affected ear. During the eighteen months or more which intervened between the first and second attack he was said to have had no symptoms whatever, but since his death I have learned from his business associates that he had for some time shown unwonted irritability and occasionally a sort of obstinacy quite foreign to his previous habit.

At my first visit I found a copious discharge of bloody serum from the ear with hardly a trace of pus. He suffered from severe cephalalgia, but there was no special tenderness in or about the ear, and no swelling.

Thorough cleansing of the meatus with dry cotton relieved the pain in the head remarkably, and with a dose of antikamnia, 10 grains, he slept some hours. At noon I was again summoned, and found the pain quite as great as before. After cleansing the meatus I found a small sac distending the skin anteriorly and superiorly which I incised, and thus released a quantity of blood and serum, but no pus. Again he was greatly relieved. At 4 P.M. the pain had returned to some extent, but was not as severe as before, and again it was relieved by a simple dressing. At 6 P.M. I found him asleep, and did not rouse him. At 8.30 A.M., July 31st, I was hastily summoned, and found the patient struggling with members of the family who were trying to keep him in bed, unable to comprehend when spoken to, eyes staring, pupils dilated moderately, pulse about seventy and very full. I sent at once for Dr. J. R. Laine, the consulting surgeon of the railroad company by which the patient had been employed, who responded, and with me took charge of the case, confirming the diagnosis of meningitis.

The discharge from the ear was still a sanious fluid, and there was no swelling or apparent tenderness about the ear or the mastoid, but in order to get an examination, otherwise impossible on account of the constant motion of the patient, we gave him chloroform and freely incised

the membrana tympani, but without revealing any pus or giving any relief. Proper treatment for the condition of meningitis was at once instituted and another consultation arranged to be held at noon, then only ninety minutes away, but when we again reached his bedside we found that the patient had just expired without regaining consciousness.

So sudden a death demanded a *post-mortem* examination, which was made by Drs. Philip King Brown and Clarence Quinan, and clearly showed that no means we could have employed, operative or otherwise, could have saved life, there being extensive disease of the inner table of the skull resulting from a former attack of otitis media, lighted up and leading to a fatal result by bacteria introduced on the occasion previously mentioned, probably from the water in which the patient was bathing.

Autopsy.—External examination of the head revealed some discoloration of the skin, most pronounced behind the right ear. The blood-vessels of the scalp were injected, and bled slightly when incised. The outer table of the skull appeared to be normal. The vault of the cranium was now removed, the inner table of which also appeared to be normal. The cerebrum and cerebellum having been removed, inspection of inferior half of the skull revealed the following conditions: An old fracture line crossed the posterior third of the squamous portion of the temporal bone, its direction being nearly vertical from above downward and a little forward. The outer table of the skull over the fracture line exhibited several linear openings from 3 to 5 mm. in length. These were only seen after removal of the pericranium. The portion of the skull removed with the right temporal bone did not include the entire length of the fracture. The fracture corresponded very closely to a line drawn from the right parietal eminence to a point about one-quarter of an inch in front and a little above the right external auditory meatus, where it terminated, the fracture line crossing the temporoparietal suture about one and one-quarter inches in front of the posterior angle (inferior) of the right parietal bone. At the lower (temporal) end of the fracture the skull was very thin and exhibited two linear openings.

On the inner table a deep groove corresponded to the fracture line and bounded anteriorly a circumscribed area of necrosed bone covered with numerous exostoses. This area of necrosis covered the entire posterior third of the squamous portion of the temporal bone, and extended upward upon the adjacent parietal bone more than an inch above the suture line; below it extended over the external third of the anterior surface of the petrous portion of the temporal bone as far forward as a point corresponding to the superior semi-circular canal. Posteriorly, the superior border of the sigmoid groove of the lateral sinus sharply defined the area of bone necrosis. By measurement the bone was found to be affected a distance of about two inches from above downward and one inch from before backward.

On section of the temporal bone through the upper third of the tympanum that cavity was found to be filled with blood-clot, as was also the mastoid antrum. The malleus was still adherent to the remains of the membrana

tympani, which amounted to little more than a ragged fringe about the annulus tympanicus.

No recognizable quantity of pus was found either in the tympanic or mastoid cavities; the portion of the mastoid process exposed in this section was somewhat injected, but otherwise appeared to be normal. The cavity of the antrum was evidently continuous with the lower posterior part of the necrosed inner table (that is, the uppermost pneumatic cells underlay this portion).

The blood-vessels of the dura mater were engorged with fluid blood. Very little blood was found in the superior longitudinal sinus. Over an area corresponding to the necrosed bone the dura was thickened. Over the entire anterior two-thirds of the right hemisphere as well as over the middle lobe of the left hemisphere the pia was quite opaque, of a yellowish-white color, an abundant purulent exudate covering the convolutions.

Horizontal serial sections of the right and left hemispheres showed that the arteries of the cerebrum ovale, major and minor, were injected, punctate hemorrhage following incision. The white matter appeared to be normal. The lateral ventricles were normal, as was also the choroid plexus. Removal of the corpus callosum and fornix revealed no abnormalities. The venæ Galeni were somewhat engorged; third ventricle normal. The sections were continued on down to the divergence of the crura cerebri. The corpora striata and internal capsules were normal on both sides. The arteries of the base were perfectly normal. They did not contain much blood, and what little was found was fluid.

Cultures were taken as follows: (a) Of the cerebrospinal fluid; (b) of the fluid in the cavity of the tympanum; (c) of the exudate on the hemispheres.

Culture (a) was a pure culture of the streptococcus pyogenes aureus.

Culture (b) was an almost pure culture of the streptococcus pyogenes. Over ninety per cent of each colony was made up of this organism. A single colony of the staphylococcus pyogenes aureus was found, and also a single colony of bacilli, both of which were probably accidental inhabitants of the cavity.

Culture (c) was a pure culture of the streptococcus pyogenes aureus.

MEDICAL PROGRESS.

Treatment of Adenoids During the First Year of Life.—CUVILLIER (*Rev. de Therapeut.*, October 15, 1897) recommends that pharyngeal or postnasal adenoids, during the first year of life, be treated medically before instituting their surgical removal. He finds that salves and powders are less serviceable than the instillation into the nasal cavities of a few drops of mentholated (1 to 60) or resorcinated oil (1 to 25 or 1 to 50) while the head is held backward. Four or five drops should be introduced into the nostrils and this treatment repeated every three hours. Cotton saturated with a borated solution of glycerin may be used in each nostril as a tampon to loosen the mucus collections. These maneuvers should be made with prudence

in order to avoid the possibility of laryngeal spasm. When, notwithstanding this treatment, coryza frequently occurs, the adenoid growth should be removed, the necessary procedure being no more serious at this age than at any other. No anesthetic is required. The operation should be quickly performed, with an adenoid forceps bent almost at a right angle and very short, corresponding to the size of the nasopharyngeal cavity of an infant of this age. It is better to make only one or two bites with the forceps at a time, and, if necessary, the procedure may be repeated once or twice at a later date. Antisepsis of the nasal cavity may be secured by the instillation of mentholated or resorcinated oil, the latter being less painful than the former. The results after operation are excellent. Respiration is re-established through the nose, nutrition becomes regular, and the growth of the infant resumes its normal course.

Shall We Return to Antisepsis?—MIKULICZ (*Deut. med. Wochenschr.*, June 24, 1897), in a recent article, takes the position that as it is practically impossible to secure perfect asepsis of the hands, it would be better if surgeons would return to the use of antiseptics which have been so generally discarded in these latter days. In hospital work he advocates the use of thin white cotton gloves, known to the trade as "footmen's thin gloves," which should be sterilized, several pairs being used during the course of an extensive operation. The hands should, of course, be rendered as free from germs as possible. Moist towels should be worn over the nose and mouth, as it has been found that even in quiet speech, particles of saliva are ejected from the mouth. Thus two important sources of infection, the hands and the breath, are eliminated as far as possible. From the point of view of the bacteriologist many spectators are objectionable at operations.

The Segregation of Lepers.—IMPEY writes to *The Medical Week*, October 15, 1897, calling attention to the unnecessary expense and annoyance of the detention of anesthetic lepers, who cannot, in his opinion, communicate the disease to others, since the bacilli of this disease are not found in any tissues except the nerves. For practical purposes all lepers should be divided into two classes: (1) tuberculous and mixed leprosy, and (2) pure anesthetic leprosy.

In his own country, Cape Colony, Impey states that there are, so far as known, about 2000 cases of leprosy, not more than one-third of which are of a tuberculous or mixed type. Anesthetic leprosy is of only about four-years' duration, and to herd the cured and non-contagious patients with the dangerous ones, is a wrong to them and an unnecessary expense to the State, and it also renders it almost certain that some of the patients will, sooner or later, contract the disease in the tuberculous form.

Fined for Endangering the Public Health.—A woman in Belfast, Ireland, was recently fined for allowing her niece to go to school and attend an examination while suffering from typhoid fever.

THE QUARANTINE BILL BEFORE CONGRESS.

In another column is presented in full the bill recently introduced in the United States Senate by Senator Caffery of Louisiana, embodying the recommendations upon this subject made by the President in his Message and by the Secretary of the Treasury. Senator Caffery comes from the State which suffered most severely during the recent epidemic of yellow fever not only in the number of cases and deaths which it occasioned, but also in the paralysis of its commerce and resulting financial distress. He knows from personal experience and familiarity with the views of his constituents the necessity of uniformity in the quarantine laws and of a strong arm of authority with which they may be administered. Although Louisiana can justly boast of one of the best quarantine organizations of all the Gulf States, she suffered from the want of an equally efficient quarantine service in the State which happened to be her nearest neighbor. Moreover, Louisiana is the State from which came the greatest opposition to the former National Board of Health. Indeed, it was through the war waged upon that body by the local quarantine authorities of Louisiana that its efficiency was impaired and its sinews were cut. The recent experience has evidently wrought a change

of heart. What she asks now is to be protected from her friends—her neighbors—by the strong hand of the Federal Government. This can only be accomplished by a uniform law applicable to all States, the administration of which rests in a centralized organization. The aforesaid bill makes the National Quarantine as administered by the Marine Hospital Service paramount to all local quarantine boards, so that no ship can enter any port without submitting to the regulations of the Treasury Department, as administered by the Marine Hospital Service, nor can any ship be detained for quarantine inspection after it has been passed by the Marine Hospital authorities. The bill also provides that whenever yellow fever, cholera, plague, or typhus fever has passed the quarantine of the United States, or in any manner any one of these diseases has gained entrance or has appeared within the limits of any State or Territory, the quarantine regulations of the United States, prepared under the direction of the Secretary of the Treasury, shall be supreme and have precedence of State or municipal laws, rules, or regulations. The President is authorized to enforce the same within the limits of any State or Territory, to control the government of vessels, railroad trains, vehicles, or persons within any State or Territory, to prevent these diseases from spreading from one State or Territory to another State or Territory, and to prevent unnecessary restrictions upon interstate commerce.

The people of the States recently afflicted by the scourge of yellow fever cannot shake off the horrors and hardships of that calamity, and look forward with dread and apprehension to the return of warm weather. The Marine Hospital Service is already organized on a sufficiently comprehensive basis to enable it, promptly upon the enactment of this bill, to extend its equipment and be ready at the first indication of any awakening of the dread disease to fulfil efficiently all the requirements of its new functions. By the passage of this bill without undue delay, the existing confidence in the uniform vigorous enforcement of quarantine and of sanitary regulations which has characterized the work of the Marine Hospital Service, will restore a feeling of security to the business interests of the South and of safety to the people.

Congress has before it for enactment this winter no measure of more pressing urgency than this Quarantine Bill introduced by Senator Caffery.

THE REGULATION OF THE PRACTICE OF MIDWIVES IN NEW YORK.

It is gratifying to know that at last there is an encouraging prospect of a general law being enacted at Albany this winter regulating the practice of midwives. From the year 1808, when a committee of the Medical Society of the County of New York waited upon Mrs. Louisa Kastner, then unwarrantedly advertising herself as a midwife authorized by the Society, and requested her to submit to examination, down to the present time, the practice of midwifery by uneducated persons and the horrible fatality attending it has been frequently discussed by that body; committees instructed to draft legislative bills in reference thereto have been repeatedly appointed, but their efforts have never resulted in the enactment of a general law.

It is difficult to understand why such an important branch of medicine should ever have been differentiated from other branches and its practice lawfully placed in the hands of an uneducated class. The explanation of this paradoxical condition of affairs probably lies in the false dictum, "Labor is a physiologic process." Quoting from an editorial by Dr. E. P. Davis of Philadelphia, which recently appeared in these columns, we reiterate the sentiments of this writer: "The dangerous half-truth, 'Labor is a physiologic process,' has shielded the indolence and greed of many obstetric teachers." The same trite and moss-grown principle has been equally efficacious in the protection of the ignorant midwife—at the sacrifice of thousands of lives.

The recent awakening of the profession to the possibility of securing relief by legislation from many professional and social abuses has stimulated the perennial effort to regulate this important department of obstetric practice. The Society of Medical Jurisprudence at its meeting in November appointed a committee to consider and report to the Society what legislation, if any, is desirable to regulate the practice of midwives in this State, and what steps this Society should take to that end. This committee has drafted a bill vesting in the Regents of the State University the power to license midwives, upon the recommendation of medical examiners having in turn power to prescribe time, place, and character of examination; and vesting in the State and local Health Boards power to prescribe the sani-

tary safeguards under which the practice of midwifery shall be carried on. The right to continue their avocation, of those midwives who have already practised long enough to acquire some experience and clientele, is recognized. To provide for this two classes of midwives are created in the proposed law: First class, embracing those who after a year's study shall show their competency by examinations; second class, consisting of those offering evidence of no better qualifications than their actual practice during two years prior to the law's enactment.

A covert but prevalent abuse attending the practice of midwives is the prevalence in their ranks of professed abortionists. The licensing and registration of midwives in accordance with the requirements of the proposed law will do much to raise the standard both morally and mentally of those entering this calling. But even then the desirability of absolutely prohibiting midwives from attending cases of abortion or miscarriage is worthy of careful consideration with a view of incorporating it in the bill mentioned. Those members of the committee engaged in collecting statistics to accompany the bill when introduced at Albany may find valuable data in the field of investigation suggested above to convince the legislature of the necessity for the prompt enactment of the measure.

THE PUBLIC PRESS AND THE ACADEMY OF MEDICINE.

SOMETHING over a year ago, a paper read before the Ophthalmological Section of the Academy subsequently appeared, with a photograph of the author, in several of the daily papers. The author, being questioned, denied all responsibility for the occurrence.

On the 18th of January, at a meeting of the same Section presided over by Dr. Pooley, attention was directed to the presence of reporters, and the disposition of the matter being left to the Chairman, he decided that they should be requested to retire. One of the gentlemen as he went out begged to be allowed to say on behalf of himself and his companions, that they were not there *sub rosa*, but in obedience to orders from their managing editors, who had received folders announcing the meeting.

The Section, after discussion, passed a resolution to the effect that "The Ophthalmological and Oto-

logical Section desires an expression of opinion from the Academy of Medicine as to the desirability of having reporters present at the meetings of the Academy and its Sections."

At the regular meeting of the Academy of February 4th, a motion was carried that "each Section should decide for itself the question as to the desirability of admitting reporters," and the astonishing fact to which we desire to call attention is that at this same meeting a motion was *lost* to the effect "that folders of the Academy should not be sent to the daily papers." This action admits of but one construction—that a majority of the members of the Academy of Medicine would not like to lose any opportunity of giving their opinions and papers for advertising purposes to the public press. Let us hope that it is only necessary to have the attention of the members of the Academy drawn to the subject to insure reconsideration and proper action.

ECHOES AND NEWS.

Doctor's Coachman Turns Practitioner.—At an inquest held in Manchester, England, as to the death of an infant aged three days, it appeared in the evidence that the mother had been delivered by a man who was "acting as assistant to a medical man." In answer to a question from the coroner, who recognized him, the man admitted that he was *coachman* to the medical man mentioned.

A Correction.—Through a misunderstanding between the printers and the editorial office, Dr. W. H. Thomson was credited in the last issue of THE NEWS as visiting physician to New York, Bellevue, and Roosevelt Hospitals. Dr. Thomson has no connection with the New York Hospital, and has recently resigned his position in Bellevue. He should, therefore, be credited with Roosevelt Hospital only.

English Criticism of "Degree-Shops."—A correspondent writes to the *Lancet* (London) to say that he knows of an instance where an American university conferred the degree of Doctor of Medicine on a layman who had merely presented a thesis. In reply, that journal remarks that "either the institution has been imposed upon or is a bogus university—a degree-shop—of which there were once many in the States."

A Nurse's Quarantine.—A nurse who had been caring for a child ill with scarlet fever in Liverpool, England, recently brought suit against the father of the child for one week's additional wages and expenses for the period during which she remained in quarantine after leaving the case. The rules of the nurse's home where she was employed would not permit her to accept another engagement until she had been in quarantine seven days. The

judge gave a decision allowing her the amount claimed on the ground that the rule above alluded to was a good one and clearly to the interests of the public.

New York State Board of Health and Antitoxin.—The board of Health of the State of New York is endeavoring to adopt means to improve the quality of antitoxin serums manufactured in this country, and to this end it proposes to have all serums offered for sale in this State submitted to a bacteriologic examination in the laboratory of the Health Department of New York City before being placed on sale. This is the plan pursued in Europe where every ounce of serum is inspected by duly authorized officials in the State laboratories. Dr. Herman M. Biggs, bacteriologist of the Health Department of New York City, states that as a result of investigations he found several of the samples of serum submitted to him unfit for use owing to the occurrence of decomposition. Some of it was also below the standard strength by as much as fifty units.

SPECIAL ARTICLE.

THE NEW QUARANTINE REGULATIONS.¹

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That "An Act granting additional quarantine powers and imposing additional duties upon the Marine Hospital Service," approved February fifteenth, eighteen hundred and ninety-three, be amended by striking out the following words in section one: "And with such rules and regulations of State and municipal health authorities as may be made in pursuance of, or consistent with, this Act," and striking out section three and inserting the following in the place of said section:

"SEC. 3. That immediately after the passage of this Act the Secretary of the Treasury shall make such rules and regulations as are necessary to prevent the introduction into the United States of any infectious or contagious disease from any foreign port or place, or the spread of such diseases from one domestic port to another, and such necessary rules and regulations as shall be observed by vessels or vehicles departing from foreign ports, or places for ports, or places in the United States, to secure the best sanitary condition of such vessels or vehicles, their cargoes, passengers, and crews, which rules and regulations shall be published, and communicated to, and enforced by, consular, quarantine, and customs officers of the United States, and the State and local quarantine officers of the United States. All rules and regulations made by the Secretary of the Treasury shall operate uniformly, so far as climatic conditions will justify, in the interest of security against the introduction or spread of said infectious and contagious diseases, and shall not discriminate against any port or place. None of the penalties herein imposed shall attach to any vessel from a foreign port, or owner or officer thereof, until a copy of

¹ A bill introduced by Senator Caffery in the Senate of the United States, December 9, 1897, read twice and referred to the Committee on Public Health and National Quarantine, and known as Senate Bill No. 2680.

this Act, with the rules and regulations made in pursuance thereof, has been posted up in the office of the consul, or other consular officer of the United States, for ten days, in the port from which said vessel sailed, and the certificate of such consul or consular officer, over his official signature, shall be competent evidence of such posting in any court of the United States. Nor shall the penalties imposed by this Act attach to any common carrier or officer, agent, or employe of any common carrier, crossing the border of the United States, until a copy of this Act, with the rules and regulations made in pursuance thereof, has been published and made publicly known.

"At any port or place in the United States where the Secretary of the Treasury shall deem it necessary for the prevention of the introduction of contagious or infectious disease from a foreign port or place that incoming vessels, vehicles, or persons shall be inspected by a national quarantine officer, such officer shall be designated or appointed by the Secretary of the Treasury, on recommendation of the Surgeon-General of the Marine Hospital Service, and at any such port or place no vessel, vehicle, or person from a foreign port or place shall be admitted to entry or enter without the certificate of said officer that the United States quarantine regulations have been complied with.

"Any vessel sailing from any foreign port without a United States consular bill of health, and arriving within the limits of any collection district of the United States, and not entering or attempting to enter any port of the United States, shall be subject to such quarantine measures as shall be prescribed by regulations of the Secretary of the Treasury, and the cost of such measures shall be a lien on said vessel, to be recovered by proceedings in the proper district court of the United States, and in the manner set forth above as regards vessels from foreign ports without bills of health and entering any port of the United States.

"National quarantine stations now in operation shall be conducted in accordance with the provisions of this Act, and the Supervising Surgeon-General, with the approval of the Secretary of the Treasury, is authorized to designate and mark the boundaries of the quarantine grounds and quarantine anchorages for vessels, which are reserved for use at each United States quarantine station; and any vessel, or officer of any vessel, or other person, trespassing upon such grounds or anchorages, in disregard of the quarantine rules and regulations, shall be deemed guilty of a misdemeanor and subject to arrest, and, upon conviction thereof, be punished by a fine of not more than three hundred dollars, or imprisonment for not more than one year, or both, in the discretion of the court.

"And any master or owner of any vessel, or any person violating any rule or regulation made in accordance with this Act, relating to inspection of vessels, or relating to the prevention of the introduction of contagious or infectious disease; and any master, owner, or agent of any vessel making a false statement relative to the sanitary condition of said vessel or its contents, or as to the health of any passenger or person thereon,

shall be deemed guilty of a misdemeanor and subject to arrest, and, upon conviction thereof, be punished by a fine of not more than five hundred dollars, or imprisonment for not more than one year, or both, in the discretion of the court.

"Medical officers of the United States, duly clothed with authority to act as quarantine officers at any port or place within the United States, and when performing such duties, are hereby authorized to take declarations and administer oaths in matters pertaining to the administration of the quarantine laws and regulations of the United States.

"The Secretary of the Treasury shall, whenever in his judgment it is necessary, make rules and regulations to prevent the introduction of infectious or contagious diseases into one State or Territory, or the District of Columbia, from another State or Territory, or the District of Columbia, and when such rules and regulations have been made they shall be promulgated by the Secretary of the Treasury and enforced by the Sanitary authorities of the States and municipalities, when the State or municipal authorities will undertake to execute or enforce them, but if the State or municipal authorities shall fail or refuse to enforce said rules and regulations, or other rules and regulations made under the provisions of this Act, the President shall execute and enforce the same, and adopt such measures as in his judgment shall be necessary to prevent the introduction or spread of such diseases, and may detail or appoint officers for that purpose.

"Whenever yellow fever, cholera, plague, or typhus fever has passed the quarantines of the United States, or in any manner any one of these diseases has gained entrance, or has appeared, within the limits of any State, Territory, or the District of Columbia, the quarantine regulations of the United States, prepared under the direction of the Secretary of the Treasury, shall be supreme and have precedence of State or municipal quarantine laws, rules, or regulations, and the President is authorized to enforce the same within the limits of any State, Territory, or the District of Columbia, and to control the movements of vessels, railway trains, vehicles, or persons within any State, Territory, or the District of Columbia, to prevent these diseases from spreading from one State, Territory, or the District of Columbia, to another State, Territory, or the District of Columbia, and to prevent unnecessary restrictions upon interstate commerce; and whenever, in accordance with the rules and regulations made as herein authorized to prohibit or permit the movement of vessels, railway trains, and vehicles, or transportation of persons, prohibitions or permits have been made or granted, any person violating said prohibition or permit shall be deemed guilty of a misdemeanor, and shall be subject to a fine of not more than one thousand dollars, or imprisonment for not more than twelve months, or both, at the discretion of the court; and any violation of said prohibition or permit shall be reported to the United States District Attorney for the district in which the offense has been committed, who shall thereupon institute necessary pro-

ceedings for the recovery of the penalty herein imposed."

That section six of said Act shall be amended to read as follows:

"That on the arrival of an infected vessel at any port not provided with proper facilities for treatment of the same, the Secretary of the Treasury may remand said vessel, at its own expense, to the nearest national or other quarantine station where accommodations and appliances are provided for the necessary disinfection and treatment of the vessel, passengers, and cargo; and after treatment of any infected vessel, or inspection of any vessel not infected at a national quarantine station, and after certificate shall have been given by the United States quarantine officer at said station that the vessel, cargo, and passengers are each and all free from infectious disease, or danger of conveying the same, said vessel shall be permitted to enter and admitted to entry at any port of the United States named within the certificate. But at any ports where sufficient quarantine provision has been made by State or local authorities, the Secretary of the Treasury may direct vessels bound for said ports to undergo quarantine at said State or local station."

That section eight of said Act shall be amended to read as follows:

"That whenever the proper authorities of a State shall surrender to the United States the use of the buildings, grounds, and disinfecting apparatus at a State or municipal quarantine station, the Secretary of the Treasury shall be authorized to purchase them at a reasonable compensation, or pay a reasonable rental for their use, if in his opinion they are necessary to the United States; and the expense of the said purchase or rental is made payable from the epidemic fund."

CORRESPONDENCE.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

AN IMPORTANT DISCUSSION OF THE MUNICIPAL CONTROL OF THE MEAT-SUPPLY—THE BLOCKLEY MEDICAL BOARD FOR 1898—DR. JOHN GUITERAS ON THE RECENT YELLOW-FEVER EPIDEMIC IN THE SOUTH—PHILADELPHIA COUNTY MEDICAL SOCIETY—THE RECENT OUTBREAK OF INFECTIOUS DISEASES.

PHILADELPHIA, December 18, 1897.

THE many recent flagrant offences in offering for sale diseased and unwholesome meats in some of the poorer districts of this city resulted in a public meeting at the College of Physicians, on December 6th, under the auspices of the Woman's Health Protective Association, to consider the subject of a better system of municipal meat inspection in this city. Among the experts in sanitation and hygiene who addressed the meeting were Dr. H. D. Gill of the New York City Health Department, who outlined in an interesting manner the methods in vogue in that city, and spoke of a number of improvements in the present defective system of inspection; Dr. D. E. Salmon, Chief of the Bureau of Animal Industry, Washington, D.

C., who considered the questions of Federal control of meat-supplies, and the dangers arising from the distribution of diseased meats; Dr. Leonard Pearson of the Pennsylvania State Veterinary Sanitary Board, who described the almost perfect methods of inspection which prevail in many of the Continental cities, rendering it practically impossible for diseased meat to reach the consumer; Dr. Benjamin Lee of the Pennsylvania State Board of Health, who spoke of trichinosis, and its relation to disease in human beings; and Dr. A. W. Clement, State Veterinarian of Maryland, who dwelt on the subject of the widespread prevalence of tuberculosis in animals. The facts adduced at this meeting proved beyond contradiction the filthy condition of many of the city's slaughterhouses, and the criminal neglect of ordinary sanitary methods practised by many butchers and drovers in caring for and handling cattle, many of which are unfit for food, and served the important purpose of calling general attention to the prevailing lack of suitable meat-inspection in this, as well as in other cities. It may be added that it is highly probable that the corps of official meat-inspectors of Philadelphia, which now numbers but four (with over 100 slaughterhouses to look after), will be at once increased to a more adequate force.

The Department of Charities and Correction has announced the personnel of the Medical Board of the Philadelphia (Blockley) Hospital for the ensuing year, these appointments being as follows: Physicians—Drs. R. G. Curtin, J. H. Musser, F. P. Henry, W. E. Hughes, S. Solis Cohen, F. A. Packard, J. L. Salinger, Samuel Wolfe, James Tyson, T. G. Ashton, A. A. Eshner and Alfred Stengel. Surgeons—Drs. W. J. Hearn, L. W. Steinbach, J. B. Deaver, Orville Horwits, Ernest LaPlace, J. M. Barton, J. William White, Edward Martin, J. Chalmers DaCosta, and A. C. Woods. Obstetricians—Drs. B. C. Hirst, E. P. Davis, G. I. McKelway, J. M. Fisher, R. C. Norris. W. F. Haehnlen, E. L. Peck, and J. B. Shober. Neurologists—Drs. C. K. Mills, F. X. Dercum, J. Hendrie Lloyd, and C. W. Burr. Ophthalmologists—Drs. G. E. de Schweinitz, and C. A. Oliver. Dermatologists—Drs. H. W. Stelwagon and J. Albert Cantrell. Pathologists—Drs. John Guiteras and W. M. L. Coplin. Laryngologists—Drs. C. J. Seltzer and G. M. Marshall. Registrars—Drs. H. B. Allyn, B. F. Stahl, and J. H. Gibbon.

At a special meeting of the Pathological Society of Philadelphia, held December 9th, Dr. John Guiteras, the distinguished yellow-fever expert, who recently completed his investigations for the Government of the late epidemic of this disease in the South, was the guest of the Society, and delivered an important address on "The Yellow-Fever Epidemic of 1897." This epidemic, said Dr. Guiteras, was characterized by the mild character of its cases and by its unseasonable appearance, two factors which have proved no small obstacles to its differentiation from an outbreak of other febrile diseases, such, for instance, as dengue; these factors have also rendered probable a secondary outbreak a year hence. The speaker corroborated the general opinion of the mild character of the infection in the colored race, and drew attention to the fal-

lacy of the belief that a native population enjoy immunity from yellow fever; in fact, many of them are mildly attacked during infancy, when the nature of the illness is unrecognized. A characteristic feature of the beginning of a yellow-fever epidemic, he said, is an increase in the death-rate of the white population of a community, affecting special classes of the population, such, for example, as seamen, if the place is a seaport; coincidentally with this, the health reports show a marked and unusual increase in deaths from such diseases as congestion of the brain and stomach, meningitis, nephritis, and bilious remittent fever, and by such diagnostic mistakes fatal yellow fever is often reported as some other disease, thus masking the real nature of the epidemic. Speaking of the specific cause of yellow fever, Dr. Guiteras drew attention to the morphologic and cultural characteristics possessed in common by Sanarelli's bacillus and the bacillus *x* of Sternberg, and pointed out that both micro-organisms had been found by their respective discoverers in very nearly the same percentage of cases. The claim made by Sanarelli is, however, considerably strengthened by the fact that he has been able to produce, by the injection of his bacillus into dogs, typical symptoms of the disease in these animals. The speaker, in discussing the clinical picture of yellow fever, placed emphasis upon the association of early albuminuria, lack of correlation between pulse and temperature, and the typical facies as an important diagnostic combination. At the close of his address Dr. Guiteras was tendered a reception at the University Club by the members of the Society.

At the last stated meeting of the Philadelphia County Medical Society, held on December 8th, a valuable communication on "The Effects of Digitalis in Producing Hypertrophy of the Heart," was made by Dr. H. A. Hare. The paper was based upon a series of experiments dealing with the action of this drug upon pigs, to which it was given in gradually ascending doses, and the effects noted during life, and after the death of the animals, which were killed within 4½ months. Ten pigs, from the same litter and of practically the same body-weight, were used in the experiments; five received tincture of digitalis in ascending doses from 10 to 50 minims twice daily during the period of observation, while the other five were used as "controls," and received nothing. All the "digitalis pigs" were livelier during life than the others, and also appeared to increase in size. After six weeks the ten pigs were killed, and it was found that the total weight of the five pigs which had received digitalis was twenty pounds more than that of the "control" animals, while their hearts together weighed ¾ ounces more. The pathologic report, by Drs. W. M. L. Coplin and W. P. Reed, showed thickening of the ventricular walls, more marked in the left than the right side of the "digitalis hearts," with an increase in the diameter of the muscular fibers amounting to one-tenth more than those of the "control hearts." From the results of this investigation Dr. Hare concludes that digitalis is capable of producing hypertrophy in the normal heart (probably because of its special affinity for the pneumogastric nerves), and that, if given, to an individual suffering with valvular dis-

ease with lost compensation, it must aid materially in inducing compensatory hypertrophy, in addition to its immediate stimulant action upon the circulatory apparatus.

Dr. James K. Young read a paper on "The Necessity of Making Accurate Measurements in Scoliosis," in which he deprecated the usual approximate method of recording such cases, and urged that instruments of precision be employed to obtain accurate tracings of the deviation of the spine. Dr. Young also demonstrated the application of the trolley scoliosimeter, Elkington's apparatus, Bradford's instrument, and other inventions of the same nature.

Dr. Lawrence Flick reported "Some Unusual Results in the Treatment of Pulmonary Tuberculosis," which he attributed to inunctions of euphorben. Five patients with phthisis, three in the advanced, two in the incipient stage, were thus treated, in all there was marked improvement in both physical signs and symptoms; the incipient cases were pronounced free from physical manifestations of the disease. It should be noted that the patients, in addition to the euphorben inunctions, received strychnin, gastric tonics, and very full doses of creosote.

Dr. H. E. Wetherill showed a number of *medical instruments of precision*, among which was a hygrometer upon which the speaker laid stress as being of value in recording the degree of moisture of different parts of the body in certain pathologic states.

The alarming increase in the mortality from diphtheria in certain sections of the city, of which mention was made in these columns last week, stirred the health authorities to the extent of inaugurating, in the affected districts, a general daily inspection of the throats of all public-school children, and of disinfecting with formaldehyd the infected school buildings and their furnishings. Investigation into the cause of the outbreak of enteric fever which occurred last week in a certain ward has led to the conclusion that the milk-supply was responsible for the increase in this disease. As compared to last week there were 11 more new cases of diphtheria reported for the week ending December 18th, the total being 139, with 32 deaths; there was a decrease of 15 in new cases of typhoid, of which the total was 110; and there was an increase of 7 in new cases of scarlet fever, with a total of 54. The total deaths from all causes were 451, or 50 more than last week. Of this total 112 were of children under five years of age.

TRANSACTIONS OF FOREIGN SOCIETIES

Paris.

THE FATE OF HETEROPLASTIC OSSEOUS GRAFTS—SEROUS PLEURISY ALMOST INVARIABLY TUBERCULOUS—LOCATION OF PROJECTILES IN THE HEAD BY RADIOGRAPHY—TYPHOID FEVER NOT PRODUCED BY EATING OYSTERS—FOREIGN BODIES IN THE ESOPHAGUS WITHOUT SERIOUS SYMPTOMS.

DUBAR reported to the Academy of Medicine, November 16th, the result of a resection of the right wrist for tuberculosis in a girl aged ten years. In order to make the joint firmer, small *osseocartilaginous fragments from the femur of a puppy* were inserted in place

of the bones which had been removed. There was a good recovery, with a painless, firm, and movable wrist. A radiograph was taken to ascertain what became of the fragments of bone, and they were seen to be fixed in the midst of newly formed fibrous tissue, having slightly increased in size.

LE DEMANY has determined from the examination of 80 cases of pleurisy, 50 of them being primary, that the rheumatic diathesis and exposure to cold play almost no rôle in the production of the primary disease. *Inoculation of guinea-pigs with the exudate from 55 pleuritic patients was followed in 47 instances by tuberculosis.* In 8 cases the result was negative. Nevertheless, in four of these, the clinical evidence showed that the pleurisy was of a tuberculous nature. The conclusion was reached that the only serofibrinous pleurisy of microbic origin is the tuberculous. Other microbes found in the pleura merely determine the occurrence of purulent pleurisy.

At the session of November 23d, MAREY described experiments in radiography with Contremoulin's apparatus in order to determine the *exact situation of projectiles in the head.* The method has also been employed in the living, with complete success, in two cases of gunshot wound. LE DENTU described one of these operations. The patient shot himself in the right temple with a revolver. A radiograph showed that the projectile was situated in the frontal lobe 28 millimeters from the cutaneous surface. An opening was made in the bone at the spot indicated, and the bullet found at a distance of 15 millimeters from the surface of the brain, and was extracted without difficulty.

At the session of the Academy of Sciences, November 8th, SABATIER, DUCAMP, and PETIT described their efforts to determine *whether oysters can be the means of producing enteritis due to the coli or typhoid bacillus.* The results of their investigations showed that these germs are not found in oysters, even if the oyster-beds are situated in water contaminated with sewage. Furthermore, oysters into which these bacilli were artificially introduced were invariably found to be free from them twenty-four hours later. The idea, therefore, that typhoid fever may result from the ingestion of these bivalves, is not worthy of credence. This view is sustained in a practical way by statistics, which show that the number of cases of typhoid fever in the town of Cette does not exceed the average for towns of similar size, although its inhabitants eat about two million oysters per year.

MONOD reported before the Surgical Society, November 10th, the details of a *case of foreign body in the rectum*, which he was able to extract without having recourse to any preliminary operation. The foreign body in this case was a glass bottle which the patient was in the habit of introducing into the rectum neck first. He always tied a string to it so that he could pull it out at will, but one day the string broke and the bottle remained in the rectum. By pressing with one hand on the hypogastric region, Monod was able, without difficulty, to pull the bottle out of the rectum with the fingers of the other hand. In the majority of cases, foreign bodies, even of the largest size, may be removed from the rectum by the

natural channel. This surgeon collected reports of 33 cases, in 27 of which extraction was effected without operation. Six of these patients died, but only 3 deaths were attributable to the maneuvers of extraction. An incision in the posterior wall of the rectum is sufficient in the most difficult cases. Resection of the coccyx being only exceptionally indicated. When the foreign body has made its way toward the upper part of the rectum celiotomy should be performed.

At the session of November 17th, MICHAUX described a *case of subphrenic abscess on the right side* and so high up that it was thought that two collections of pus were present, one in the pleural cavity and the other below the diaphragm. A large thoracic clamp was made and turned upward, thus disclosing the entire cavity of the abscess. The patient improved for a time, but died within a month. The autopsy showed that the lesion was a suprahepatic peritoneal tuberculosis. PEYROT described a subphrenic abscess also situated above the liver, and which he had drained by operation. Exploratory puncture of the liver showed that this organ contained a hard mass, the nature of which could not be determined; at the autopsy it was found to be a calcified hydatid cyst. ROUTIER mentioned two cases of subphrenic abscess in which the symptoms were puzzling, and in both instances resection of the costal wall was followed by cure.

HARTMANN resected the appendix in a patient subject to recurrent attacks of inflammation of this organ, and found its cavity to be entirely obliterated in the middle. This gave an opportunity to compare the *virulence of the microbes in the obliterated terminal portion with those in the permeable portion* next to the cecum. In both portions coli bacilli were found, but while cultures made from the contents of the permeable portion exerted no noxious action upon guinea-pigs, cultures from the closed portion were extremely virulent, sufficing to kill a guinea-pig within thirty-six hours.

RENDU communicated to the Medical Society of the Hospitals, November 12th, the details of a case of *infectious gonorrheal rheumatism with death from endocarditis.* The patient sought treatment for pain in the abdomen. Vulvitis, urethritis, or vaginitis were not present, but only slight uterine congestion. Some days later, symptoms of septicemia became well marked. A little liquid withdrawn from the cavity of the cervix uteri, entirely serous and transparent, was examined bacteriologically and found to contain gonococci in large numbers. Peri-arthritis of the left elbow developed, and pus from the resulting abscess also contained gonococci; no other microbes were found. Endocarditis and pericarditis, also of gonococcic origin, developed and terminated the life of the patient.

At the session of November 19th, VARIOT mentioned two cases in which a foreign body remained in the esophagus of a child a long time, in one case a whole year, meanwhile producing no symptoms except an occasional fit of coughing. RENDU knew of a similar case in which a child twelve years of age claimed to have *swallowed a piece of money about the size of a dime.* Nobody believed him, as there were at first no morbid symptoms.

Later, attacks of dyspnea appeared, but it was only with the help of radiography that the presence of a coin in the middle of the esophagus was clearly determined. These cases show the necessity for this method of examination when patients present a similar history.

At the session of November 26th, CAUSSADE announced that experiments made by DIEULAFOY and himself prove that the *virulence of the coli bacillus is greatly increased by its growth in a closed appendix*; and this is true not only for inoculations made with the bacillus itself, but also of those made with its toxins.

At the session of the Biological Society, November 13th, CHABRIE read a paper upon the *elimination of potassium salts in nephritis*. Six patients were observed with the following results: There was a diminution of the potassium salts of the urine, amounting, in one patient, to two-thirds of the normal quantity, in two others, to one-third of the normal quantity, while the other three exhibited variable potassium discharges coincident with improvement in condition, and following the employment of a milk diet. It appears from these observations that potash plays an important part in Bright's disease, and that the use of articles of food which contain these salts in large proportions should be absolutely forbidden to such patients.

At the session of November 20th, HOBBS said that a wet-nurse, aged twenty-three years, died six days after the beginning of a *diarrhea accompanied by the classic symptoms of cholera*. The bacteriologic examination of the stools showed the presence of a germ presenting all the characteristics of the coli bacillus. Its virulence was great, ten drops of a bouillon culture being sufficient to kill a guinea-pig within eighteen hours. The same bacillus was found in the kidney, intestines, spleen, and breasts of this patient.

At the session of the Therapeutic Society of November 10th, BARDET said that while a *chemic or mechanical irritation may set up mucomembranous colitis*, in the majority of cases, especially in men, this disease is due to hyperacidity. It is, therefore, necessary in these cases, to examine into the condition of the stomach. MATHIEU said that in cases of genuine mucomembranous colitis, almost the whole intestine is affected, and not alone the sigmoid flexure as some observers have claimed. It has also been stated that this disease is to the intestine what eczema is to the skin, being apparently like the latter affection, increased by irritation of the affected locality or of its neighborhood, by emotion, fatigue, or visceral disturbances of any kind.

At the session of November 24th, a note was read from MONCORVO describing the result of the *treatment of chyluria in the tropics* by means of the administration of ichthyol. The dose used was from 7 to 20 grains daily. A marked improvement soon followed, and patients who had been treated without benefit with other drugs were completely cured by the use of ichthyol.

Portable Piano for Invalids.—An English firm has designed a small portable piano, which is suspended from a frame over the bed and enables an invalid to while away many weary hours.

REVIEWS.

THE DISEASES OF WOMEN. A Handbook for Students and Practitioners. By J. BLAND SUTTON, F.R.C.S., Eng., Surgeon to the Chelsea Hospital for Women; Assistant Surgeon, Middlesex Hospital, London, and ARTHUR E. GILES, M.D., B.SC., London., F.R.C.S., Edin., Assistant Surgeon, Chelsea Hospital for Women, London. With 115 illustrations. Philadelphia: W. A. Saunders, 1897.

THIS is a small volume of about 400 pages. As the authors say in their preface, it has been their earnest desire to relate facts and to describe methods in a way that may be useful to students in preparing for examination. The subjects are, therefore, briefly treated and rather in the form of definitions than in that of a continuous treatise. The illustrations are good, some of them representing original work by Giles. The paper is good and the type clear, but the binding does not seem strong enough for the weight of the paper.

THERAPEUTIC HINTS.

For the Vomiting of Pregnancy.—POZZI reports good results from the treatment of this affection by means of hypodermic injections of cocain in the epigastric region, and states that this method has proved successful after hypodermics of morphin and the internal administration of cocain had been unsuccessful tried. He injects 1/6-grain of cocain once or twice daily immediately before meals in the region mentioned. The improvement is permanent, and no unfavorable concomitants have been noted.

M. Sig. One teaspoonful three to four times daily.

INDEX.

- ABDOMINAL actinomycosis, 780
hysterectomy, 806
for uterine myomata, 812
- Abnormalities of the cervix uteri and vagina, 318
- Abortion, treatment of, 589
- Abortive treatment of influenza by calomel, 772
- Abscess of the nasal septum, 158
of the uterus, 710
- Absence of organization of first aid to the injured, 245
- Abuse demanding attention of the Board of Health, 211
of the Geneva insignia, 245
of hospital charity, 639
of medical charity, 336, 521, 534, 806
- Acceptance of Widal's reaction, 25
- Accident insurance and carcinoma following trauma, 705
for students, 668
- Accidents following thrombosis of the portal vein, 779
- Acid foods and drinks, 74
- Acromegaly, case of, 308
- Actinomycosis, 82
- Actinomycotic appearances of tubercle bacilli, 572
- Action of digestive ferments on toxins, 575
of hypnotics, 418
of quinin, 304
- Actol as a disinfectant, 304
- Acute alcoholism, 516
ascending paralysis during treatment for rabies, 217
colic, 352
edema of the lungs, 26
gout, 484
infectious gastritis in infants, 678
mania, 548
nephritis in children, 497
opium poisoning treated with oxygen, etc., 208
otitis media after la grippe, 539
rheumatism, 388
streptococcic macroglossia, 27
- Addison's disease, symptoms of, 329
- Addition to St. Vincent's Hospital, 667
- Additions to the Germantown Hospital, 606
- Address at Bellevue, 732
in medicine at Yale University, 22
of Dr. Burr, 480
of T. G. Roddick, 289
- Adenitis, iodoform in, 201
- Adenoids removed with fatal result, 501
- Adherent pericarditis, 90
- Administration of diuretin, 144
- Admission of American students to German universities, 672
- Advanced syphilis and anemia, 388
- Advisability of tampon after curettage, 363
- Advocate of blood-letting, 438
- Aero- and hydrotherapeutics, 126
- Æsculapian Assistance and Interment Company, Limited, 86
- Afraid of appendicitis, 181
- Agglutinating reaction found in infantile enteritis, 779
- Airol in diarrhea, 532
- Alarming symptoms after ingestion of kerosene oil, 366
- Albumen in abdominal fluid, 448
- Albuninuria of delirium tremens, 51
of dyspepsia, 575
- Alcoholic selection, 476
- Alleged microscopic power of the normal eye, 184
- Alleman, L. A. W., convergent strabismus, 326
- Allen, Dr. Harrison, death of, 668, 740, 805
- Alumni Association of St. Mark's Hospital, 441
- Alvarenga prize, 553
- Amaurosis following intranasal operation, 465
- Ambulance classes for sailors, 535
- Amebæ in dysentery, 25
- Amenorrhea, 320
- American Academy of Medicine, 92
of Railway Surgeons, 371, 410
- Association for the Study and Cure of Inebriety, 739
of Obstetricians and Gynecologists, 117, 249, 278
- Climatological Association, 125
- Electro-Therapeutic Association, 371
- female students at University of Zurich, 477
- jubilee fund endowments, 476
- Laryngological, Rhinological, and Otolological Society, 153
- medical students in France, 411
- students in Germany, 372
- Pediatric Society, 352
- Public Health Association, 410
- Anas in a new local anesthetic, 501
- Anastomosis of mesenteric vessels, 90
- Anatomy of the kidney, 129
- Anesthesia, a new method of, 683
at Mt. Sinai Hospital, 770
by the Schleich mixture, 807
- Anesthetics, 386
- Anesthetization of children, 113
- Anginas in children, 57
- Animal experimentation, a bill to abolish, 19
- Annual meeting of the Chautauqua Medical Society, 148
- Another case of hiccough, 181
- Anthrax among tanners, 805
and the disinfection of hides, 306
- Antibubonic serum, 376
- Anticholeraic serum, 372
- Antineuralgic, 420
- Antipyrin and arsenic in chorea, 144
- Antiseptic dwelling, 739
road-watering, 505
- Antisepsis of the barber-shop, 410
- Antisyphilitic treatment and tuberculosis, 59
- Antitoxin in laryngeal diphtheria, 95
treatment of diphtheria, 464
- Antitubercular serum, 126
- Aortic aneurism, 24
- Apenta water for constipation, 580
- Apparent death and premature burial, 241
- Appendicitis, 288, 315, 546
complicating diseases of the uterine adnexa and pregnancy, 485
gangrenous and perforative, 694
the operation for, 459
- Application of the X-ray in surgery, 712, 809
- Appointed State Medical Examiner, 670
- Appointments abroad, 476
- Appointment of Dr. Bates, 475
of Dr. Kemp, 703
of Dr. Mosely, 308
- Appointment of Dr. Nainmack, 441
of Dr. Ophuels, 667
of Dr. Stephen Smith, 410
of Dr. Warner, 307
of surgeon-general of the navy, 570
- Apoplexy in the surf, 271
- Appropriation for a bacteriologic laboratory, 338
- Aristol in nasal operations, 210
ointment, 812
- Army examining boards, 505
Medical Board, 214
- Arrangements for the Moscow congress, 26
- Arsenical intoxication, baldness, and tuberculosis, 20
- Arterial sclerosis, 678
varix of the lower lip, 207
- Arthritis deformans, 313
- Asepsis and antisepsis in obstetrics, 543
- Aseptic treatment of burns, 114
- Ascites, chylous, 469
- Asleep for three months, 213
- Association of appendicitis with pustules, 379
of Hospital Managers, 574
of Military Surgeons, 117
- Asthma, 678, 784
- Astigmatism in school children, 82
- Astoria water supply, 477
- Astringent gargle, 388
- Atkins, Dr. W. T., death of, 147
- Atrophic laryngitis, 580
- Attendance at Moscow, 309
upon German medical societies, 741
- Atonic dyspepsia, 352
- Atony of the rectum, 314, 664
- Attorneys for State hospitals, 118
- Austrian Plague Commission, 56
students duelling, 122
women and the regulation of prostitution, 341
- Auto-intoxication, 543
of gastric carcinoma, 310
- Autopsy club in Chicago, 22
on a bridge-jumper, 117
- Avery, Dr. Charles H., death of, 640
Charles H., obituary of, 739
- BABIES of Paris, 211-271
- Baby detective, 213
farming, 123
- Bach, J. A., granular conjunctivitis, 109
- Bacilli aerogenes capsulatus, 453
- Bacillus of acute articular rheumatism, 775
- Bacteria and the produce trade, 343
incubating nursery, 308
- Bacteriologic examination of drinking water, 444
of Philadelphia milk-supply, 507
examinations, 22
- Bacteriology, general knowledge of, 305
of pertussis, 347
- Bacterium coli in urinary passages, 51
- Bad results from petrolatum, 367
- Baldness, tuberculosis, and arsenical intoxication, 20
- Ball, M. V., insanity from confinement, 80
- Banks, W. M., surgeon of old, 298
- Barber-shop a menace to public health, 610
- Barnes, A. C., hypodermic syringe, 406
- Baruch, Simon, health resorts and sanatoria, 33
- Baron Rothschild's blood, 342

- Bates, Surgeon-General Newton L., death of, 571
 Beef from cows killed by lightning, 338
 Behring's serum for diseases other than diphtheria, 420
 Belladonna and strychnia pills cause death, 805
 poisoning, 189
 Bellevue and its relation to medical progress, 732
 Benzoate of mercury, 178
 of soda for grippé, 352
 Bequests to charity, 601
 to Chicago charities, 639
 Beri-beri in Philadelphia, 538
 Best methods of teaching anatomy, 351
 Biggs, H. M., preventive medicine, 321
 Bichlorid catgut better than kangaroo tendon, 471
 Bicycle and phthisis, 535
 Bilharzia ova, 738
 Bill before Congress, 83
 Congress abolishing animal experimentation, 19
 Billings, J. S., Jr., infantile malarial fever, 499
 Bipolar pressure in doubtful fracture, 51
 Bishop, L. F., neurasthenia in women, 71
 Bismuth, newer preparations of, 136
 poisoning, 472
 Blackburn, A. E., opium poisoning, 208
 Black clothing unhealthy, 243
 Blanchard, G. W., pachymeningitis, 48
 Blepharitis marginalis, 546-580
 Blindness from drinking essence of peppermint, 53
 Blockley medical board for 1898, 835
 notes, 56
 Board of education and oculists, 118
 health to correct abuse, 211
 Body hidden in the cargo, 476
 Bogus dentist fined, 776
 doctor convicted, 476
 university degrees, 243
 Bombay again stricken, 475
 Boston College of Physicians and Surgeons, 763
 Bottini's operation for prostatic hypertrophy, 576, 811
 Bourroughs, Dr. C. R., death of, 667
 Bowels, obstruction of, 168
 Brain, gunshot wound of, 268
 softening from ligation of jugular vein, 209
 Bremer's color test for diabetic blood confirmed, 778
 Brewer, G. E., anatomy of the kidney, 129
 British Medical Association, 270-410
 Association in session, 409
 medicine in Greater Britain, 293
